John Peter Mettauer.—He selected for his subject "John Peter Mettauer," saying that little was known of his childhood and youth beyond the fact that, raised in an atmosphere of surgery, he imbibed a love for this profession and early determined to adopt it as his life's work. He was born in 1787. Mettauer's medical education was carried on under the most favorable conditions obtainable in America at that time. For a period of about forty years the number of surgical patients who gathered to Mettauer for treatment was sufficient to keep him constantly with from 45 to 60 cases under his care. Often it was true that about every good house in the community sheltered some person who was convalescing or awaiting his turn for operation. The speaker had heard his operations for cataract put in number far beyond the 800 that could be accounted for. Dudley's great record in cutting for stone 225 times in a practice of forty years must yield to Mettauer's total of 400 operations, and the number of strictures relieved was commonly put at something over 200. Three operations were recalled, performed in the last week of his life, when at the age of eighty-eight years his eyes were yet keen enough and his hands steady enough for him to make a successful operation for cataract, for stone, and for amputation of the breast. But Mettauer's most brilliant work in the way of operations was his method with vesicovaginal fistula, and his successful employment of wire sutures made of lead, in which he antedated by a good many years even Sims, whose name was generally associated with this operation. So successful was Mettauer that he declared his belief that every case of this sort was curable by his method, and so far as his efforts were reported, the speaker was not aware that he ever failed in one. Proper pride and regard for his own reputation in the coming years must make every surgeon careful to a degree in assigning credit for useful and honorable achievements to those who had preceded him, and there was in the history of surgery no claim more clear and unmistakable than that of John Peter Mettauer to the honor of discovery in this case, and he was plainly entitled to rank in medical history and in the grateful memory of his successors in the same class with McDowell and Dudley and Sims and Mott. Mettauer's first reference to the operation of vesicovaginal fistula appeared in the *Boston Medical and Surgical Journal*, Vol. XXII, p. 154, twelve years before Sims' communication, and it clearly outlined the operation which ought always to be associated with his name. Mettauer was decidedly of the opinion that every case of vesicovaginal fistula could be cured, and his success justified the statement. Reference was made to the eccentricities of Mettauer, and among them was his invariable custom to wear on all occasions and at all times a preposterously tall hat. One of his children, now surviving, had told the speaker that she never saw her father without his hat on. He never attended service in the churches, and the explanation was always assumed to lie in the unwillingness either to remove the covering from his head or to attend church wearing his hat. He would decline to take off his hat in court on the occasions when his expert testimony was sought, and the sole occasion on which a Judge seems to have insisted that the doctor should be uncovered brought from Mettauer the suggestion that if his evidence was essential to the cause he would be pleased to give it with his hat on, and that if it were not so he would be quite as well pleased to leave the court-room, meanwhile, of course, wearing his hat. Dr. Johnston said that so great was his interest in seeing full justice done to the genius of Mettauer that he was seriously contemplating some extended work in the way of a biography.

End Results in Surgery of the Kidney.—Dr. Albert Vander Veer, of Albany, N. Y., read a paper on this subject, which was based on a review of ninety cases occurring in his own practice. The first largest group was composed of movable or floating kidney. These numbered twenty-three cases, exclusive of those where excision of the capsule for neuralgia, examination for stone, and decapsulation for Bright's disease was done. Nineteen of these cases occurred in the female, about two-thirds of whom were married, the lesion being on the right side. There were four males, the lesion also occurring on the right side, and the entire number recovering. One required removal of the kidney four years after for abscess of the pelvis and stone; good recovery.

He next presented a series of twenty-four cases of nephrotomies, in which there was a surgical lesion of the kidney, grouped under the heading of pyelitis, pyonephrosis, pyonephritis, or ascending pyelonephrosis. The series was divided as follows: Male, right side, two recovered, one died; male, left side, six recovered. Nine of these cases finally required nephrectomy, one

of the latter resulting in death. Of the remaining fifteen cases all made good recoveries, but one of them, after a period of four years, had a slight sinus, not deep, no pus, patient in excellent condition; the other patient recovered from the kidney complication, but developed a pelvic abscess, which was still draining, and she was gradually losing ground. In the cases of nephrectomies for hydronephrosis there were eight, as follows: Male, right side, two recovered; female, right side, three recovered; female, left side, two recovered, one died. Regarding the removal of the kidney by the transperitoneal incision, the author stated that it was an exceedingly easy and convenient way of removing a large cyst or tumor, the patients doing nicely afterwards. Of these there were four cases.

He then cited two cases of hydronephrosis in young women who were entirely cured by simple aspiration. Of nephrotomies, followed later by nephrectomies, there were nine cases, as follows: Male, right side, two recovered; male, left side, one recovered; female, right side, three recovered; female, left side, three recovered. All of these cases made a good recovery from the two operations, with the exception of two patients, one dying a few months after from multiple abscesses of remaining kidney, and the other, still alive, was gradually failing in strength.

The author was greatly impressed with the study of tuberculosis of the kidney, as to whether the invasion occurred from below or from systemic infection. There were seven of these cases, as follows: Male, right side, one recovered; male, left side, two recovered; female, right side, one recovered; female, left side, three recovered. There was a total of eight cases of malignant growths in connection with the kidney, as follows: Sarcoma.—Male, right side, two recovered, one died; male, left side, one died; female, right side, one recovered; female, left side, one died. Carcinoma.—Female, right side, one recovered, but died later from return of the disease. Hypernephroma — Male, left side, one recovered. Of decapsulation of the kidney for nephritis, there were two cases that recovered; results excellent. Of traumatisms and injuries of the kidney, there were six cases. Of cases of renal neuralgia, associated with suspected stone of the kidney, the author was not able to confirm his diagnosis by exposure of the organ. The entire group was made up of six patients, and in only one instance was the diagnosis confirmed by needling of the kidney.

The author then reported some irregular cases, and concluded his paper by reporting two cases of abdominal surgery which illustrated errors in diagnosis, in which the real trouble was with the kidney.

In a review of the cases presented in this paper, one was impressed with the very excellent results following the operation of fixation of the kidney. In the hands of all operators the mortality list was exceedingly small. Wearing of a bandage, with kidney pad, was exceedingly irksome to many patients who gladly consented to surgical intervention, when the prospects for recovery were so good.

The combined operation of nephrotomy and nephrectomy later for abscess of the kidney was appropriate for such cases as would not bear too long an operation, and where there might be a large kidney, made up of multiple abscesses in such a way as to make manipulation of the organ quite difficult. Simple drainage benefited the patient for a time, often causing a diminution of the mass to be removed later. In the purely cystic form of kidney, a true pyonephrosis, an immediate nephrectomy was proper in the majority of cases. Following a nephrotomy or nephrostomy a fair number of cases recovered without further intervention. In a large pus kidney there was always some danger in a nephrectomy causing an infective peritonitis. In traumatisms of the kidney firmness and decision on the part of the surgeon were an absolute necessity. There were no other form of emergency surgery more exacting. In cases of movable or floating kidney, giving such marked symptoms that the surgeon was often led to believe that he had a stone to deal with, the speaker admitted that our diagnoses were very far from correct, and the cases here reported were disappointing by reason of not finding a calculus present. It was sometimes difficult to diagnose between a neuralgic kidney and one containing a calculus in its pelvis. Splitting of the capsule relieved pain in cases that could only be classified as a neuralgic condition. It was yet a mooted question as to how much could be accomplished by resection of the kidney for relief of abscesses and growths. The cases of tuberculosis reported manifested decidedly the importance of an early operation, and gave a most encouraging outlook for these patients regarding permanent recovery. Malignant growths made the mortality list, and yet there was much hope for these cases if reached early. Surgery of the kidney was becoming more and more exact with the splendid advance made in methods of examination of the urine, etc. Errors of diagnosis would occur less frequently in the practice of abdominal surgeons as methods of examination became more perfect.

The writer was impressed with the oblique incision, which had been employed in nearly all of his cases during the past ten years. The one case of hernia reported resulted from the old incision, parallel with the spine and transversely through the muscle, causing a lumbar hernia, but none of the others presented this complication. It will be observed that in a total of about 90 patients there were 123 operations done. This was readily accounted for because of the patients requiring more than one operation. The rate of mortality was exceedingly small, malignant disease and abscesses of the kidney being alone responsible.

Dr. William J. Mayo, of Rochester, Minn., asked the essayist whether he took out the ureter or considered it necessary to remove it in cases of tuberculosis of the kidney. Also, whether any of the cases in which nephrotomy for tuberculosis of the kidney was performed had been followed by permanently good results. Recently he had gone over the histories of some 36 nephrectomies for tuberculosis of the kidney, and had found that a large number of people who were supposed to have tuberculosis of both kidneys in the early stage had only one kidney involved. Careful examination had shown in the majority of these cases, according to his recent experience, that the tuberculosis was confined to one kidney. He thought a large majority of cases of tuberculosis of the kidney were one-sided to start with; that his experience, as furnished largely from post-mortem examinatons, was that the second kidney became involved at the time of death, and that therefore he had post mortem rather than living evidence of the fact that in the early stages the percentage of cases in which tuberculosis of the kidney was bilateral was small.

Dr. Archibald MacLaren, of Minnesota, mentioned the ease with which a kidney could be removed after resection of the twelfth rib. He got this idea from Dr. Mayo. He had tried this in a recent case and found he could do the operation much easier by resecting the twelfth rib, although he opened the pleura. The opening could be plugged with gauze.

Dr. Vander Veer, in closing the discussion, said, in reply to Dr. Mayo, that the tuberculosis was confined to one kidney in his cases, and he had no record of bilateral kidney tuberculosis. In regard to the removal of the ureter, in the first case he operated upon he did not remove the ureter, and in one case he had to do a secondary operation on account of relapse. In regard to Dr. Carson's case, he had seen almost a duplicate of it in that there was a sarcoma which involved the gall-bladder and right lobe of the liver.

Non-Parasitic Cysts of the Spleen.—Dr. Chas. A. Powers, of Denver, Colo., in a paper with this title stated that this subject had a twofold origin. *First*, the few and comparatively recent clinical reports; *second*, the somewhat more numerous accidental post-mortem findings. In September, 1895, a young man of eighteen was referred to him, who presented a large right-sided abdominal cyst. The mass was of four years' growth. There had been a gradual loss of flesh and strength, anorexia, headache and general pressure symptoms. Fluctuation was plain. The diagnosis of a splenic cyst seemed positive. A free incision was made over the prominent part of the tumor, the walls of which were found to be about one-half of an inch thick, semi-cartilaginous and solidly adherent to all the adjacent structures. Extirpation seemed impossible. Later autopsy findings confirmed this. The single cyst held several litres. A posterior incision was made with through drainage. The walls of the cyst did not collapse and the patient died of septic absorption from the cyst wall on the twelfth day. The anatomical diagnosis was hemorrhagic cyst of the spleen. From the autopsy findings the author could not see how the cyst could have been successfully extirpated.

He presented a brief analysis of thirty-two tabulated cases. In considering the treatment, he spoke of puncture, incision and injection, incision and drainage, marsupialization, resection of cyst and splenectomy.

Status Lymphaticus and the Ductless Glands.—Dr. Roswell Park, of Buffalo, N. Y., defined the term status lymphaticus and stated that the reason for bringing the subject before a body of surgeons was because the condition itself had so much to do with the question of toleration of anesthetics, and the matter of repair of wounds, that it really was one of exceeding importance. Not a few cases of sudden death during and after operation were to be explained by the abnormalities constituting this condition. These had usually been attributed to the anesthetic or the anesthetist, and it might be that had the latter appreciated all the dangers offered by the condition he would have guarded his anesthetic, or perhaps abstained from giving it. Nevertheless, the anesthetizer was not always to blame, because he was often called in without previous knowledge of the case, it being really the function of the medical attendant to carefully study it and determine its peculiarities. The relation which the lymphatic system and the lymph-making organs bear to each other and to the ductless glands was as positive as it was obscure. Lymphoid tissue throughout the body seemed to increase as the thymus normally disappeared. In infantile marasmus the thymus had usually completely and prematurely disappeared, its condition being a fair index as to general nutrition. But it was hypertrophy rather than atrophy of the thymus which most interested the surgeon, since those individuals who die suddenly and unexpectedly usually had an enlarged thymus. There certainly existed strange relationships between the pituitary body, the thymus, the thyroid, the coccygeal body, the testes, the ovaries, and perhaps the bone marrow. In this list the quite recent researches relative to the parathyroids should also be included. A clearer recognition of the function of the latter seemed to have changed the whole aspect in which we should regard Graves' disease, it being made quite probable that this condition was due rather to atrophy of the parathyroids than to excess of the thyroid or its secretion. In the ordinary forms of cystic goiter, where thyroid secretion was not augmented, the symptoms of Graves' disease were lacking. It was usually after removal of the thyroid proper that the opposite symptoms of Graves' disease appeared, *i.e.*, myxedema and cachexia, while when the parathyroids were taken away the peculiar symptoms of Graves' disease appeared.

The life history of the thymus was closely related to that of the testes. Atrophy of the former would seem to depend upon complete maturation of the latter. These statements could be corroborated by a study of cryptorchids and castrated animals. The status lymphaticus was also described under the terms lymphatism, lymphatic constitution and status thymicus, the condition having apparently more to do with thymus than with any other isolated organ. Thymus extract produced in animals a fall of blood pressure with acceleration of the heart, and, in fatal doses, collapse. Thymic enlargement might cause death by pressure on important structures, even distinct from the trachea. Thymic asthma, a condition known for some time, was one in which death sometimes occurred most unexpectedly and quickly. In these cases not only was the thymus enlarged, but there was found a general hyperplasia of the lymphatic tissue, with enlargement of the lymph nodes and of the spleen. The relations between status lymphaticus and rickets were frequent and pronounced. Nearly all cases of the former displayed the ordinary clinical evidences of the latter. The participation of the lymphatic system was most casually apparent in the involvement of the faucial, laryngeal and lingual tonsils, *i.e.*, the so-called adenoids of the throat specialists. It was notable that it was in these cases the death most often occurred during or after anesthesia. Thymic asthma was practically the same thing as laryngismus stridulus. The occurrence of this in children ought always to serve as a warning, as well as an indication for careful study and treatment. Should, then, chloroform be given to such a case, inadverently or unnecessarily, the agent would not be nearly as responsible for the death as the practitioner who employed it. The condition was to be recognized by the ordinary evidences of rickets which were usually present, by generalized enlargement of the lymph nodes, the presence of adenoids in the naso-pharynx, a history of laryngismus stridulus or special liability to spasm of the glottis, perceptible enlargement of the thymus or by notable enlargement of the tyroid or spleen. In the young these conditions simulated cretinism. Such a clinical picture as would afford the above features should serve as a warning and make one abstain from the use of anesthetics unless absolutely necessary, while it should also prompt carefully directed treatment. This treatment should consist in careful attention to elimination, as well as to nutrition, while thymus or pituitary extract should be administered internally, as well as the glycero-phosphates or some similar up-building tonic. If, now, it should be necessary to clear out the nasopharynx in such a case, the parts should be first desensitized by cocaine, to which a little adrenalin might be added, even previous to beginning anesthesia. If the patient be known to be subject to glottic spasm, one should be prepared to do a tracheotomy on an instant's notice, and especially so if the thymus be perceptibly enlarged. One might even have to use a long

trachea tube. Operations of convenience should be postponed until the patients can be carefully built up. Operations of necessity may be practised with the above precautions, while in cases of impending or actual emergency one might depend upon artificial respiration after tracheotomy and the use of adrenalin.

Patent Urachus, with a Review of the Cases Reported; Operation on a Case Complicated with Stone in the Kidney.—Dr. Geo. Tully Vaughan, of Washington, D. C., explained the defective development in embryology which leads to the formation of patent urachus and of Meckel's diverticulum. He gave a short review of the literature and stated that the older anatomists held different opinions as to whether the urachus was a tube or a solid cord. He divided cases of patent urachus into the complete, blind, blind internal, and blind external, and into congenital and acquired varieties, and explained the occurrence of some cases of acquired patent urachus by the pressure of urine in the bladder from obstruction to its normal outflow, causing Wut's valve (a small valve which guards the bladder opening of the urachus) to give way and permit urine to enter the urachus, when, if infection took place, abscess formed, and pus broke through the umbilicus or discharged into the bladder. He briefly recounted 52 cases reported in the literature and added one case of his own, of which 38 cases were operated on, with 32 recoveries, 3 deaths, and in 3 the result was not reported. He divided the methods which had been tried for closing the open urachus into 8 classes, as follows: (1) The application of caustic or of the actual cautery to the umbilical opening. (2) The use of the cautery and of ligatures or sutures. (3) The use of ligature or suture only. (4) Plastic operations, the application of a flap of skin to close the opening. (5) To open or slit up the urachus, curet or cauterize, and pack. (6) Removal of sources of irritation from the urachus, such as stones, pus, etc., and keeping the parts clean. (7) Removal of obstruction to the flow of urine from the bladder through the urethra, as a tight prepuce, strictures of the urethra, hypertrophy of the prostate, and tumors or stone in the bladder. (8) Extirpation or dissecting out of the urachus and sewing or ligating the part next to the bladder, after the manner of treating the appendix in appendectomy. The author did not approve of the method of simply closing the umbilical end of the fistula, lest an infected suppurating area be left which might cause septicemia or peritonitis. He considered slitting open and packing the abscess cavity a rational operation, but thought the operation of election was to dissect out the urachus with the entire diseased area. Dr. Vaughan used this method in his case—a man of forty, who had an acquired patent urachus since the age of seventeen. A month after the patent urachus had been cured it was necessary to perform nephrolithotomy on the right kidney, and nine months later the same operation on the left kidney. A brief consideration was given to tumors and cysts of the urachus.

(To be Continued.)

The Yellow Fever Situation.—Up to the present time there is little change in the southern yellow fever situation. The Federal authorites under the Marine Hospital and Public Health Corps have been called in, and are in practical control of the situation. It remains to be seen how well they may be able to apply the methods which are now held to be preventive. About 700 cases of infection have been reported to date with a mortality about 20 per cent.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-sixth Annual Meeting, held at Portland, Oregon, July 11, 12, 13 and 14, 1905.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

(Continued from Page 236.)

THIRD DAY—JULY 13TH.

Some Complications of Pregnancy Treated Surgically.—Dr. F. C. Donoghue, speaking of the complications of pregnancy that require operative interference cited appendicitis, ileus, ovarian tumors and fibroids. He concludes his study with citations of cases as follows: When there is a history of a well-marked attack of appendicitis in a young woman, operation should be performed as an antecedent to marriage. Operation should be advised prior to marriage if tumors of the uterus or appendages are known to be present.

Pulmonary Tuberculosis as an Obstetrical Complication.—Dr. Charles Sumner Bacon, of Chicago, computes from the statistics of Chicago and other cities that there are probably between 24,000 and 31,000 pregnant women in the United States suffering from tuberculosis. Except in very rare cases tuberculosis is not a cause of sterility, therefore an ethical as well as a physical question is raised in connection with marriage or the desire for children in a woman suffering from tuberculosis. The effect of pregnancy on the woman is bad. Such effect is more apt to appear when the desire is already well advanced, or when nutrition is low from other causes. For this reason nausea and vomiting increase the danger. The pressure against the diaphragm may interfere with the circulatory system. The exhaustion of attending labor sometimes leads to fatal termination. In all cases the enforced confinement in imperiectly ventilated rooms is injurious, therefore in mild cases pregnancy may be considered a serious complication of tuberculosis, and in advanced cases a very dangerous one. The effect of tuberculosis on pregnancy is slight except where there is considerable fever and coughing, in which cases absorption is common. The fetus is rarely infected. The chances are that the child will be born free from tuberculosis, but that it may possess a predisposition to the disease. A pregnant woman in an advanced stage of tuberculosis is apt to die shortly after labor, if the labor has been severe; in milder cases the woman is apt to go to pieces during the puerperium.

Restriction on Marriage.—The question of imposing restrictions on the marriage of tuberculous individuals by legislative enactment has been widely discussed without satisfactory answer. Each case requires judgment concerning the expediency of allowing the pregnancy to continue when a couple in comfortable circumstances desire a child, and the wife had only some slight tuberculous involvement of the lungs. She can be put into the best hygienic surroundings during her pregnancy and puerperium. When, however, a woman must care for her house and remain indoors, and when she would be obliged to nurse and care for her baby, conception should be absolutely forbidden. For these patients artificial sterilization is a legitimate and praiseworthy operation. It is better to determine on an operation that does not remove the ovaries. The vaginal resection of the tubes is generally the simplest and best, un-

less some other pathological condition indicates laparotomy, when, of course, the abdominal resection would be done. When a probability of the cure of consumption remains, some other means of preventing conception may be advised. It is not necessary to advise abstinence from sexual intercourse. The question of interrupting the pregnancy depends upon the gravity of the patient's tuberculosis, and the kind of care she can afford to have. In case of inability to have hygienic surroundings or when there is a complication of tuberculosis with heart or kidney disease, an abortion should be performed. The operation should be decided on before the twentieth week. Later an attempt should be made to carry the child to the period of viability. Rapid emptying of the uterus is the best method of inducing abortion. Anesthesia, preferably by means of ether, is not contraindicated. After the period of viability is reached labor should be induced if there is failure of nutrition, exhausting cough or severe dyspnea. Otherwise it may be postponed till the thirty-sixth week. The bougie method should not be employed, but rather the method of operation should be that which hastens labor. In the most urgent cases, a vaginal Cæsarean section may give a better chance of saving mother and child. Oxygen should be freely used at the first sign of exhaustion, also strychnine as a tonic should be given hypodermically as indicated.

During the forty-eight hours of the puerperium, oxygen, strychnine and physiological salt solution should be at hand, as the most imminent danger is from circulatory disturbances. Later the nutrition and fresh air are of the most importance. The patient should, if possible, lie most of the day in the open air. The child should never be nursed by its mother, nor remain in the same room with her. When possible it should be fed by a wet nurse. Complication of puerperal fever with tuberculosis of the puerperium is, of course, the greatest danger. On the whole, Dr. Bacon believes that by the use of oxygen during labor, and the thorough use of the fresh air, rest and feeding cure, before and after labor, that many of the consumptive pregnant women in the United States can be brought through pregnancy and the puerperium, and eventually, perhaps, be cured.

Maternal Syphilis.—Dr. George S. Whiteside, of Portland, Ore., said that syphilis in the mother without paternal syphilis is rare, while the reverse is common; therefore maternal syphilis may be defined as only the disease of the pregnant woman. He called attention to the lack of careful discussion of the subject in textbooks, and to the great difficulty of making a diagnosis of syphilis in married women. Their own ignorance of the disease, their belief in their husbands, combined with the reluctance of a man to confess his unfaithfulness to his wife's physician, all tend to obscure the diagnosis unless the symptoms are very definite. Therefore, he cautions physicians to look oftener for syphilis, and they will find it explaining obscure symptoms. He advises the free use of mercury for pregnant syphilitic women as the only way of protecting the health of the fetus from inheritance. If the child survives the first acute febrile outbreak of secondary symptoms it will probably respond to treatment and very likely grow up a well individual, especially if born in the better classes. Even in cases where some deformity of bone has taken place, as in hydrocephalus, anti-syphilitic treatment often causes an absorption of the products of the disease, and later the deformity is not noticeable. Mercury is best administered to the infant by inunction, but it may be necessary to use hydrarg. cum cretâ in spite of the action of the bowels. Treatment should be continued for two months after all symptoms have disappeared.

Physiological and Legal Status of the Fetus in Utero.—Dr. W. H. Sanders, of Montgomery, Ala., considered this subject from an ethical point of view. Truly a child was alive from the very moment of its conception. He pointed out certain differences between the processes of conception in plants and animals, and argued that it was not justifiable to consider the human child as a living being with its rights and privileges only after it had been delivered from its mother. It was really an independent organism nine months previously.

Present Day Methods of Conducting Labor Cases.—Dr. J. A. McKenna, of Lansdowne, Pa., made a strong appeal for fuller asepsis and antisepsis in maternal works. From the fact that thousands of women still die of puerperal sepsis it was urgent that this factor should be eliminated. He was not in favor of intrauterine douches, but laid much emphasis on the proper cleansing of the hands of the obstetrician. A physician's hands were septic instruments, and only the most painstaking cleanliness could render them even approximately sterile. The forceps are a potent cause of septic infection, and should be used as rarely as possible.

Female Bony Pelvis.—Dr. Effa V. Davis, of Chicago, gave the results of a series of pelvic measurements made in her private, hospital, and dispensary practice for the past five years. In her measurements of 124 pelves she had found that 26 per cent. were deformed. Of these 70 per cent. were of the contracted pelvis order, 15 per cent. were flat. In her women with deformed pelves she had had 61 per cent. of normal deliveries. In contrasting the influence of surroundings, occupation, diet, etc., on the size and weight of the infant, she had found that in 88 women, who were well-to-do, ate good food, and were not compelled to work, the average weight of the child was 8.06 pounds. In 38 who were in moderate circumstances, but who did much of their own work, and led a more active life, the average weight was 6.7 pounds, while in nine patients who were badly fed and overworked, and who lived in very poor surroundings, the average weight of the child was 5.77 pounds. She had found that more deformed pelves were found among her clients who were natives of the United States than among the foreign born. She insisted on a regulation of the diet to control the size of the child in all those who had small pelves, and who were afraid to have large babies. She concluded her study as follows: Deformity occurs often enough to make pelvimetry a practical part of the examination of pregnant cases. Generally contracted pelves form by far the most common deformity in American women, though the rachitic pelvis is often present in those who have been artificially or imperfectly breast-fed in infancy. Inebriety in the parents is the most constant element toward degenerate types in the deformities studied. The size may be regulated by diet and exercise if carried out strictly for a proper time during the last three or four months of pregnancy.

Maternal Impressions.—Dr. E. T. Shelly, of Atchison, Kan., spoke with much emphasis, denouncing the maternal impression hypothesis as an unmiti-

gated and unwarranted superstition. Teratologists were emphatic on the subject and with unanimity stigmatize the idea as a popular delusion, but practitioners could not be made to give it up, notwithstanding the overwhelming evidence of embryology, anatomy and physiology against it. He held that it was very unwise, even criminal, for the general practitioner to countenance the belief in his patients, and thought that if they all combined to "down" the delusion many happier hours would be vouchsafed the pregnant woman.

Syncytioma Malignum.—Dr. Lauratt Branson, of Iowa City, reported the history of one case of this condition, and read an essay on the subject.

(To be Continued.)

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held March 8, 1905.

The President, Harlow Brooks, M.D., in the Chair.

The Identification of the Pneumococcus in Blood Cultures.—Dr. Thomas Flournoy described a characteristic appearance of the pneumococcus which he had seen in his work. Although made independently, his observations could only be taken as corroborative of Schottmüller's and of Rosenow's, which had appeared previously. In the course of a number of blood cultures made upon cases of lobar pneumonia it was noticed that colonies of the pneumococcus developed a brilliant green color in blood-agar plates. The blood cultures had been obtained by inoculating 1 c.c. of blood into a tube of melted agar and plated at the bedside of the patient. In this way a uniform mixture of blood and agar was obtained. The specimens were chiefly from severe, well-marked cases of lobar pneumonia. One was from the blood of a case of meningitis which was due to the pneumococcus. From the plates inoculations were made into other media and into mice. The green color was constant in the colonies of all these cases. It was seen best macroscopically and by transmitted light, but could also be seen under the microscope. The bacteria isolated in the cases mentioned were all fairly easy of identification by the ordinary cultural and staining methods. No work had been done on more doubtful strains. Apparently, however, the pneumococcus in a mixture of blood and agar develops a color not found with the ordinary pathogenic cocci. The explanation of the development of this color might possibly lie in some process comparable to the breaking down of old hemorrhagic foci in the body.

Dr. E. Libman, in the discussion, said that he had noticed the phenomenon but had not made many tests himself as most of his pneumococcus work was done on fluid media. It seemed that it was a method which was worthy of further trial because it would be a very rapid means of diagnosis, particularly if combined with some of the newer capsule stains.

Preliminary Report Concerning the Effect of the X-rays on Karyokinesis.—Dr. Harlow Brooks said that he had only a few words to say on the work which he and Mr. Goldhorn had been doing, because they had so far found only a few things of definite character. The investigation had been suggested by a presentation of Dr. Tilden Brown's a few weeks ago, before the Section on Genito-Urinary Diseases, in which he stated that in one hundred per cent. of the cases in which he had investigated the spermatic secretion of X-ray operators he had found absolutely no spermatozoa. The results of the few cases examined by the speaker confirmed this. Investigations were carried on to find what changes led to this absence of spermatozoa. Rats were selected for the experiment on account of the fact that in these animals spermatogenesis takes place very actively. So far the animals had been exposed only to the deep penetrating ray; that is, the ray which is designed to affect the deeper structures. Exposures were made for from fifteen to twenty minutes daily up to eighteen days. So far the results had been only very suggestive. Plates were shown indicating some of the changes found. At first exposure to the X-ray greatly excited the secretion of spermatozoa and if anything they were rather more active than normal. Although much work was still to be done they felt confident in saying that the X-ray increases the production of spermatozoa: that the X-ray after a considerable number of exposures does cause certain degenerative changes in the cytoplasm of the cells: that the X-ray does excite marked changes in the chromatin of the spermatocytes. So far the changes were not distinct enough to allow of conclusions being drawn from them. They were like changes found in a lesser degree in the normal. Later on karyokinetic changes took place which it was believed eventually resulted in the destruction of the chromatin of the spermatocytes and the formation of spermatozoa deficient in chromatin or entirely lacking heads.

Dr. James Ewing, in the discussion, inquired whether Dr. Brooks had any intention of using radio-activity as well as simple X-ray treatment. As he understood the nature of radio-activity and X-rays there were at least three forms of energy manifested. One of these was concerned with the emanation of a gas which was more active on the tissues. Did Dr. Brooks intend to employ all three forms of radio-activity?

Dr. Brooks said that so far they had found their studies so much more difficult than they had anticipated that they had no desire to undertake anything more. They had found great difficulty in carefully controlling the experiments. Many things had been seen in supposedly normal testicles which had not been before described.

The Practical Value of R. Stern's Bactericidal Test of Typhoid Sera.—Dr. Mary E. Goodwin gave a short account of her experiments with the above test, prefaced with an abstract of Stern's work. R. Stern, of Breslau, after examining the blood of fifty-nine typhoid and ninety non-typhoid cases for its bactericidal power on typhoid bacilli, decided that the bacilli were destroyed by much higher dilusions of the typhoid blood than of the normal. He found no fixed relation between the day in the disease when the blood was taken and the mount of immune body it contained. He gives as his strongest serum one which showed a decided reaction in a 1-4,000,000 dilution. The earliest day on which the bactericidal power was marked was the eighth, in one case the serum reacting in a 1-40,000 dilution and in another in a 1-4,000 dilution. The agglutinating power of the typhoid sera was not shown in nearly as high dilutions as the bactericidal power. He concludes by saying that the higher the dilution showing bactericidal action the greater the probability of the case being typhoid. His technic is briefly as follows: After inactivating the sera at 55° C. for thirty minutes, he makes the dilutions with 0.85 per cent. salt solution. For the complement he takes fresh rabbit serum in a dilution of one part to eleven of salt solution. The typhoid culture used was one which had been isolated about one year and was of moderate resistance, he having found that those recently isolated were too resistant, while the old cultures were killed by the rabbit serum alone. He put together in small test tubes 1 c.c. of the

serum dilution, ½ c.c. of a 1-5,000 dilution of a twenty-four hour bouillon typhoid culture in bouillon and ½ c.c. of the diluted rabbit serum, always using as a control, ½ c.c. of salt solution with ½ c.c. of diluted culture and ½ c.c. diluted rabbit serum. His control he plated from immediately, then put all the tubes at incubator temperature for two to four hours. At the end of that time he plated them all in agar, incubated the plates and counted after twelve to eighteen hours. All of this process Stern says can be done in one-half hour for one serum and the time reduced when more than one serum were tested at the same time. In testing 27 typhoid sera and 7 normal sera in the Board of Health Laboratory, Dr. Goodwin had found the test more difficult than the general tone of Stern's article suggested. The rabbit serum differed so much in its immune body content that sometimes it was necessary to test several rabbits before finding one that would not destroy too large a proportion of the bacilli added. After several failures a Mount Sinai Hospital culture and a New York Hospital culture which seemed to be suitably resistant were found. Among the few cases examined no serum was found of such unusual strength as Stern's, which showed the decided reaction in a 1-4,000,000 dilution. None of the sera showed a reaction above 1-200,000; the highest dilution of a normal serum showing a reaction was 1-100. The earliest serum tested was from a ten day typhoid. A 1-500 dilution gave a plate of 8,000 colonies while the normal serum control contained 100,000 in the same dilution. The bactericidal power was found in much higher dilutions than the agglutinating. It took a much longer time to make the test, about two hours for a single serum and an hour for each additional one. The test seemed too complicated for routine laboratory work but of undoubted value in obscure cases where a diagnosis could not be made. The full value of the results cannot be estimated until work has been done on obscure cases of colon and dysentery infection where one might be misled by the large amount of common immune body present.

Dr. W. H. Park, in the discussion, said that during the course of the work experience had been gained which seemed to him of some interest. The first results had been very disappointing. After reading Stern's first article the technic seemed to be very simple. Specimens of serum were taken from six typhoid cases and from four normal persons so as to get a rough estimate of the value of the test. The making of the tests took a full day. On the next morning it was found that the culture used was so sensitive that the rabbit blood alone had killed all the bacilli so that the plates were sterile. For a moment it seemed as though the test were a failure, but Dr. Steinhardt suggested that some other culture might show just sufficient resistance to resist the rabbit blood but be killed by the addition of a typhoid patient's serum. The Mount Sinai culture obtained from Dr. Libman was then tried and found to be of about the right resistance. A second point of interest was that during the course of four or five months this culture has shown no change and probably would never become as sensitive as the one first tried. Dr. Park thought that even in his second paper Stern made the test appear much simpler than it really was. However, with suitable cultures and great patience Dr. Goodwin had obtained results which, though not as definite as Stern's, indicated that the test might be of value in doubtful cases. Only a large number of tests could establish this. Dr. Goodwin would be very glad if anyone who had a doubtful case would send her some serum for further experimentation.

Concerning the Causes of Gall-Stones.—Dr. Edwin Beer read a paper on the causes of gall-stones, his purpose being (1) to indicate a new method of investigating the problem, and to show the results this new method had borne in his hands, and (2) to interest the members of the Society, so that more cases might be brought together and studied. A review of the work done by Naunyn and his pupils, which work has given rise to our present conception of the etiology of gall-stones, and of the confirming experiments of Mignot and Miyake, was briefly given. No one seemed to have tried to follow and analyze the genesis of stones in the human body. Dr. Beer's attention had been turned to the liver and its ducts. Here obstructions and inflammatory conditions are found which parallel the conditions which Naunyn thought underlay the process of gall-stone production. Eleven cases were collected at autopsy in which there had been a common duct obstruction for more than four or five weeks and in which a more or less severe inflammation of the extra and intrahepatic ducts had developed. In seven cases the common duct was obstructed by calculi, in four by tumors of various kinds. In the first series of four cases, as a result of the conditions of the experiments, stones formed in the liver ducts. In the second series of four cases, though apparently the same conditions were present, no stones developed, though stagnation of bile and inflammation of the mucous membrane of the bile passages were present. The absolute regularity of the results seemed to preclude chance, and though the series of cases was small, seemed to point to a new factor in the production of gall-stones. If we were to call this new factor an altered liver metabolism or a diathesis we could understand why stones developed in the liver ducts when stagnation and infection developed in cholelithiasis cases, they having the predisposition as evidenced by the older stones, and why they would not develop under similar conditions where no liver disturbance and no cholelithiasis were present. Dr. Beer's conclusions were as follows: (*a*) Naunyn's factors—stagnation of bile plus inflammation of the bile passage mucosa—do not seem to be sufficient by themselves to lead to gall-stone formation even though the time allowed for the working of the causes be adequate. (*b*) The first series of cases show that these two factors lead to stone formation in patients who previously had gall-stones. In these series we have the first real evidence of the factors underlying gall-stone production and the causes of cholelithiasis.

Dr. Otto H. Schultze, in the discussion, said that among the cases which came to the Morgue, in which gall-stones were rather common, the same thing had been shown as mentioned by Dr. Beer; namely, that in some cases of compression of the common bile duct where inflammation had taken place and every opportunity had been given to the factors mentioned by Naunyn, no gall-stones were found, and in some cases where gall-stones were found the common bile duct and the ducts throughout the liver seemed to be quite normal. When stones were present in the bladder it seemed to him as likely that the stones caused the inflammation as that the inflammation was a factor in producing the stones.

Dr. Charles Norris said that so far as his experience went he quite agreed with Dr. Schultze. The gall-bladder was frequently found to contain stones when there were no signs of previous inflammation. In old cases there was often a thickening of the wall of the gall-bladder.

Dr. E. Libman said that he could not speak positively concerning his cases without consulting the records, but

his general impression was that the material ran as Dr. Beer had said. He did not remember any case where the stone had formed after compression of the ducts by tumors. He did remember at least one case in which there was occlusion of the common-duct by gall-stones with stones in the hepatic duct.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

The 120th Stated Meeting, held February 8, 1905.

The President, Joseph F. Terriberry, M.D., in the Chair.

Pityriasis Rosae.—Dr. George T. Jackson presented this case, the patient being a man twenty-five years of age. After briefly stating the history of the case and making a few general remarks on the nature of the disease, Dr. Jackson emphasied the importance of not employing too much local treatment in these cases but rather of relying largely upon internal alteratives. There was no discussion.

Vesical Calculus.—Dr. W. S. Reynolds reported a case of vesical calculus in a male child, and exhibited an X-ray plate showing the calculus *in situ* before it had been removed. He also passed around the stone, which is about the size and shape of a pigeon's egg. The speaker directed special attention to the interesting fact that the calculus had been distinctly palpable on rectal examination and that the sensation imparted to the examining finger was very similar to that in cases of prostatic enlargement in the adult.

Appendicitis and Abscess of the Liver.—Dr. Adolph Rupp said that liver abscesses occurring in connection with acute appendicitis are not often mentioned in discussions on appendicitis. This is not to be wondered at when more than 1,000 successive cases may be operated by a surgeon without meeting a case of liver abscess associated with appendicitis disease. Happily liver abscesses occurring in connection with appendicitis are rare; but their rarity makes them none the less interesting and important pathologically or clinically.

Case.—S. L., merchant, aged forty-eight years; was seen at his office at 2 P.M., October 8, 1904, giving a history of indigestion. No fever, no acceleration of pulse, only vague intermittent colicky pains, anywhere and everywhere over the abdomen. Now and then nausea. Complained of lumbago and malaise. Was seen again at 6 P.M., because the codeine-bismuth-caroid mixture had given no relief. At this time no fever, and no change since two o'clock. Gave a quarter of a gr. of morphine hypodermically, and continued the above mentioned mixture. Diet only water. The sclera were slightly jaundiced, as well as the skin. October 9, 9 A.M., patient subjectively better and comfortable; but now a localized intumescence in the appendicular region could be made out, beside McBurney's point. Temperature 101° F. Diagnosis of appendicitis made, and surgical treatment advised. Patient entered Dr. Wm. T. Bull's Hospital, and was operated at 8 P.M. by Drs. Poole and Walker, with attention to all necessary details, and after a manner that left nothing to be otherwise desired.

The surgical history of this case lasted about one month, October 9 to November 10, when the patient died in collapse. In looking over the tracing of the temperature chart, the run of the fever can be divided into five unequal sections, each succeeding section being an aggravation of the preceding one; and it is quite natural to assume that some special pathological cause intervened to produce the change, in the course of the general pyemic infection.

Post-mortem examination revealed no general peritonitis; hepatitis, and two large abscesses, one the size of a large fist, the other about half that size, in the middle portion of the right lobe of the liver, rather anteriorily and to the left. Liver generally infiltrated with pus or small abscesses. The right lung was adherent to the ribs and diaphragm, solified, and the seat of septic pneumonia. Kidneys normal. Appendicular stump normal.

From the facts developed in the history of this case, Dr. A. Rupp believes that the appendicular disease was only incidental, and that no "inflammatory product" originating in the appendicitis "caused" the liver abscesses; but that the same original infecting cause or causes which gave rise to the early mental depression which lasted throughout, and became aggravated as the disease advanced, gave rise simultaneously, or in rapid succession, to the appendicitis, engendered the rapid formation of pus, which in turn infected the wound, and developed the liver abscess and the septic pneumonia. The septic developments were rapid. The temperature chart shows that when the outflow of pus was facilitated the temperature rise was lessened; but when the strength of the patient was rapidly declining, and conditions unavoidably became such that the escape of pus was rendered impossible, and became stored, as in the lung, the temperature rise and fall became abrupt and intermitted with very brief intermissions.

Therapy.—In this case the surgical operation was necessarily only an expectant remedy. It removed only one infected organ, and that organ was not the source of the subsequent complications. Dr. Wm. T. Bull had suggested the use of antistreptococcus serum. But, from his experience, he said he was "afraid" of it; however, he left its application for me to decide. I decided negatively, because even if a remedial serum were at hand, it could have been of no curative value in this case, and the sources of the toxic and anatomopathological causes could not have been reached by it. All other symptoms were treated as they arose. Morphine alleviated the severity of the chills, at least in so far as the feelings of the patient were concerned. Lavage of the stomach gave so much comfort, the patient asked for the procedure.

Dr. E. H. Poole confirmed Dr. Rupp's report on the history of the operation.

Dr. Brooks Wells considered it a very interesting case and remarked that he had observed similar cases in which the clinical picture simulated acute yellow atrophy of the liver, and in which the pathological examination showed degeneration of the liver following a septic pyelophlebitis.

Dr. C. S. Cole urged the importance of early operation and recited the history of a similar case observed during his service as house surgeon at the City Hospital, in which a diagnosis was not made till the time of autopsy. He expressed the opinion that exploratory puncture in these cases was usually disappointing and that blood counts unless showing a leucocyte count of at least 20,000 were not to be relied upon.

Dr. Morris Manges remarked that Dr. Rupp's case was certainly an interesting one, but thought that liver complications with appendicitis were not by any means so rare, referring to reports of Lindhart and the reports of the Mount Sinai and Presbyterian hospitals. Two forms of cases were met with: those in which there occurred mesenteric thrombosis and pyelophlebitis and those in which there occurred liver abscesses following general septic pyemia. He recited the history of a case observed by himself in which death had occurred

at the fourth day in spite of early operation. He believed that exploratory puncture was of great value and that leucocyte count above 15,000 was a very important sign.

Dr. Rupp, in closing the discussion, maintained that Dr. Manges' assumption that his case was similar to those reported elsewhere could not be based upon observed facts, and was of the opinion that Dr. Manges' views would coincide with his if he had seen the case himself.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held March 8, 1905.

Dr. Howard M. Fussell in the Chair.

New Apparatus.—Dr. H. E. Wetherill called attention to his hemoglobin scale and color-test book for the better determination of hemoglobin moisture, perspiration, urine and the color of the feces. He also showed a new hematokrit which measures in a two-way motion instead of one, and gives 25,000 revolutions per minute.

Fracture of the Cervical Spine.—Dr. Charles W. Burr exhibited a patient with this affection. The patient was a white man, fifty-six years of age, who had fallen in November, 1898, from a cart, striking his neck and shoulders. He was unconscious for a time and was taken to a hospital. At first he had severe pain in the neck, shoulders and both arms. He could not move the arms and could not walk. He stated that he could move the legs some. About six months later he was brought to the Philadelphia Hospital. At that time he could walk fairly well with short, stiff steps. He held his neck very stiffly, and movements in the arms were limited by rigidity and by weakness. The grip was very weak. The deep reflexes were increased. The skiagraph reveals a fracture of the body of the fifth cervical vertebra with fracture of the lamina. At the present time he walks well. His head is held stiffly. He can move it a little but with pain. There is considerable movement of the arms with rigidity. The knee-jerks are a little increased. The plantar jerks are normal. There is a little muscular wasting in the deltoids but none elsewhere. There is some spasmodic retention of urine.

Dr. M. K. Kassabian gave some statistics of fractures, showing that a very small percentage represent those of the spine. In his own 1,500 cases of fracture there was only four per cent. of fracture of the spine.

Dr. Morris Booth Miller stated that in such a fracture operation should only be undertaken when there is pressure upon the cord or from bone. Anchylosis gives a fair chance of slow absorption of hemorrhage and gradual restoration of function. To secure that no device is better than a modified jurymast.

How Can the Physician Profit by Preventive Medicine?—Dr. J. Madison Taylor, in this paper, presented evidence to show that it is necessary that preventive medicine shall be exhibited to the profession as a means of advantage to themselves as well as to the community. He submits that the relationship of the physician to the patient is on the wrong basis; that the practitioner should be given free opportunity to inspect the members of a household at regular peiods or at will, and not called only when there is illness; that disease is now being studied from the standpoint of economics, hence prevention is to be welcomed as a source of general wealth; that legislatures can be made more effective if physicians will do their part toward the prevention or limitation of preventable disease; that physicians should more clearly point out the ways to reform and educate the public; that they should accept the authority of the health boards more cordially and work with them to accomplish results. He recommends that physicians should adopt a different fee system, and states that it is a false position for the physician to earn no fee, except by being invited to meet exigencies; better, he says to adopt the plan long since found necessary by lawyers, of demanding a retaining fee or yearly stipend of the householder, thus giving them access to the house to rectify constitutional peculiarities and save from peril. He alluded to the neglected duty of the physician of discouraging the use of many medicines, bitters, tonics, cough medicines and the like, whose chief attractiveness is the contained alcohol or narcotics.

The Osmic Acid Treatment of Tic Douloureux.—Dr. W. Wayne Babcock reported a case of trifacial neuralgia of extreme severity. The conditions had persisted for thirty-five years, despite eight operations, including two attempts to remove the Gasserian ganglion, and the excessive use of drugs had at one time led to temporary insanity. About nine months ago a two per cent. solution of osmic acid, under cocaine anesthesia, had been injected into the inferior dental nerves. More recently the infra-orbital, palatine, and supra-orbital nerves were injected. The patient has gained thirty-five pounds, and his physical condition is revolutionized. The case was cited to indicate that osmic acid injection may be of value in cases of the most persistent and pronounced type of tic douloureux. No major operation, he stated, is warranted in the treatment of trifacial neuralgia until the futility of osmic acid injections into the peripheral nerve trunks has been proved.

Dr. L. J. Hammond called attention to the relations of the nerve fibers comprising the trifacial, and thought that absolute cure of these pains should not be expected until not only the trifacial but the different branches of the fifth nerve were dealt with.

The Problem of the Treatment of Laryngeal Tuberculosis.—Dr. W. G. Harland read this paper, which gave briefly what is known about the prevalence and natural history of tuberculosis of the larynx. The paper states that the vocal cords, interarytenoid fold and arytenoids are parts most often affected, involvement of epiglottis or epiglottic folds being more serious. Most forms of the disease pursue a harmless chronic course, edema and deep ulceration, however, are dangerous. The laryngeal lesion Dr. Harlan considers probably does little harm, except when it causes dyspnea, pain or difficulty in swallowing; it forms an index of general health and resistive power. Treatment is directed toward lessening irritation in the upper air tract, toward healing ulcerations, and toward building up general health. The X-ray he has found to be of use in some cases. He thinks that serum therapy promises much.

Dr. W. Wayne Babcock referred to a case of laryngeal tuberculosis seen within the last four or five months. On the day he first saw the patient she had received an intralaryngeal application. She had dyspnea and became unconscious. A rapid tracheotomy was done, after which she improved and gained in weight. The tube was removed. Further applications were not made by the laryngologist for fear of the edema, but after two or three months the edema again developed. A second tracheotomy was done and since that time the patient has worn a tube continuously. Her voice is better and she has gained in weight.

Dr. Ross Skillern thought that if the laryngologist gave the greatest possible amount of relief with the

smallest amount of actual manipulation of the diseased structures he is doing good work.

Dr. L. J. Hammond has operated on eight cases of laryngeal phthisis in the past sixteen or eighteen months with good results. He thinks the operative procedure is based upon rational principles, in that in this condition, as in a tuberculous condition of the joints, the best treatment is to put the parts to rest.

Dr. George E. Pfahler mentioned a case referred to him by Dr. Cleveland in which he is making the X-ray applications externally, using the tube of high vacuum and at a distance of from 15 to 20 inches. Distinct improvement has been noted in the case by Dr. Cleveland.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Regular Meeting, held March 17, 1905.

The President, Homer Gibney, M.D., in the Chair.

Equinovalgus Deformity.—Dr. Royal Whitman presented the following cases: The first patient, a girl eleven years of age, illustrated the practical cure of equinovalgus deformity, caused by paralysis of the tibialis anticus muscle. This operation, which he had described before on several occasions, was conducted as follows: The tendon of the longus hallucis was divided, drawn through a hole bored in the navicular, looped over and sewed to itself and to the shortened tendon of the tibialis anticus, at a sufficient tension to hold the foot in slight dorsal flexion. Arthrodesis was then made between the head of the astragalus and the navicular and the two bones were sewed to one another with strong silk. The foot was then placed in an attitude of moderate varus and a plaster bandage applied. Soon after, the patient was encouraged to walk about, the plaster apparatus being retained for about three months in order to impress the new attitude upon the foot. This operation was, as in this instance, as a rule so effective that no apparatus was required. It might be noted that the accessory tendon of the great toe was quite sufficient to hold it in proper position.

Clubfoot.—*Case II.*—This patient, a boy six years of age, illustrated the effect of the Phelps' open incision in correcting clubfoot. He had performed a number of these operations recently in a type of cases familiar in hospital practice in which, because of neglect of after operation, a certain degree of varus persisted. He thought no operation was as effective as this in assuring a permanent result in cases of this class.

Case III.—This patient, a girl sixteen years of age, came to the hospital from Porto Rico. She presented a congenital clubfoot that had never been treated and yet the deformity had been completely overcorrected by forcible manipulation without dividing a tendon even. The case was presented to contrast it with the preceding, as an illustration of the fact that the resistance of congenital deformities of this class by no means corresponds to the age of the patient. It was his custom in the treatment of clubfoot in youth, and adult age, whenever possible, to divide the operative treatment into several sittings, forcible correction always preceding more radical procedures. In this case the correction was easily accomplished in three operations.

Excision of the Ankle for Tuberculous Disease.—*Case IV.*—The patient, a woman twenty-five years of age, was admitted to the Hospital for Ruptured and Crippled last summer. She presented advanced tuberculous disease of the ankle of three years' duration. On investigation the disease was apparently confined to the astragalo-tibial joint. The astragalus was removed and in order to eradicate the disease of the tibia it was necessary to open its medullary cavity. It would be noted that the result was not only a cure of the disease, but free motion had been restored. The ankle joint was most favorably constructed for radical treatment since, as in this instance one might not only remove the disease but restore function. Another point was of interest in view of the question of plugging cavities in bone with iodoform filling, that although this might have been tolerated the patient's condition could hardly have been improved by such treatment.

Tendon Transplantation for Spastic Hemiplegia.—*Case V.*—This patient, a girl eight years of age, presented on admission to the hospital, the ordinary equinovarus deformity accompanying hemiplegia. The contractions having been overcome, the tendon of the tibialis anticus with the lower portion of the muscular substance was divided into equal parts, and the outer half was attached to the cuboid bone. The foot was fixed in the overcorrected position by a plaster of paris bandage for several months and the original deformity appears to have been overcome. In cases of this class it must be borne in mind that the operation simply restores in some degree the balance of the foot, but that cure can only be assured by constant supervision.

Torticollis.—Dr. Homer Gibney showed this patient. The boy was admitted last November, Dr. Gibney's service. He held his head inclined to the right, chin pointing over right shoulder—a compensating lateral dorsal curvature. Tendons of the sternocleidomastoid were divided subcutaneously, after which a jacket and jury mast were applied. The jacket was continued until within the past week when it was removed. There is no limitation of motion, no scar, spine quite straight and deformity entirely overcome.

Injury of the Cervical Vertebrae, with Symptoms of Osteitis.—Dr. Myers presented this case. Probably fracture of the second cervical vertebra. Cured with perfect motion in five and a half months. M. P., boy, four years of age. October 1, 1904, fell out of bed, turning a somersault. His two brothers fell on his neck. When his mother picked him up he seemed to have no power in the muscles of his neck, his head falling from side to side. He was put to bed; no other treatment. October 22, 1904, first seen by Dr. Myers at St. Luke's Hospital. Head was held a little flexed, not rotated to either side and all motions of neck, especially rotation, were markedly restricted by reflex muscular spasm. Great tenderness over second cervical vertebra. Reflexes increased, but no disturbance of sensation below the point of injury. Temperature 98.8° F.; respiration, 28; pulse, 86. He was put on a Bradford frame, with his head tied down. November 15, motion increasing somewhat in all directions. Second vertical vertebra still tender. Skiagraph shows no dislocation. Reflexes normal. November 21, retention head brace applied. Bradford frame continued. January 28, 1905, no vertebral spines especially prominent. Rotation to right and left 60 degrees. Inclination to right and left 60 degrees. Flexion and extension but slightly restricted now. No pain. February 2, brace removed and five days later he was allowed up. February 21, no deformity. Motions free. No pain or spasm. Discharged cured.

Osteoperiarthritis.—Dr. Carlton Wallace showed a child nine years of age, a typical case of hereditary specific disease. It is interesting because one sees few of these in orthopedic hospitals and clinics. She has

osteoperiarthritis of both knees, ostitis of both tibiæ and two or three ulcerations. She was sent to Sea Breeze Hospital, an experimental institution for the sea air treatment of surgical tuberculosis, last June. Was seen in November and it was diagnosed then as specific. There was much tenderness then over both tibiæ, but this has disappeared under potassium iodide treatment. She cannot stand erect and the knees are held at an angle of 170 degrees, but the joints are not especially painful. Her general condition has much improved and she has gained eight pounds in weight. She was discharged in March, there being no evidence of tuberculosis.

Equinovarus.—Dr. Hibbs presented the following cases: J. K., boy, aged three years, entered the New York Orthopedic Hospital June 21, 1904, with both feet in a position of marked equinovarus. The deformities of his feet were corrected by manipulation under ether at several different times. After this, however, there remained such an amount of twisting of the tibiæ that it was necessary to do an osteotomy on both. This operation was done January 13, at the junction of the middle and lower third. It was necessary to rotate the lower fragment with the foot outward, about 60 degrees to correct the deformity. There was little difficulty in the treatment of the deformity of the feet, but this condition of twisting of the tibia sometimes seen in such cases, cannot be overcome except by osteotomy.

K. G., girl, aged eleven years, entered ward June 17, 1904, with feet in a position of equinovarus, slight amount of internal rotation, no twisting of tibiæ. Walked on dorsal edge and outer aspect of foot, where there was a great callous. On July 11, July 20 and August 1, stretched and put up in plaster. August 13, tendo Achillis lengthened 1½ inches in both legs. Feet placed at 90 degrees in plaster.

Boy, aged three years, entered ward October 19, 1903, with a paralysis of the small finger, the result of severing a branch of the ulnar nerve. October 23, the branch of the ulnar nerve supplying the little finger was sutured and the hand put up in plaster. November 14, dressings removed, wound healed. Nerve showed signs of the beginning to revive. December 4, no evidence that the function of the nerve had been restored as there was still loss of power in the flexors of the small finger. Discharged. This boy had not been seen by Dr. Hibbs again until March 16, when it was observed that there was power in that tendon. The boy does not use the finger quite properly yet, but neurologists who have seen the case say he is steadily gaining ground.

NEW YORK OBSTETRICAL SOCIETY.

Stated Meeting, held March 14, 1905.

The President, J. Riddle Goffe, M.D., in the Chair.

Tubo-Ovarian Abscess. Five Years Subsequent to Vaginal Salpingo-Oophorectomy for Pyosalpinx of Other Side.—Dr. Le Roy Broun presented a specimen of tubo-ovarian abscess with uterus which he had recently removed for acute symptoms referred to the right iliac region. The abscess was first emptied through a vaginal incision, and then the sac which communicated low down with the large intestine was removed through the abdomen. On account of the desperate condition of the patient, the opening in the intestine was treated extraperitoneally by gauze drainage into the vagina. The recovery has been complete except for the presence of a small fistula. This experience, he says, will cause him to hesitate about leaving the other tube if one is the seat of purulent salpingitis.

Double Tubo-Ovarian Abscess. Complete Hysterectomy.—Dr. Le Roy Broun presented the uterus and adnexa he had removed from a patient, thirty-three years of age, who had been sick for a week with symptoms of acute salpingitis, following by one month symptoms of an acute urethritis and a profuse vaginal discharge. Recovery was uninterrupted.

Calcareous Degeneration of a Fibromyoma.—Dr. Le Roy Broun presented this specimen that he had removed from a paranoiac, who had been delivered eight years previously of stillborn child. She had believed the child was alive, but had been kept by the physician for experimental purposes. She had been very anxious to have children, and considered herself to be again pregnant.

Fibro-Sarcoma of the Ovary.—Dr. Malcolm McLean presented a large solid tumor of the right ovary removed from a patient twenty-five years of age, who had first presented herself about eight months prior to the time of its removal. The symptoms had been pain in the lower abdomen, the presence of a rapidly growing tumor and a diminution in the amount of the menstruation. The examination gave the physical signs of a subperitoneal fibromyoma. The peritoneal cavity contained about two quarts of yellow viscid fluid, and the thickened parietal peritoneum showed numerous small tubercles. Recovery had been complete. The pathological report showed it to be a round-celled sarcoma with an abundance of fibrous tissue.

Teratoma.—Dr. Malcolm McLean presented the photograph of a newborn child that presented a teratomatous mass springing from the pelvis and lower fourth of the child's body which was considerably larger in diameter than the head of the child. The pregnancy was marked by an unusual amount of abdominal soreness and tenderness. The labor progressed favorably until the presenting occiput reached the pelvic floor. A little extra effort succeeded in the delivering of the head, but further progress and delivery was accomplished only after considerable manipulation. After the shoulders were delivered it was evident that there was something detaining the rest of the fetus and abdominal palpation showed the uterus contained a form larger than the body of a normal child.

Sudden Elevation of Temperature During Labor.—Dr. H. C. Coe related the history of a patient, who had severe rigor with rise of temperature of 104° F.; at the termination of the first stage of a labor that had been induced two weeks early by means of cervical gauze packing because of a low output of urea and symptoms of a threatening toxemia. Temperature declined to 101° F. at the completion of the labor and her subsequent convalescence was uneventful except for a sharp attack of sciatica. During the fourth week another rise of temperature occurred for two days, which was thought to be due to grippe. The urine, which had returned to normal, again showed a low urea output after a more liberal diet, but without any evidence of renal trouble. Dr. Coe asked for the probable cause of the febrile movement during labor, and the significance of the low urea output in pregnant women, especially in cases in which there are no toxic symptoms. He asked if this alone is indication for premature interruption of the pregnancy.

Dr. Cragin said small amounts of urea are occasionally seen without symptoms, and mentioned two cases of his own, in which only 75 grains were passed a day, but both went to full term without symptoms. A milk diet and a large amount of fluid will make the urea low, and it is found that normal pregnant women do not pass as much urea as was formerly supposed. Among 100 cases ex-

amined at the Sloane Maternity Hospital during the last month of pregnancy, the largest amount executed was 300 grains a day, and any amount between 250 and 300 seemed to be normal. A woman passing 50 or 75 grains a day without toxemic symptoms may be allowed to go to full term, but under careful observation.

Dr. E. H. Grandin stated that it is not so much the amount of urea but the amount of urine passed in twenty-four hours, taking into account, of course, the diet.

Dr. W. S. Stone referred to a case of severe toxemia he had recently seen, in which the urea output was twice the normal amount.

The Prophylaxis and Treatment of Pyosalpinx — Dr. James N. West from an analysis of the reports of many thousands of pathological examinations of tubal contents has concluded that 62½ per cent. are caused by gonorrhea; about 16 per cent. from the results of incomplete abortion: the remainder of uncertain origin; a few arising from pathogenic organisms conveyed to the tubes from other parts of the body, as tubercle bacilli, colon bacilli, *Bacilli lanceolatus*. Seventy-eight per cent. then of the cases of pyosalpinx are possibly preventable. From his experience with washing out the uterus of two freshly infected cases through a cervical speculum with an alkaline solution followed by 1/240 solution of silver nitrate, he is encouraged to try the same treatment again. Pyosalpinx from infection following an incomplete abortion, he believes, can be entirely prevented by operating upon every case of inevitable abortion under anesthesia and perfect aseptic technic. His treatment of pyosalpinx would depend upon the stage to which the disease has advanced. In an acute and virulent stage, he would advise rest in bed, suitable dietetic and hygienic measures, icebag to the abdomen and hot vaginal and rectal irrigations, alternately every four hours. As soon as the acute symptoms have subsided, he would operate, although procrastination has the advantage of meeting less virulent micro-organisms. In the more advanced cases, in which the walls of the tubes and ovaries have coalesced into one large abscess sac with several communicating chambers, lying in the cul-de-sac, he would perform a vaginal incision, and after washing out the cavity with two per cent carbolic solution through a return catheter, a drainage tube is inserted and surrounded lightly with iodoform gauze. The tube is left in for five weeks. His general plan of procedure is to remove the tubes, leaving one or both ovaries, if possible. If the uterus seems to be necrotic, the seat of an abscess, or very badly injured in the course of the operation, it also is removed. The vaginal incision is first made if the cul-de-sac is bulging with a large abscess. If not the abdominal opening is made at once. Vaginal drainage is always used if there has been great traumatism, if pus has been spilled, and if there is excessive oozing from ruptured adhesions. Injury to the intestines and complications with the appendix are so frequent that in all cases where the tubes are to be removed, he thinks the operation should be done through an abdominal incision. Of 13 of his own cases during the past year, eight had vaginal drainage; in two the ovaries and uterus were also removed. All cases recovered. His conclusions are: (1) That all cases of abortion should be operated upon; (2) that gonorrheal invasions should be fought from their start to their finish; (3) that the greatest possible aseptic precautions should be used whenever the uterus is entered by fingers or instruments; (4) that all cases of pyosalpinx should be operated upon; (5) that certain cases may be relieved by a proper form of drainage; (6) that an operator should not enter upon a case with a fixed determination to do a radical operation; (7) that the vaginal route is unsuitable for a radical operation; (8) that vaginal gauze drainage is the best form, and has its definite indications and use.

Dr. E. H. Grandin, in the discussion, considered prophylaxis is the most important part of the subject, and would consist not only in proper hygiene on the part of the woman, and instruction to the physician and nurse, but also in teaching both men and women the dangers of the gonorrheal infection. The treatment of pyosalpinx should be surgical, operating in the interval whenever possible. If a swollen tube approaches the vaginal vault and is surrounded by a plastic exudate, the pus may be best evacuated through a large vaginal incision. He only uses gauze drainage. In other cases he prefers the abdominal route because the eye assists the finger. In gonorrheal infection he would remove both adnexa and also do a supravaginal hysterectomy.

Dr. R. H. Wylie was surprised to hear that gonorrhea is the cause of such large proportion of cases of pyosalpinx, as he had been led to believe that incomplete abortion was a more common cause than is generally supposed. The operative procedures advocated in the paper were those he had been using for a long time, except that he does not leave in the tube for such a long time. The abdominal route, he considers, is best for conservative work, as in young women he prefers to leave the other tube, although in chronic cases with much destruction of tissue, he would remove it but leave the ovary. He does not believe in waiting for the interval to operate, because the cases will recover if done in the acute stage, provided the work is done cleanly and the disc and tissue is removed.

Dr. Le Roy Broun considers the use of gauze in draining tubo-ovarian abscesses is objectionable, because of the amount of pain it causes in its removal and renewal. He prefers to use two tubes, sewed together, one small tube with only one or two fenestra at its upper end, and a larger one with fenestra along its entire length.

Dr. Ralph Waldo said that of 25 patients operated upon at Lebanon Hospital since June 1, 1904, for pyosalpinx, there were only four who had a history of gonorrheal infection. The others gave histories of septic endometritis, in most instances the result of an induced abortion. He ordinarily operates early in the disease through an abdominal incision, and if there is no reason to believe that a collection of serum or blood will result, the abdominal wound is tightly closed. Otherwise he usually drains with gauze through the abdominal incision.

Dr. H. C. Coe thought some confusion had been introduced into the discussion by considering acute salpingitis in the same category with pyosalpinx. In acute cases his experience had not been favorable to operation, and he did not think operations could be done at that time with impunity. He was accustomed to teach that the classical descriptions of pyosalpinx and the conditions upon which a diagnosis is based, are more often absent than present.

The placing of a tube within ordinary abscess cavity, he thought would not assure drainage of the origin of the purulent focus, and leaving a tube for such a long time would be apt to form a permanent fistulous tract.

Dr. J. Riddle Goffe spoke of the difficulty in the scientific determination of when a man is cured of gonorrhea so that he may safely marry, and related the history of two patients who had contracted gonorrhea from their husbands after they had been pronounced cured by eminent genito-urinary surgeons.

Dr. A. B. Tucker reported a patient in which both tubes and one ovary were removed for pyosalpinx. She subsequently became pregnant, and was delivered of a

living child. In the light of such an experience he believed in saving all the structures possible, as even the stumps of excised tubes may become patulous and allow impregnation to occur.

Dr. James N. West, in closing the discussion, said that he had found that gauze drainage, which was all removed by the sixth day, allowed the abscess to reform, and on this account he had introduced the rubber tube. He does not believe in removing both tubes if one is apparently healthy. The statistics in regard to the relative frequency of gonorrhea and abortion as a cause of pyosalpinx, he thought, showed that gonorrhea is less prevalent in American than in France and Germany.

CHICAGO LARYNGOLOGICAL AND OTOLOGICAL SOCIETY.

Stated Meeting, held March 7, 1905.

The President, William L. Ballenger, M.D., in the Chair.

Specimens of Cartilaginous Septum.—Dr. Wm. L. Ballenger exhibited specimens of cartilaginous septa which were removed with a knife he had recently devised. They were exhibited to show the shape in which they exist after removal. The method of removal by his knife does not in any way destroy the specimen, but preserves it in its entirety for study. The advantages of the knife, which he described, are that it shortens the operation, preserves the specimen, and obviates the mutilation that would be caused with punch forceps.

Stenosis of the Nares.—Dr. F. G. Stubbs described a plastic operation for stenosis of the nares. He also described an interesting case of tuberculosis of the larynx.

Some of the Newer Remedies.—Dr. Joseph C. Beck said he had looked up the literature on newer remedies, and was able to collect 11,064 such compounds as are recognized and used by the medical profession. The important question is to decide the value of these preparations.

Anesthesin.—In a case of painful ulcer of the septum, a local application of five per cent. ointment of this agent, twice daily, relieved the condition immediately. In a case of painful, specific ulceration of the tongue, the use of anesthesin bon bons was followed invariably by relief, so that the patient could eat a meal with comfort, but without them it was impossible. One case of earache, one of acute pharyngitis, after painful deglutition, one of hypersensitive rhinitis, and one of eczema, with intense itching of the external auditory canal, were relieved by anesthesin.

Argyrol.—He has been unable to see any appreciable effect of this remedy in the routine treatment of nasopharyngeal affections, and now resorts to the old, reliable solutions of nitrate of silver.

Adrenalin.—Much has been said against the use of this drug, owing to the secondary bleeding in operations. He has had his share of that trouble, still he would not do without the use of it. He referred to the peculiar action that this drug has had on two of his cases, namely, producing shock. In both there was no cocaine used, but symptoms very much like it appeared. He said others have had similar experiences from the use of adrenalin, and it is thought to be due to the ischemia of the nasal mucous membrane, with extension into the inner cranial cavity, causing marked ischemia of the meninges, and eventually the brain. This is the only explantion he has been able to find in literature. As to adrenalin itself, he prefers it to any preparation of the suprarenal extract, having tried the adrenalin adrin, adnephrin and epinephrin.

Aspirin.—He has found this remedy *par excellent* in all cases of grippe-like effects, associated principally with ear, nose and throat diseases. He has obtained immediate relief in doses of five or six grains. In several cases of acute frontal sinusitis, with marked pain, it acted admirably, though in somewhat larger doses—5 to 20 grains, three times per day.

Brometone.—The bromides are used by him considerably in ear cases in which tinnitus aurium is such an annoying symptom. These salts are not only very unpleasant to take, but disturb the stomach and produce bromism. His substitute for the salts or potash of soda or potash is brometone, in doses of 15 grains, three times a day, and he has found it to be satisfactory.

Camphorozol.—After more than two years' experience with this remedy in chronic suppurative ear diseases he says unhesitatingly that it is the best cleanser and deodorizer he has found.

Iodo-Nucleoids.—He has been able to come to some conclusions as to the value of this iodide preparation in comparison with the iodide of soda or potash, salts or iodipin. When this preparation was first put upon the market, he was told that it was superior to the other iodide preparations, in that the same results could be obtained in very much smaller doses without the production of iodism, disturbance of the stomach, acne, etc. He immediately selected three cases, and found it wanting, as he also found later, while he was using small doses, and when he reverted to the use of iodopin he was very much relieved at the immediate change of the condition of the patient. It soon followed that the small dose of iodo-nucleoids had to be increased the same as one does with the other iodides, and when he did so the change became apparent, that is, better results were obtained. After increasing the dosage of iodo-nucleoids he obtained results equally as good as when he used the old, reliable remedies, without any gastric disturbance or other symptoms of iodism, which is a distinct advantage.

Eucain Lactate.—In the few cases in which he has tried the 15 per cent. solution of eucain lactate applied to the nasal mucous membrane for any steady effort for operative procedures, he has found it wanting in every case. He was compelled to reanesthetize with cocaine before he could proceed with the operation.

Pollantine.—He has treated 12 cases of hay fever the past season with pollantine, but when the season was over he was very much disappointed as to the results. Only one case was completely relieved. Dr. Dunbar, on a recent visit to Chicago, stated that the antitoxin that was put on the market would act as a specific in those cases in which hay fever was due to the pollen of rye, which is frequently the cause of hay fever in Germany, and in the hay fever due to ragweed or goldenrod. The patient Dr. Beck speaks of as having been cured is a buyer of wheat and rye, and examines a great deal of grain. Almost all the hay fever cases stated that they did not have their hay fever as hard as usual, and universally declared that their rye symptoms were much lighter.

Thiosinamin.—Two years ago he read a paper before the Academy of Ophthalmology and Oto-Laryngology on the use of this drug in chronic otitis media, with a clinical report of 14 cases. He wished to supplement that report by 200 more cases with the observation that the drug acts in almost every

case in producing positive general symptoms, such as great fatigue, often nausea and loss of appetite. The results as to the immediate improvement of hearing and tinnitus are all slight. Grave changes may occur in the scar tissue or connective tissue in acting as a protective rather than as pathological, and grave lesions may occur. He mentions this drug because he knows that a good many men are using it indiscriminately, especially general practitioners, and three cases came to his notice with disastrous results. These three cases were reported in detail.

Ferrotropin.—Whenever he is called upon to prescribe an iron product in arsenic cases, associated with some ear, nose and throat affections, he usually does so by giving this pleasant iron preparation, which is easy to take and shows very early results, causing none of the disagreeable teeth symptoms. It does cause constipation, at times, owing to the chocolate it is mixed with.

Dr. E. Fletcher Ingals has used anesthesin in powder form, and while occasionally it has acted as a good anesthetic to open wounds, sometimes it has seemed absolutely worthless. Perhaps used in the form of an oily preparation it would be more satisfactory. He has obtained fairly good results from brometone in doses of not more than five grains, in such cases as the essayist has described. As to pollantine, he has only seen one patient in whom it seemed to do any good, and yet the ultimate result in this case was anything but satisfactory.

Dr. Norval H. Pierce has used anesthesin in a well-marked case of painful acute pharyngitis without any result. He has found that it produces some benefit in cases of itching of the external auditory canal. As to iodo-nucleoids, he thinks they produce as good results as the other iodides. He is quite convinced of that after some experience with them. He has been disappointed in the use of pollantine, in that he has not seen a case that has been cured, and inasmuch as the remedy is actually worth its weight in gold, he believes it is almost prohibitive in the large majority of cases of hay fever.

Dr. O. J. Stein has used the Dunbar preparations for hay fever. He mentioned 26 cases which he recently reported before the Chicago Medical Society. When used very early in the morning, before the patient leaves the house, or at the onset of the first sign or symptom of hay fever, every one of his cases, excepting three, had a positive amelioration of the symptoms that were coming on.

Sensory Nerve Endings at the Entrance to the Larynx, with special reference to the structure and function of the taste buds.—Dr. J. Gordon Wilson said that laryngologists are apt to regard the function of the larynx as essentially for voice production, and to overlook the fact that it has another function of great importance in the animal economy, a function compared with whose antiquity the voice is but a thing of yesterday, namely, the protection of the respiratory passage from irritants and during swallowing. The closure of the larynx is the one never-failing office of that organ; the arytenoid cartilages and their muscles are the only ever-present structures. "The original function of the vocal cords was to protect the air passages—speech being a superadded function." (Bland-Sutton.) In birds the function of the larynx is to guard the trachea; the vocal function is entirely removed from the larynx. In order to effect this closure, the vestibule of the larynx is extremely sensitive; from an anatomical point of view this fact was recognized by the number and variety of its sensory nerve endings. This is the more impressed on one when a comparison is made between a relative number and distribution of the endings on the lingual with those on the laryngeal surface of the epiglottis, the laryngeal far surpassing in variety and number the lingual. In addition, there is lodged in the vestibule of the larynx a sense of which few are aware—the sense of taste; a special sense whose presence is strongly upheld by some and equally strongly denied by others. All are agreed that over the upper part of the laryngeal mucous membrane taste buds are distributed, comparable to those of the tongue; but they still remain mysterious organs, about which little has been written, and about whose function we are still in the region of conjecture. The nerve trunks which carry fibers to the vestibule of the larynx are well known; but with regard to their central origins and their peripheral terminations much has yet to be done. The main nerve supply is the superior laryngeal. By this means there are conveyed fibers from three distinct sources, from the vagus, from the glosso-pharyngeus, and from the sympathetic. While the nerve branches are chiefly distributed on the side to which they belong, numerous fibers can be traced across the middle line, and after section of the superior laryngeal on one side, nerve degeneration is seen on the other side of the middle line. The main branches break up into subepithelial plexuses, from which arise the nerve endings. The nerve endings may be divided into two groups, subepithelial and epithelial. The subepithelial group presents both encapsulated and unencapsulated varieties. The encapsulated are chiefly modified Meissner corpuscles, nerve coils, and some varieties difficult to classify. The unencapsulated are chiefly tree-like endings, but Ruffini endings, and coils can also be seen. Of all these varieties the most numerous are the tree endings. The epithelial nerve endings are present in three varieties: (1) In ciliated epithelium; (2) in stratified epithelium; (3) in connection with the taste buds. In all these forms the varieties of endings are non-medullated and varicose. Drawings were shown of all these varieties of nerve endings. The taste buds lie in the stratified squamous epithelium. They are not concealed in furrows, as in the circumvallate papillæ of the tongue, but lie on an exposed surface. They are comparable in structure to those of the tongue. They are abundantly supplied by nerves; around the bud (perigemmal); within the bud (intragemmal), and at the base (subgemmal). The two principal hypotheses in regard to the function of these buds were discussed: (1) As to whether they were mere phylogenetic residues; this hypothesis resting on the decrease which is apparent from a comparative study of the taste buds in vertebrates, and on the restriction of area which occurs in man at various stages of development. (2) Whether they were reflex organs to intensify the closure of the larynx during the passage of food—a hypothesis which is based upon their abundant nerve supply, their localization, and their functional activity.

Bronchoscopy for the Removal of a Collar Button from the Lung.—Dr. E. Fletcher Ingals stated that on May 23, 1904, a Mr. C. D. E. was sent to him by Dr. F. W. Wilcox, of Minona, Ill. He was twenty-two years of age, had formerly weighed 142 pounds, but at the time he visited him only weighed 107½

pounds. Fourteen months previously he had accidentally drawn a collar button, presumably of vegetable ivory, into the air passages. He at once felt the sensation caused by it near the upper part of the sternum on a level with the second rib. Subsequently he had some soreness in the same place. Pneumonia developed on the left side within twenty-four hours and lasted for one month. All of the symptoms the patient had were described in detail. Fluoroscopic examination showed a dense shadow all over the left side, excepting a small area in the infraclavicular region, where the shadow was less marked. The patient was sent to the Presbyterian Hospital, a skiagraph made, but nothing could be seen, the lungs being so dense that even the ribs did not cast a shadow near the root of the lung. Three other negatives were taken with similar results. At five o'clock in the afternoon of May 23, assisted by several internes, the patient was given chloroform, and by upper bronchoscopy he attempted to remove the button. Although he had previously given the patient one-sixtieth of a grain of atropine, there was still abundant secretion in the trachea and a large amount of expectoration. Indeed, the patient coughed practically all of the time during the operation, which lasted from the time the chloroform started until he desisted, in all about two hours. During this time the patient spat large quantities of bloody pus, which was only kept out of the speaker's eyes by placing a pane of glass between his face and the bronchoscope. The pus rendered it very difficult to see, and compelled Dr. Ingals to swab out the passages almost continuously. After swabbing out the pus, he could only get two or three seconds before the patient would cough again. This seemed to result from the passage of the bronchoscope into an abscess. The patient took the chloroform so badly that they were not able to keep him profoundly under it, and Dr. Ingals frequently touched the bronchial tubes and the walls of the abscess cavity with a solution of cocaine, but the amount of pus was so great that it had little effect. In the examination of the left lung he was unable to see the numerous branches of the bronchi that are usually apparent, though he followed one of the branches far down until the bronchoscope was introduced its full length, 33 cm. below the incisor teeth. He searched carefully by inspection and palpation with a small hooklet, but was unable to locate the foreign body. There was considerable granulation tissue about the bifurcation of the trachea that for some time interfered seriously with the inspection, and one mass presented the appearance of a small polypus which nearly filled the bronchoscope. He had not yet been told of the peculiar choking spells, and therefore did not have in mind anything of a polypoid nature in that region. The mass that he saw he did not dare to remove, fearing that it might be connected with the bronchus in such a way that he would open through the tube and cause a pneumothorax. During the operation a part of the time he used for removing the pus a strip of one inch gauze, which was crowded down the bronchoscope with a large wire, the end of which had been flattened and forked, like that used in the ordinary uterine packer. This worked fairly well, but much of the time he used cotton swabs attached very securely to long brass carriers. At one time in swabbing out the pus the sliding ring for fastening the cotton in the carrier caught on the end of the bronchoscope and he had a little difficulty in disengaging it. As the swab was withdrawn he examined it and found the swab of cotton intact, but it seemed to him a little smaller than the other. He concluded that this was due simply to its having become saturated with the pus. Some time later he discovered at the end of the bronchoscope a white mass which looked like a large swab of cotton. He grasped this with the forceps and withdrew it, thinking that it must be a pledget of cotton that had been lost at the time the instrument caught. Not wishing to direct attention to the interne, who had been fastening the cotton on the carriers, he simply called attention to it by a look and threw it aside without examining it. This mass appeared fully twice as large as any of the pledgets of cotton after they had been saturated with pus, and considering the subsequent history he is now confident that it consisted of the collar button surrounded with necrosed lung tissue. During the operation the patient's pulse varied from 110 to 150, but all the time was fairly full and regular. Immediately afterward he appeared to be doing well. The next day there was no temperature and patient said he felt fine. Two days later, he was discharged and went to his home in the country. Two weeks later Dr. Ingals received a report that he was improving very rapidly, did not cough except a few times in the morning, had a ravenous appetite, and had gained 11 pounds. A month later another report stated that he was feeling fine and had gained 22 pounds. Two weeks later the patient came to see Dr. Ingals so changed in appearance that he did not know him. He coughed very little indeed, had no pain, no dyspnea on exertion, had a ravenous appetite, and weighed 130 pounds. An examination of the left chest showed only slight dulness from the second to the sixth rib, showing that the lung had cleared up greatly from the third rib to the sixth, flatness below the sixth rib, otherwise in front and laterally signs over the chest much as at the first examination, excepting that the apex of the heart was found about one and a quarter inches to the left of the mammary line. Posteriorly, the respiratory sounds were good over the left lung as low as the eighth rib, but feeble or absent below that level. The fluoroscope still showed a shadow over the left lung, but much less dense than formerly. In response to a letter, the patient called upon him a few days ago—February 20. He said that he had been working twelve hours a day since September, had no cough, no temperature, health fine and weighed 136 pounds. Examination of the chest showed very slight diminution of resonance over the left side as low as the sixth rib in front and laterally, and as low as the eighth posteriorly, with a vesicular murmur in the same region about two-thirds as intense as upon the right side. The lung was somewhat contracted and the heart drawn one and a half to two inches to the left of its normal position. No respiratory sounds could be heard below the eighth rib posteriorly, probably due to drawing upward of the lung and diaphragm. The normal superficial area of cardiac dulness had disappeared over the right half of the lower part of the sternum, on account of the increased activity of the right lung, and the dislocation of the heart to the left caused by retraction of the left lung. The patient felt perfectly well, and, considering the history, he feels justified in reporting the operation as a complete success, although he did not at the time examine critically the mass that seemed to have been causing the trouble.

BOOK REVIEWS.

The Urine and Feces in Diagnosis. By Otto Hensel, Ph.G., M.D., Bacteriologist, German Hospital, New York, and Richard Weil, A.M., M.D., Pathologist, German Hospital, New York, in collaboration with Smith Ely Jelliffe, M.D., Ph.D., Instructor in Pharmacy and Therapeutics, Columbia University; Visiting Neurologist, City Hospital, New York. Illustrated with 116 engravings and 10 colored plates. Lea Brothers and Company, Philadelphia and New York.

During the last decade a proper interpretation of the condition of the feces, and a more than ordinary routine in the examination of the urine have become necessities in diagnosis. In the urine the Bence-Jones albumose, melanin diacetic acid, indican, various bacteria, etc., have yielded valuable diagnostic suggestions. In addition, tests for the functional efficiency of the kidneys, cryoscopy, the estimation of the purin bases, etc., have become essential in the study of difficult metabolic or renal conditions. Most of these tests are simple enough, but, buried in a mass of literature, their easy application has not been recognized. So a new book on the urine finds its principal excuse for existence in these newer things, and our authors have dealt with them in a practical clinical manner that will appeal to the practitioner. We are sorry to see in this good book that the authors cling to the long-exploded idea that indicanuria belongs to hypochlorhydria, and never to hyperchlorhydria.

But it is to the second section, that on the feces, that we turn with most welcome. Until now textbooks in English have given very cursory treatment of the feces question, and the recent valuable work in this field has been closed to one not conversant with the German language. Yet there is a rapidly growing desire for more knowledge on the subject, and this would seem to be the "psychological moment" for a feces book in English. Taking as their guide the epoch-making work of Schmidt and Strasburger, and the bacteriological studies of Ford, the authors have succeeded in covering the field in a practical way, without too much condensation. The chapter headings, Macroscopic, Microscopic, Bacteriological and Chemical Examinations, Animal Parasites and Characteristic Pictures in Disease, give a very inadequate idea of the scope of the work; such subheadings as, the estimation of the duration of the passage, amount of feces, Conner's classification, Schmidt's test-meal, Nothnagel's bodies, and vegetable detritus, indicating more nearly its completeness. The whole subject is treated with considerable detail, but is kept within the range of the general practitioner. A fair criticism might be that Ford's method for the identification of bacteria has been given too much space. There are many illustrations, both urinary and fecal, mostly following recognized authorities.

Conservative Gynecology and Electro-Therapeutics. A Practical Treatise on the Diseases of Women and Their Treatment by Electricity. By G. Betton Massey, M.D., Attending Surgeon to the American Oncologic Hospital, Philadelphia. Fourth edition, revised, rewritten and greatly enlarged. F. A. Davis Company, Philadelphia.

The progress of electro-therapeutics has necessitated extensive rewriting to modernize this fourth edition. The author considers the remedial power of electricty to be due to an alteration in the molecular activity of the cells, which alteration can be changed at will. Electricity is of especial value in gynecology, in that the prevalent nutritional and functional affections of the uterus and adnexa readily yield to its influence. This agent furthermore offers a choice of treatment in a class of affections notoriously maltreated by methods involving sacrifice of organs. The writer states that it is impossible for the scientific mind to consider electricity, or anything else, a cure-all, and while the pages are largely devoted to a demonstration of the value of electricity in certain definite conditions, any simpler means of treatment that might prove effective are not to be neglected. The volume contains a complete, though brief, dissertation on Roentgen rays, by Dr. Herman Grad, of New York. The entire work is attractive, admirably illustrated and of decided practical value and scientific interest.

Gynecology, Medical and Surgical. Outline for Students and Practitioners. By Henry J. Garrigues, A.M., M.D., Gynecologist to St. Mark's Hospital, Consulting Obstetric Surgeon to the New York Maternity Hospital, Consulting Physician to the New York Mothers' Home and Maternity, Honorary Fellow of the American Gynecological Society, Honorary Fellow of the College of Physicians of the German Dispensary, Ex-President of the German Medical Society. With 343 Illustrations. Pp. 461. J. B. Lippincott Company, Philadelphia and London.

This book is designed for students and general practitioners who seek acquaintance with the essentials of modern gynecology. The first third of the book, called a General Division, includes a chapter on Puberty and Climacteric, describes methods of examination, etiology and treatment in general, and the significance of bloody and mucous discharges from the genitals. Reference is made to another work of the author's for a description of the anatomy and physiology of the pelvic organs. The Special Section comprises the remainder of the book, in which diseases of the genital organs, urethra and bladder are described. A special chapter is given diseases of the rectum and anus, and another to sterility. The etiology, pathology and treatment for the most part is based on the writer's personal ideas and experience, frequently to the exclusion of modern beliefs and methods. The surgical descriptions are brief, a few generally accepted operations are described in detail, a number given passing mention, and others of recognized merit receive no notice. The book is designed for beginners and as such has much to commend it, but it is lacking in the detail and scope demanded by a work of reference which is to be of value to the specialist.

A Hand-book of Nursing. Revised Edition, for Hospital and General Use. Published under the direction of the Connecticut Training-School for Nurses, connected with the General Hospital Society, New Haven, Connecticut. J. B. Lippincott Company, Philadelphia and London.

This volume is more than a revision of the edition published in 1878, it is a new book. The various subjects are presented clearly, intelligently and with pleasing brevity. The greater part of the book is devoted to medical and surgical nursing. A second part gives directions for Obstetrical Nursing, labeled "Monthly Nursing," and a third section includes Family Hygiene and Emergencies. The sanitary suggestions for colleges and schools for girls are excellent. The book is intended to supplement class-room instruction and is well adapted to subserve the purpose for which it was written.

The Medical Examination for Life Insurance, and its Associated Clinical Methods, with chapters on the insurance of substandard lives and accident insurance. By Charles Lyman Greene, M.D., Professor of the Theory and Practice of Medicine in the University of Minnesota, Ex-President of the National Association of Life Insurance Examining Surgeons, formerly Medical Director of Minnesota Mutual Life Insurance Company, etc. Second Edition, revised and enlarged, with 99 illustrations. P. Blakiston's Son & Co., Philadelphia.

The medical examiner for a life insurance company has for his object, not, as with the practising physician, the subsequent treatment of the patient, but solely the prognosis as to life; consequently he thinks nothing of the treatment, and places little credence on the statements of the examinee, who is financially interested. In addition to the diagnosis, therefore, he considers as very important, heredity, occupation, previous illness, the tendency of humans to deceive for the sake of gain, and other usually minor or irrelevant matters. The patient does not come to him complaining of palpitation, or frequent urination or constipation or cough, and the examiner must of himself determine whether the patient is now and promises to be in normal health or below normal. So none of the ordinary books on diagnosis or medicine fill the requirements of the life insurance examiner, and a work such as this of Greene is a practical boon.

After a short talk on the history of life insurance, the author proceeds to outline the problems of the examiner, the methods of physical examination, the significance of the urine findings, and how to examine sputum, urine, etc. A special chapter on the relation of heart disease and tuberculosis to insurance is well worth perusal. The author's dictum that "a thorough knowledge of the normal chest is all-important to the medical examiner" might well be brought home to every practitioner, whether an insurance examiner or not. Indeed, we find much in this book that may be read with profit and pleasure by every physician. The illustrations, especially those accompanying the chapters on physical diagnosis, are very good and very helpful.

International Clinics, a Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, etc., by Leading Members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.B., of Philadelphia. Volume I, Fifteenth series, 1905. J. B. Lippincott Company, Philadelphia and London.

Though 110 pages of the present volume of the International Clinics are devoted to a review of the progress of medicine during 1904, a department, by the way, which, considering the number of reviews of medicine in one form or another that are now published, seems scarcely in place in the International Clinics, there are a number of very practical and interesting clinical lessons. New York clinicians are especially well represented. Dr. Morris Manges has an excellent article on Aortic Stenosis and Adherent Pericardium; Dr. James J. Walsh, a clinic in which he insists that the eye and the hand are more important in the diagnosis of heart disease than is the ear; Dr. Robert H. Dawbarn has a clinic on the Starvation of Malignant Growths, by depriving them of blood supply, with a discussion of the limits of application of this method of treatment; Dr. Russell A. Hibbs has a clinic on the treatment of knee-joint disease; Dr. Ernest Gallant, a clinic on the Treatment of Glenard's Disease. To those who are not familiar with it under this designation, it may be as well to say that this is floating kidney. One of the most interesting articles in this number is that by Dr. Charles K. Mills, of Philadelphia, on the legal consequences of drug addiction. There are besides the usual contributions from foreign sources.

Infantile Mortality and Infants' Milk Depots. By G. F. McCleary, M.D., D.P.H., Medical Officer of Health of the Metropolitan Borough of Battersea, London. P. S. King & Son, London, Eng.

Such a book as this may be of value in Britain, but concerned solely with the methods of regulating the distribution of milk to the poor of large cities, it can have no general demand in this country. Indeed, much of its material is taken from American books or records; and in our meetings the subject has been reviewed again and again by our leading pediatrists, so that our milk supplies to-day are better than in any other part of the world. There are twenty-six illustrations, mostly of depots in different European cities, but they add nothing to the text, except perhaps one or two of the Battersea station in England. We would recommend the author to visit our own Walker-Gordon, Fairfield or Briarcliff dairies.

Abdominal Pain, Its Causes and Clinical Significance. By A. Ernest Maylard, M.B., B.S.(Lond.), Surgeon to the Victoria Infirmary, Glasgow; Late Examiner in Surgery to the University of Glasgow, and Victoria University, Manchester; formerly Demonstrator of Anatomy, Guy's Hospital, London, and Ex-President of the Glasgow Pathological and Clinical Society; Author of a Treatise on the Surgery of the Alimentary Canal. P. Blakiston's Son & Co., Philadelphia.

For a long time the Germans have given tireless study to the symptom pain, which becomes manifest in almost all pathological conditions, and Dr. Maylard, realizing the fatal ignorance oftentimes displayed on the part of the general practitioner relative to abdominal pain has attempted to present as clear an analysis of this subject as present observations permit.

As he truthfully observes: "The old idea of a 'stomach-ache,' with the continual administration of an aperient to clear out the canal, or a sedative to soothe the patient's suffering, has given place to the more watchful and investigative attitude of seeking to ascertain the causes of the 'ache.'"

Pain *per se*, its nervous origin and correlation, splanchnic and somatic, is first taken up, following which the symptom as it relates to the various abdominal viscera is described from a standpoint both of character and etiology. A tabulated analysis of the regional manifestation of pain and its multitudinous probable causes has been made, which is not only a convenient résumé, but will prove helpful in arriving at an earlier diagnosis of obscure abdominal processes.

Why the author, after presenting an entirely useful treatise on the subject given, should wander off into an abbreviated "touch and go" kind of dissertation upon abdominal surgery is not exactly clear. The information which he intends it to convey can be found to much better advantage elsewhere, and its incorporation here detracts from the strength of the book.

A Text-Book of the Practice of Medicine for Students and Practitioners. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College, of Philadelphia, etc. Lea Brothers & Company, New York and Philadelphia.

There have been many Practices of Medicine written in America, and many more will follow. Each in its turn, from Thacher's to the present time, has enjoyed a popularity commensurate with its usefulness.

The vast majority of the more ambitious works have reflected the experiences of clinicians—at least so far as works in the United States are concerned—and have mirrored the prevailing opinions of the times with greater or less accuracy and wealth of bibliographic research. A few only have been conceived with regard to the philosophy of disease, seen in its wider aspects—at the present time we know of but one such of native production.

Hare's work belongs to the more conventional and usable type. It is eminently descriptive and practical, particularly the latter, and offers much in contrast with the modern unfortunate tendency in more philosophical works, in the way of the treatment of disease.

Hare believes, and we follow him, that for the vast majority of students of medicine, and practitioners as well, the promulgation of therapeutic principles is not enough to guide one in the vast labyrinth of sickness; what is wanted as well are specific details—and these he provides with richness of illustration and from the wealth of a vast experience. The philosophies suffer, but this book is not meant for the specialist.

Further, the present volume offers to the reader a remarkable wealth of statistical material, bearing on incidence, mortality, morbidity, prognosis, etc., which is of great service in obtaining a general oversight of the disease in question. The statistical material is not utilized to its full value by a thoughtful presentation, but it can be found nowhere else in as rich profusion, and the individual reader should be able to utilize it according to his own needs.

Another excellent feature of the work is its highly descriptive and clinical character. It is almost monographic in most of the more important chapters in the inclusion of clinical types, and although some omissions are evident, they may truly be said to be unimportant.

From one point of view the reviewer cannot but help feel that the work could be improved, and that concerns the purely theoretical position of the grouping of the subjects. Thus, if the author attributes value to the group of "diseases due to animal parasites," why is malaria not included? or if his first group of "infectious diseases" is meant to denote a classification in a true sense, why are not the animal parasitic diseases, trypanosomiasis, and others, not infectious?

We freely admit, however, that the matter of grouping is of little value, particularly from the standpoint of the student, and does not in any sense affect the quality of the material presented.

Although the book is over 1,000 pages, and undoubtedly the author feels that is too compressed at the present time to do him full justice, we have been looking for the "Medical Practice" that would adequately outline the diseases of the mind. Why they should be neglected is, we believe, unfortunate, particularly when mental diseases are so common and so important.

It might seem, and it is probably true, that a Practice of Medicine that can faithfully reflect the modern aspect of the labor of the workers in medicine the world over cannot be written in 1,000 pages by any one man—the task is enormous—yet we can consistently say that Dr. Hare has undoubtedly accomplished a great work in this new Practice. The present generation demands a full grown and mature volume, and Hare's "Practice" will stand the test of true merit most conspicuously.

BOOKS RECEIVED.

Diet and Nutrition. By Dr. M. Einhorn. 12mo, 64 pages. Wm. Wood & Co., New York.

Chirurgie du Systeme Nerveux. By Dr. G. Marion. 8vo, 531 pages. Illustrated. G. Steinheil, Paris.

The Eye, Mind, Energy and Matter. By Dr. C. Prentice. 12mo, 131 pages. Published by the author.

The Intestinal Catarrhs. By Dr. E. Blake. 8vo, 356 pages. Illustrated. W. T. Keener & Co., Chicago.

Abdominal Pain. By Dr. A. E. Mayland. 8vo, 304 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Johns Hopkins Hospital Reports. Volume XII. 8vo, 548 pages. Illustrated. Johns Hopkins Press, Baltimore.

Diseases of the Heart. By Dr. E. H. Colbeck. Second edition. 8vo, 350 pages. Illustrated. W. T. Keener & Co., Chicago.

Atonia Gastrica. By Drs. A. Rose and R. C. Kemp. 12mo, 203 pages. Illustrated. Funk & Wagnalls, New York and London.

Diseases of the Nervous System. By Dr. L. Harrison Mettler. 8vo, 989 pages. Illustrated. The Cleveland Press, Chicago.

Infantile Mortality and Infants' Milk Depots. By Dr. G. F. MacCleary. 12mo, 132 pages. Illustrated. P. S. King & Co., London.

Annual Report of the Commissioner of Education for the Year 1903. 8vo. Volumes I and II. Illustrated Government Printing Office, Washington.

Appendicitis, its Diagnosis and Treatment. By Dr. J. B. Deaver. Third edition. 8vo, 492 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Essentials of the Practice of Medicine. By Dr. W. R. Williams. 12mo, 460 pages. W. B. Saunders & Company, New York, Philadelphia and London.

Operative Surgery. Volume II. By Dr. J. D. Bryant. Fourth edition. 8vo, 1,559 pages. Illustrated. D. Appleton & Company, New York and London.

Diseases of the Eye and Ear. By Drs. A. N. Alling and O. A. Griffin, 12mo, 252 pages. Illustrated. Lea Brothers & Company, Philadelphia and New York.

Vermiform Appendix and its Diseases. By Drs. H. A. Kelly and E. Hurdon. 8vo, 827 pages. Illustrated. W. B. Saunders & Company, New York, Philadelphia and London.

Detection of Poisons and Strong Drink. By Dr. W. Autenrieth. Translated by Dr. W. H. Warren. 8vo, 22 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Historical Relations of Medicine and Surgery to the End of the Sixteenth Century. By Dr. T. C. Allbutt. 12mo, 125 pages. The Macmillan Co., New York and London.

American Year-Book of Medicine and Surgery. 1905. 8vo, 696 pages. Illustrated. Medicine. 702 pages. Illustrated. W. B. Saunders & Company, New York, Philadelphia and London.

Progressive Medicine. Volume I, March, 1905. Edited by Dr. H. A. Hare. 8vo, 298 pages. Lea Brothers & Co., New York and Philadelphia.

Bacteriology in Surgical Technic for Nurses. By Dr. E. M. A. Stoney. Second edition revised by F. R. Griffith. 8vo, 278 pages. Illustrated. W. B. Saunders & Company, New York, Philadelphia and London.

SPHYGMOGRAMS FROM TWO CASES OF BRADYCARDIA.

BY GEORGE DOCK, M.D.,
OF ANN ARBOR, MICH.

COMPARATIVELY few tracings have been published from cases of bradycardia. Even reports of such cases are not always convincing, because pains are not always taken to show that the heart beat is really infrequent. In a very recent report the pulse suddenly dropped to about half its former rate. As the heart beat is not described, nor the sounds mentioned, there is reason for thinking this was a case of alternating pulse (postoperative), a very different condition from bradycardia. Besides noting the rate of the heart beat, and the character of the sounds, it is essential to take tracings of the pulse, and also simultaneous tracings of the apex beat as well as the venous pulse. In the cases now reported it was not possible to get cardiograms or tracings of the venous pulse, but the sphygmograms of the radials seem of sufficient interest to excuse this and other unavoidable imperfections.

Case I.—Pulse about 30 for six years; in the last two years attacks of loss of consciousness; sudden death. C., farmer, aged sixty-three years. Health good up to four years ago, when there was an attack resembling influenza. At this time the pulse was found to be 28; the skin was cold. Various remedies were used but the pulse never exceeded 30. The general health became fairly good, but shortness of breath remained. There was impotence for a time. Convulsions were not observed at any time.

I saw the patient once only, June 24, 1902, with his physician, Dr. James Hueston, of Ypsilanti. He was a man of large frame. The heart was slightly enlarged, the apex beat strong; there was a diastolic murmur over the midsternum. The peripheral arteries were only moderately sclerotic. Radial pulse of medium size and fulness; wave well sustained but diastole long; 28; regular, following the heart beats with perfect regularity. There were no unusual pulsations in the neck. No capillary pulse. The other organs and the urine were negative. I made a diagnosis of probable Stokes-Adams' disease (the paroxysmal features of which, however, were not explained to the patient) and advised a course of atropine, partly in order to determine its effect on the pulse rate. This was given in full doses by Dr. Hueston, who never, however, found the pulse above 32.

Soon after my examination the patient began to have attacks of loss of consciousness, falling suddenly at long intervals. The unconsciousness lasted three to four minutes. Some attacks followed exertion, others not. The final attack came on while picking fruit. The man fell down and was found almost at once to be dead. I often heard of him from Dr. Hueston in the meantime and he made many promises to come for examination, but never did, and as he lived some distance in the country I never found it possible to see him. I was fortunate enough to make an autopsy with Dr. Hueston. There was moderate arteriosclerosis, with very slight corresponding changes in the liver, kidneys and spleen. The kidneys were granular but the microscopical alterations were relatively slight, with the exception of some minute old infarcts and recent hemorrhages. The vessels of the brain were not unusually sclerotic for a man of his age. The cerebellum, pons and medulla showed no macroscopic changes. Sections of the medulla at the level of the vagus center show a slight diffuse increase of neuroglia, but the vessels and the nerve cells are not perceptibly altered.

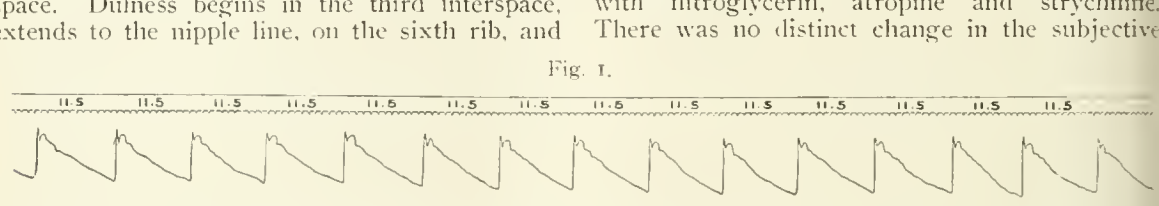
The heart, weighing 500 grams, is slightly hypertrophied, shows only mild fibroid changes in the walls. The left auricle is thickened and fibroid, the right auricle shows slight separation of the muscular bundles. The auricular appendages are not affected. Microscopically the muscle fibers are well preserved, with no fragmentation. Both auriculoventricular orifices are slightly dilated. The aortic valves are slightly thickened and retracted. The aorta at the level of the coronaries is moderately sclerotic, but the coronaries from their orifices down show very little sclerosis without nodular thickening, retraction or dilatation. The sphygmogram (see Fig. 1) shows a shallow notch below the summit due to a slight exaggeration of the ventricular systolic wave, but the dicrotic wave is often very low. The chief feature is the slow rate, equal to 26.5 beats per minute, with a great regularity in the duration of each pulsation (11.5 fifths of a second), as well as in the height of the stroke. Several long tracings were taken, and all show the same details.

Case II.—Dyspnea, pain, palpitation of the heart; bradycardia (15 to 30) and arhythmia. A. D., farmer, aged sixty years, seen with Dr. J. L. Ramsdell, of Albion, March 19, 1904. The patient was strong and muscular, and never ill until about one year before. He then began to have dyspnea on exertion, very slight pain, palpitation of the heart; no anginal symptoms. Dr. Ramsdell saw the patient four days before my

visit and found the pulse 25. He then gave strychnine. A few hours before I saw the patient Dr. Ramsdell found a rate of 15.

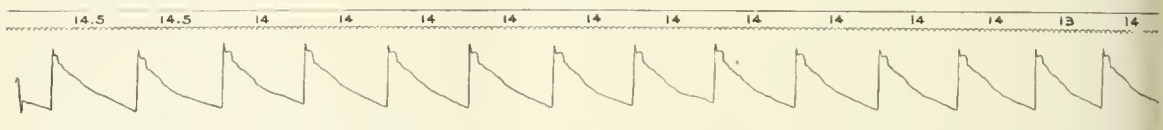
I found the patient spare, well preserved, but arteriosclerotic looking. I noted: "The apex beat is in the nipple line, in the fifth intercostal space. Dulness begins in the third interspace, extends to the nipple line, on the sixth rib, and to the left edge of the sternum. At the apex the sounds are weak and there is a short systolic murmur conducted about one inch in various directions. This is followed by a soft diastolic murmur. The action is irregular. Sometimes the beat is very slow but regular, sometimes one or two beats follow a stronger one, but without regularity. The radial artery is of moderate size, the vessel tortuous, irregularly thickened; the pulse of moderate size, irregular, 25 to the minute. Usually there is a long pause, sometimes the pulse is followed by two weaker beats in rapid succession corresponding exactly to the heart sounds. There is no venous pulse. Blood pressure (Riva-Rocci after Cook, 5 cm. band), 185. Extremities warm, no edema. Has had tendency to cold skin all winter. The urine is negative. There are no brain or eye symptoms."

Fig. 1.



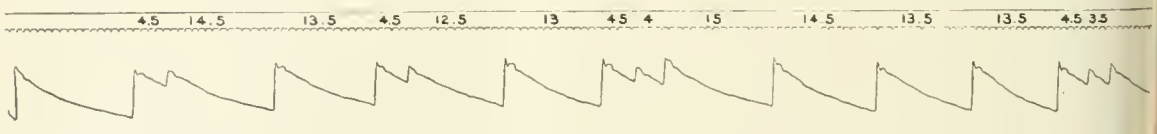
The time shown in one-fifth seconds; the figures above the tracings indicate the length of the pulse in this same fraction.

Fig. 2.



The time shown in one-fifth seconds; the figures above the tracings indicate the length of the pulse in this same fraction.

Fig. 3.



The time shown in one-fifth seconds; the figures above the tracings indicate the length of the pulse in this same fraction.

The tracings taken at this time illustrate the cardiac and pulse rhythm. Usually there is slow pulse, with intervals of about three seconds. Without obvious cause this changes to a very irregular pulse, or sometimes a regular irregularity, with intervals of from less than one second to five seconds or more. Both of these are shown in tracings, Figs. 2, 3, and 3*a*. The waves with short intervals are always weaker than the long ones. Sometimes two waves follow a long pause and then the second pause is shorter than the first, but followed by a higher wave.

I made a diagnosis of arteriosclerosis with myocardial degeneration, and advised treatment with nitroglycerin, atropine and strychnine. There was no distinct change in the subjective and general condition after that, and no notable increase of the pulse rate.

April 9, Drs. R. S. Morris and C. E. Edmunds kindly saw the patient for me and made some observations. The general condition was about the same as before. "The apex beat 1½ to 2 cm. wide in the fourth intercostal space outside the nipple line. Dulness from the third interspace to the nipple line and the left edge of the sternum. The first sound at the apex weak, accompanied by a soft short murmur, transmitted about one inch upward and to the left, also toward the base. The second sound at the apex is strong and clear. The diastolic pause is very long. At the second right interspace the sounds are almost inaudible, also at the level of the third costal cartilage over the sternum. In this area the systolic murmur can also be heard, and followed up to the right sternoclavicular articulation, but not to the left.

"The peripheral arteries show marked sclerosis. Radial pulse 24 at first, later 30, but regular. The blood pressure (Cook), 176; Erlanger, systolic 162, diastolic, 105 to 110. One mg. of atropine was injected but no change of the pulse rate followed. The patient had taken 1/150

grain atropine t.i.d. The pupils were wide in the beginning of the examination and did not become larger in the subsequent forty-five minutes of observation."

Tracings taken at this time show (Fig. 4) a pulse of almost perfect regularity beating at the rate of 24.4 per minute. The patient died a few weeks after this, without any distinct change in his pulse conditions. An autopsy was not permitted.

These two cases have a relationship chiefly in the slow pulse. I think the first one should be classed among cases of Stokes-Adams' disease, though not a typical case. The slight retraction of the aortic valves does not seem to have been of much importance.

In the second case there were no Stokes-Adams symptoms, though these might have developed if the patient had lived longer. In this case the peripheral arteriosclerosis was more marked than that in any part of the body of Case I, but was no greater than occurs in many cases that never have bradycardia, Stokes-Adams symptoms or other unusual circulatory changes.

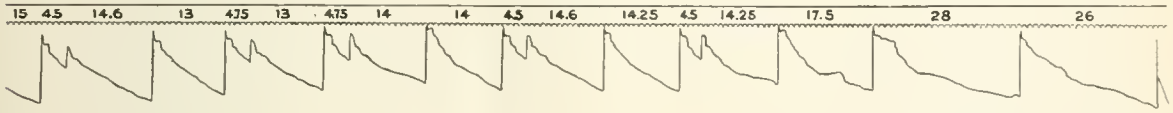
Both are cases of true bradycardia in that the heart beat had the same rate as the very infrequent pulse. Both failed to react to atropine in full doses. This makes unlikely a principal participation of the vagus center or trunk, which is also rendered unlikely in Case I by the very long duration.

Aside from a vagus cause, the bradycardia might arise from: Diminished automatic excitability; lowering of conductivity or lessened contractility, or a combination of these.

Inasmuch as digitalis sometimes causes slow pulse by a toxic action on the heart muscle, I should say that in neither case was it given in such a dose as to produce an effect.

The regularity of the wave, the absence of signs of intermission in the tracing and of venous or cardiac signs on inspection and auscultation make it probable the slow pulse in Case I was due to lowered automatic excitability. The same may be said the regular curves in Case II. The irregular part in the latter case offers some interesting suggestions. There is a marked indication of "Luciani's periods" in the small waves, a disturbance of rhythm that occurs in certain disturbances of stimulus conduction in the heart muscle and capable of artificial production by asphyxia. In the patient, however, notwithstanding the great disturbance of the pulse at that time, there were no evidences of asphyxia, even with intervals of 3 to 5½ seconds between the heart beats. This condition, however, probably did not continue very long.

Fig. 3*a*.



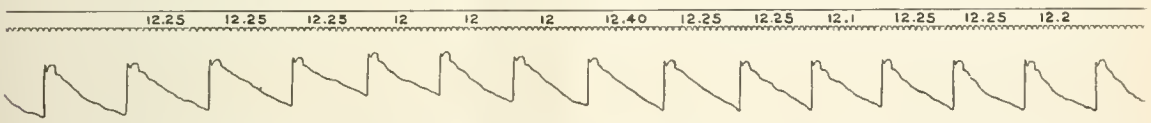
The time shown in one-fifth seconds; the figures above the tracings indicate the length of the pulse in this same fraction.

Another possible explanation of the arhythmia is that the long waves are due to intermission, the shorter ones showing the true rhythm; but the duration of the waves, as shown by the time marker, makes this unlikely, while the clinical evidence, again, was opposed to this view. The two long waves in Fig 3*a* suggest missed beats, but in ausculting at other times with waves of five seconds' duration I could detect no marked contractions.

The same sort of evidence negatives the supposition of "heart block," which might produce a tracing not unlike Fig. 3. A disturbance of contractility, or a negative inotropic action, might be supposed to be at work in both cases, but our knowledge of such disturbances in the human heart is too fragmentary at present to apply it to this case. Further experimental work and more thorough clinical investigation are much needed in this most interesting branch of cardial pathology.[1]

I should add that my friend and former colleague, Dr. A. R. Cushny, who has studied the tracings, also concludes that the chief element was diminution of automatic excitability in both cases.

Fig. 4.



The time shown in one-fifth seconds; the figures above the tracings indicate the length of the pulse in this same fraction.

ON THE IMPOSSIBILITY OF DIFFERENTIATING SO-CALLED "PARATYPHOID" FROM TYPHOID FEVER EXCEPT BY A BACTERIOLOGICAL EXAMINATION OF THE BLOOD.*

BY WARREN COLEMAN, M.D.,
OF NEW YORK.

If cases of infection by intermediate members of the typhoid-colon group of bacilli, when pursuing a typhoidal course, cannot be distinguished from typhoid fever without the aid of laboratory methods, the introduction of the term "paratyphoid fever" is clearly unjustifiable. I shall endeavor to prove that so-called paratyphoid and typhoid fever are identical clinically and that they can be differentiated only by the recovery of the bacillus concerned from the blood.

Schottmüller introduced the term paratyphoid fever in 1901. In 1902, in a paper entitled "Types of Infection Produced in Man by Intermediate Members of the Typhoid-Colon Group of Bacilli,"[1] I took the ground "that paratyphoid infections do not constitute a clinical entity; that there is as great diversity among the different types of typhoid fever, as between typhoid fever and paratyphoid infections; that the idea of the specificity of typhoid fever should be abandoned, and that the scope of its etiology should be broadened to include *Bacillus alkaligenes fæcalis, Bacillus typhosus, Bacillus paratyphosus* and certain members of the paracolon group." At the time this paper was written only about fifty cases of paratyphoid infection had been published. As the number of cases has increased and the subject has become better known, I have not only seen no reason to modify the above view, but have become more thoroughly convinced of its correctness.

A brief review of the bacilli constituting the typhoid-colon group will enable me to explain my conception of the subject more clearly. I shall consider only the bacilli pathogenic for man. Petruschky's *Bacillus alkaligenes fæcalis,* which lies just without the group on the typhoid side, must be included, because it has produced typhoidal symptoms. The other members of the group are *Bacillus typhosus*, the paratyphoid bacilli which are not identical either in biological or serum reactions, the paracolon bacilli, which likewise differ among themselves, *Bacillus enteritidis,* consisting of different strains, *Bacillus psittacosis* and *Bacillus coli communis.*

All of these bacilli have produced diseases characterized by typhoidal symptoms, with the possible exception of *Bacillus coli communis.* I grant at once that infections by these different organisms are distinct diseases *from the bacteriologist's standpoint.* But bacteriological are not necessarily clinical entities. Pneumonia and infective endocarditis are examples. Further, if clinical distinctions are to be made on the basis of biological differences in organisms, we must be consistent and give a name to each subvariety of infection. It needs but a moment's reflection to see where this policy would lead us in the typhoid-colon infections.

The pathological anatomy of the cases of infection by the intermediates which have come to autopsy has differed from that of typhoid fever. Peyer's patches have escaped, though four of six cases showed intestinal ulcers. What the ultimate significance of these facts will be, I think no one can tell. But since the number of cases studied is so small, it will clearly be wiser not to draw conclusions from them.

The Clinical Diagnosis of Typhoid Fever and Paratyphoid Infections: Twenty-one-Day Cases.—A positive clinical diagnosis of even a typical case of typhoid fever is beset with difficulty and is generally made after the fact. No case is typical, until the disease has finished its course. More than once has general miliary tuberculosis been mistaken for typhoid fever. (I do not, of course, refer to the probable diagnosis of the usual case. We are dealing with *exact,* not probable, diagnosis.)

Some of the reported cases of paratyphoid infection have been described as typical attacks of typhoid fever. Some have been mild, some severe. Among them they have presented all the symptoms and many of the complications of typhoid fever. There has been no symptom of typhoid fever constantly absent. There has been no symptom constantly present that we may not get in typhoid fever. All that the most ardent advocates of the use of the term "paratyphoid fever" claim for it as a distinct disease is, that the cases are milder, that they are of shorter duration (I shall consider the cases of less than twenty-one days' duration later), that the mortality is lower, and that some complications, *e.g.*, myositis and purulent arthritis, are more frequent. But it must be borne in mind that these conclusions have been drawn from less than two hundred cases and that the majority of the cases reported as infections by an intermediate have not been subjected to the only final diagnostic criterion—the recovery of the bacillus from the blood. But even admitting that all the cases reported as such were infections by intermediates, I claim that one would find as many statistical discrepancies among an equal number of cases of typhoid fever taken at random.

My personal experience is limited to one case. But that case passed for a typical, mild case of typhoid fever, until Buxton found that the bacillus we had isolated from the blood, gave the cultural reactions of paratyphoid bacilli.

Short-Duration Cases.—If the *final* diagnosis of a typical case of typhoid fever is difficult, what shall be said of the diagnosis of the irregular cases? Witness the former elaborate discussions on "simple continued fever." I have no hesitation in saying that I believe the majority of these cases to have been caused by some member of the typhoid-colon group of bacilli. The time has

* Read at a meeting of the Section on Medicine, New York Academy of Medicine, April 18, 1905.

even come when we must take into consideration the possibility of the occurrence of primary systemic infection by the colon bacillus itself. The literature upon the subject is slowly accumulating. Buxton and I have had one case which did not give the typhoid serum-reaction, and from the patient's blood we isolated *Bacillus coli communis* in pure culture.

The argument that the cases of so-called "paratyphoid fever" have been of shorter duration than typhoid will not serve to distinguish them clinically. During the past summer I have had ample proof of this at Bellevue Hospital. I do not recall having seen in any one season so many cases of short duration, and otherwise irregular, typhoid. The diagnosis in some of them was placed beyond dispute by the recovery of typical typhoid bacilli from their blood. One lasted ten days, another fourteen, and their symptoms corresponded perfectly with those of some of the reported cases of "paratyphoid fever." These cases show, then, that short duration is not distinctive of infections by the intermediates.

Serum Reaction.—By way of differentiation, certain authors have attributed much diagnostic significance to absence of the serum reaction against *Bacillus typhosus*. Even positive diagnoses of paratyphoid infections have been made upon such negative evidence. But a negative serum reaction in a case of suspected infection by some member of the typhoid-colon group means one thing only—that the agglutinins have not developed, or at least not in sufficient quantity to give a reaction. Variability in the time of appearance of the reaction is well known. I have seen it delayed to the seventy-first day of an irregular case.

Even a positive reaction with a partyphoid bacillus at higher dilution than with *Bacillus typhosus* does not prove that this bacillus is the cause of the infection. Grünbaum and Jolly [2] have recently (January) published a paper on the inconclusive nature of the results of the agglutination reaction in cases of typhoid fever. They tested the reactions of the blood of positive typhoid cases (proven by bacteriological examinations of the blood) against paratyphoid bacilli and obtained agglutination in 70 per cent. of the cases examined. In some cases the paratyphoid bacilli were agglutinated at higher dilution than typhoid bacilli. In 55 per cent. of the cases a colon bacillus reacted with the sera, and *Bacillus enteritidis* (Gärtner) in 22 per cent.

This only confirms what Durham demonstrated some years ago that the reactions of the typhoid-colon group are special, but not specific. The various members of the group give a group reaction, that is, any immune serum may react with several or more members of the group at low dilutions (frequently at 1 : 10 to 1 : 40, more rarely at 1 : 100).

It is, therefore, necessary to exercise caution in drawing conclusions even from positive reactions. If a serum reacts at 1 : 1,000 with a paratyphoid bacillus and at 1 : 100 or less with *Bacillus typhosus*, the case is probably, but not certainly, one of paratyphoid infection. However, a group reaction at 1 : 20 is sufficient for practical purposes. Prophylaxis and treatment are the same in any typhoidal case of infection by any member of the group. And it cannot be too strongly urged that the diagnosis of paratyphoid infections concerns the bacteriologist more than the practising physician.

A successful bacteriological examination of the blood, with proper identification of the bacillus recovered, becomes then the only final criterion of diagnosis in the differentiation of infections by various members of the typhoid-colon group of bacilli. (This statement, of course, does not refer to cases of infection by Gärtner's *Bacillus enteritidis*, except when they take the typhoid form.)

In further substantiation of my position I would call attention to the fact that the term "paratyphoid fever" has been discredited in Germany, Belgium and Russia.

Conclusions.—(1) That paratyphoid infections cannot be distinguished from typhoid fever except by the recovery from the blood of the bacillus concerned and its proper indentification. (2) That the present state of our knowledge makes it advisable to consider typhoid fever clinically as a disease which may be caused by several members of the typhoid-colon group of baccilli. (3) That the term "paratyphoid fever" is not only unnecessary but misleading.

EXPERIMENTS WITH RADIUM EMANATIONS.[1]

BY WENDELL C. PHILLIPS, M.D.,
OF NEW YORK;
PROFESSOR TO THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

At the suggestion of Mr. Hugo Lieber, a properly constructed tube, the interior of which was coated with radium, so constructed that the emanations could be made use of experimentally, was placed in my hands for the purpose of experimentation along the lines covered by my work in the field of ear, nose and throat diseases, with a desire that a report should be made at the March meeting of the Medical Society of the County of New York. A somewhat careful research of the literature upon the subject brings to light the fact that the emanation from radium was described Owens,[2] also by Dorn.[3] Madam Curie[4] mentions that "Radium is a substance which accompanies the barium obtained from pitchblende; it resembles the barium in its reaction, and is separated from it by differences

of solubility of the chlorides in water, in dilute alcohol or in water acidified with hydrochloric acid."

Emanations.—"The gases present in an enclosure containing a solid salt of radium are radio-active. This radio-activity persists when the gas is drawn off with a tube and collected in a test tube."[5]

Rutherford says: "Emanations produced by radium, thorium and actinium, but not by uranium or polonium, are the power of continuously emitting into the surrounding space a material emanation, which has all the properties of a radio-active gas. Emanations are material and exist in a gaseous state, possess the property of chemical inertness and in this respect resemble the gases of the argon family."

Beck[6] mentions the emanations from radium without giving specific data. Several writers have made mention of the emanations without clearly defining any clinical methods for their employment, and on the other hand not giving any exact report of cases treated. Dr. Piffard has already given his views on the properties of radium *in extenso* and I have thought best to make use of the time allowed, in presenting a report of some experiments with the emanations.

It seemed to me that before commencing experiments upon patients it might be wise to determine whether the emanations possessed any bactericidal power. Accordingly a pure culture of streptococcus was exposed for a period of two minutes several times during the day, and it was found that the bacteria did not lose their activity. Inoculations from the exposed culture grew in new media with the usual speed, and the culture itself showed no effect from the action of the emanations.

A culture made from a pure culture was exposed immediately after inoculation for the same time, the exposure to the emanations taking place before the newly inoculated media was placed in the incubator, and the culture prospered in the usual way. A mixed culture taken from the ear discharge was in no way affected by exposure to the emanations. It was not thought wise to continue experiments along these lines, as the results did not seem to warrant any further effort.

In view of the statements by various observers and also by the discoverers of the emanations from radium, viz., that the activity of the air in the enclosed tube rapidly loses its radio-active force when fresh currents of air have access to the tube, it was always so applied to the part to be treated that the first current (naturally carrying the greatest amount of radio-active substance) fully bathed the part. An exposure of two minutes was the time usually employed. From the discoverer's standpoint it requires some time for the emanations to again form in the tube and saturate the contained air, so the treatment was generally repeated daily.

5 Quoted from original article of Madame Curie.
6 Laryngoscope, December, 1904, page 879.

Case I.—December 30, 1904, A. J., aged thirty-three years. In childhood had all the exanthemata, but without ear complications. At the age of nineteen contracted syphilis and was under treatment for three years and pronounced cured. Four years ago had an attack of laryngitis and could not use voice for five months. Three years ago began to have discharge from the right ear, which came without pain. Discharge had occasionally ceased for a few weeks, but was fairly continuous. Two months ago while cleansing the ear the patient noticed a growth in the canal and on one or two occasions slight rubbing had caused it to bleed.

Diagnosis.—Chronic suppurative otitis media with a large mass of granulation or polypoid tissue, which filled the entire external auditory canal. The hearing, of course, was practically *nil*. The growth was fairly well organized, although bleeding could easily be caused by rubbing. After cleaning the canal thoroughly the growth was exposed to the radium emanations for two minutes. Subsequent to this the growth seemed to be somewhat drier. The treatment was carried out daily, the effect each time being that at first the growth would appear red and after a few seconds it became pale in appearance. January 4, 1905, the growth seemed to be somewhat smaller in size. The treatment was continued daily for about thirty days and was finally discontinued because the growth did not decline in size or change materially in appearance, except for the moment.

Case II.—S. M., aged forty-eight years. For four years has complained of excessive discharge from both sides of the nose, with obstructed nasal respiration and pain in the head. During three months previous to the first application of the emanations her nasal cavities had been completely cleared of polypoid degeneration and the anterior ethmoidal cells had been thoroughly curetted. This brought about much relief to her pain, difficult breathing and quantity of discharge. At the present time there is some discharge evidently coming from the ethmoid cells and probably the sphenoidal cells. There has been complete loss of the sense of smell. The emanations were first applied December 30, 1904, after cleaning the nares. The tip was carried well up into the ethmoid region, the length of time being about two minutes. There seemed to be some drying of the tissues following this application. These applications were made daily, and on January 4 the patient said the pains in her head were better. From this time until January 14 the quantity of discharge varied, some days being considerable, on other days very little. The patient thinks that following the treatment there is some relief from the stuffy feeling in the head. From January 14 to February 13 the treatment with the radium emanations was continued in about the same manner as before the applications were made.

Case III.—J. M., aged thirty-six years. Had

running in the left ear since childhood with nearly complete loss of hearing. There is a large perforation in the drum and a small polypus. First application of radium was made January 4 and was continued daily until January 9, when he failed to appear and has not been seen since. On January 9, however, the last day of treatment, there was no discharge to be seen in the canal.

Case IV.—M. S., aged twenty-seven years. Ear has discharged for nine months; large perforations in both drums. Emanations were first used January 3, 1905. On January 8 the patient reported less discharge. The microscopical examination of the pus revealed bacilli identical with the Klebs-Löffler. On February 11 the emanations were discontinued, as there was now no appreciable change in the condition.

Case V.—G. B., chronic suppuration of the middle ear with polyp in the canal. Radium emanations first used January 6 and were continued daily until January 15, when the polyp was removed by the means of a snare. After this time the emanations were used until January 29, when they were discontinued, as there was no appreciable benefit.

Case VI.—M. M., aged seventeen years. Was first seen January 1, 1905. Diagnosis, atrophic rhinitis and ozena. The method followed in this case was first to remove all crusts from the nasal cavity, and after drying the surfaces the emanations were made use of in both nostrils for two minutes at each sitting. This treatment was carried out daily until February 10, 1905. There was some improvement in this case, probably resulting from the daily careful removal of all crusts. A careful examination of the case afterward showed a return to the original condition, so that the emanations could not be considered to exert any marked influence upon this type of inflammatory process.

Case VII.—M. C., aged twenty-four years. Also a case of atrophic rhinitis with a well-marked chronic catarrhal otitis media. In this case the emanations were not only used in the nasal cavities, but were included in the circuit when the middle ear was inflated by means of the catheter. This treatment was made use of for twenty-five days, when it was discontinued because no decided advantage from the use of the emanations could be ascertained, either to the otitis media or to the atrophic rhinitis.

Although this somewhat unfavorable report is based upon but few cases, the experiments were carried out with great care as to detail and without bias of any form. No opportunities were obtained for applications to infectious throat diseases, but the experiments made upon bacteria would seem to cover that field and definitely determine that the emanations would be useless in this class of cases.

It would have made this report more complete (1) if series of cases of malignant and benign tumors of the nose and pharynx; (2) syphilitic ulcerations; (3) tuberculous ulceration (especially faucial) and in thoracic diseases, could have been subjected to the emanations. This was, however, impossible in the time at my disposal.

I am indebted to my assistant, Dr. Kopetsky, for carrying out many of the details of these experiments.

SUPRAPUBIC PROSTATECTOMY.

BY A. I. McKINNON, M.D.,
OF LINCOLN, NEB.

Hypertrophy of the prostate, with its attendant train of symptoms, residual urine, cystitis, pyelonephritis, occasional periods of complete retention, etc., is now becoming generally recognized as a distinct surgical proposition.

Regulation of the habits of life and the recommendation of the careful use of the catheter has been until recently our main reliance for the alleviation of symptoms, and will probably still continue to be used in selected cases. The constant use of the catheter, however, is invariably followed by dangerous complications, and not infrequently periods of complete retention, with all the dangers and discomforts of distention, supervene. This symptom is certainly an absolute indication for radical procedure.

Too often mere suprapubic aspiration is selected as the best means of securing relief in this condition, and I wish to protest against such procedure, as tapping an infected bladder with walls thickened as the result of chronic cystitis is liable to cause a leak at point of puncture. The judicious plan of treatment is to perform suprapublic cystostomy, and this should be done at once and drainage of the bladder instituted. This operation is simple, and it may be done anywhere under local anesthesia, and complete enucleation of the gland can follow immediately, if patient's condition warrants the giving of a general anesthetic. Otherwise the bladder can be treated through suprapublic opening, and the complete enucleation deferred until such time as an anesthetic may be safely given.

This brings us to the question of when to operate in cases of enlarged prostate. The answer supplies itself when we consider the probable outcome of the condition if allowed to remain, and the simplicity of the operation itself. The mortality of catheterization is probably greater than that of the radical procedure, particularly if the latter be performed at an early stage of the enlargement—hence I recommend operation in all cases where the prostate is large enough to cause symptoms.

Various methods of operation have been devised which narrow down to those (1) which are partial with knife or cautery, palliative in their intent, and not to be recommended because they have all the disadvantages and none of the advantages of the complete operation; and (2) complete enucleation of the gland, which is the

operation to be recommended in every case of hypertrophy with symptoms.

In taking this latter course two routes are open for performing it, viz., the perineal and suprapubic.

The successful complete enucleation of the prostate is one of the most satisfactory of surgical procedures, and the relief to the patient who has been obliged to urinate or use a catheter every hour or two day and night is marked. The choice of method, whether by the upper or lower route, is one which time alone will decide. Both will probably continue to be used as indicated by the particular case.

For the occasional operator there is no doubt that the suprapubic operation is the more simple one, and the liability of embarrassing complications much less. Convalescence is more comfortable and the danger to life is practically nil. One of the complications most distressing to the comfort of the patient and most disastrous to the reputation of the surgeon, injury to the rectum, is practically eliminated by the choice of the upper route, the only distressing sequel to this method being a possible resulting fistula; but this, if persistent, can be easily remedied by a simple plastic operation.

The operation of enucleation of the prostate by suprapubic cystotomy is as follows: The bladder is distended by air or water, a vertical incision is made through skin and fascia, the recti retracted and bladder exposed; an incision is made through the bladder and the edges grasped with forceps. Silkworm-gut sutures are introduced through entire thickness of abdominal wall securing the bladder, tied and left long. With the left fore-finger as a guide, a snip is made with scissors through the mucous membrane of the trigone directly behind the internal meatus. The finger is gently insinuated into this opening and the separation of the gland from its capsule is commenced. One or two fingers of the gloved right hand are now passed into the rectum and the prostate pushed up, and with the left index finger the enucleation is continued. This is generally very easily accomplished, guided by the fingers in the rectum; occasionally a band of fascia will require separation with a blunt-pointed scissors or dissector. When the prostate has been well loosened from the mucous membrane it may be grasped by a volsellum forceps and pulled up, making it easier to strip.

If it is desired to see the field of operation the patient may be put in the Trendelenburg position, the bladder walls retracted and the field thus exposed.

The prostate having been removed, the bladder is flushed out with a hot salt solution and is distended with a large amount of iodoform gauze, after the manner of a Mikulicz drain. This packing prevents hemorrhage, ensures antisepsis and drains away the urine as soon as it accumulates. I consider this packing of the bladder one of the most important points in the after-treatment, as it prevents septic absorption and renders the bladder walls healthy. It also prevents the ammoniacal odor of the urine, so distressing after bladder operations. The gauze may be left in four or five days. An occasional hypodermic or suppository of morphine may be needed for the first few days. After the removal of the gauze the edges of the wound are approximated with adhesive strips, and it will generally close in two or three weeks, and the patient will be urinating naturally through the urethra. An occasional washing of the bladder may be indicated, but where gauze pack has been used frequent irrigations are not necessary.

The patient is able to be up and around the room in two or three days. A liberal dressing of absorbent gauze and cotton frequently changed will keep him tolerably dry and comfortable during convalescence.

The points I wish to emphasize are:

1. Suprapubic cystostomy under local anesthesia instead of aspiration as an emergency measure in cases of complete retention from enlarged prostate.

2. The simplicity and freedom from complications and sequelæ of the operation when performed by the suprapublic method.

3. The virtue of packing the bladder with iodoform gauze after the method pointed out.

PREVENTION AND TREATMENT OF PUERPERAL SEPSIS.

BY L. C. FISCHER, M.D.,

OF ATLANTA, GA.;

VISITING PHYSICIAN, KINGS' DAUGHTERS' HOSPITAL, GYNECOLOGIST, TABERNACLE INFIRMARY, ATLANTA, GA.; GYNECOLOGIST TO HALCYON SANITARIUM.

I DO not feel that I should offer any apology to this assembly of men who are so vitally interested in the subject under discussion. Though it has been written about for ages and discussed by our most able men, we are constantly reminded of the need of more knowledge and more systematic work along this line by seeing or hearing of some woman losing her life at time of confinement. The picture is typical; the woman is confined; on or about the third day we find that she has had a slight chill, that the temperature has risen as a result; then it is that we begin to make excuses to the family for her condition, that she is bilious, that her kidneys are out of order, etc. I know that there is not a man before me to-day who, fully realizing his responsibility, does not watch his obstetrical cases with great care for the first few days after confinement; most of us with the constant fear that this one may be the case of infection that will cause us to feel much chagrined. I have no class of work that causes me more anxiety.

It was my misfortune to be called to a very severe case of infection in the first few months of my professional career. At that time I did

not feel that I was sufficiently posted to treat the case, and so told the husband. At my suggestion two consultants were called; they were both men of ability and reputation. At the time that they saw the woman the posterior cul-de-sac was as tight as could well be without rupture. I know now that that pelvis was full of pus. I had never done nor had I seen done a vaginal puncture for the relief of this condition. In a few hours after seeing the woman she developed general peritonitis and died a few days later. This case was treated with salts, calomel and opium. While the results might have been the same had other methods been pursued, I shall always feel that that woman's life was lost by not receiving the proper treatment at the first.

The statistics of puerperal infection cannot be relied upon. Most of us know of cases of puerperal infection and death reported as being due to typhoid fever, malaria, occlusion of the bile passages, to previous bad health and other like excuses. In this day of advances in all sciences the death-rate from puerperal sepsis is practically the same in private practice as it was years ago. Statistics of private work are unreliable in the South for several reasons: First, there are those in the profession who will not report a death as due to puerperal sepsis for fear of losing professional prestige in that locality, thereby losing fees. Then there are others who fail to report the true cause of death from ignorance of the real condition. Also a great amount of work is done by midwives, especially among the very poor whites and negroes. Just here I should like to say that there should be some law governing the practice of these midwives; they should be forced to stand an examination along the line of their work. Too many women are sent to the Great Judgment Bar by their uncleanly, not to say filthy work. The reports from the hospitals, although reliable and valuable, do not give us any idea of what is occurring on the outside. In hospitals and maternities the surroundings are the best, with the best physicians of the locality to conduct the case, with trained assistants, with nursing by competent hands, with time to prepare the patient, her bedding and clothing, with all instruments and dressings sterilized after the most improved methods; whereas, on the other hand, in private work we have to contend with all kinds of cases, in all stations of life, with all kinds of nurses, often a meddlesome negro nurse who is a midwife as well as a nurse.

While on a recent visit to New York I saw Dr. W. M. Polk operate upon two cases of infection in one day that were sent into Bellevue Hospital from the crowded districts of New York. The same afternoon I saw Dr. Stewart operate for the same condition.

At a recent meeting of the Philadelphia Obstetrical Society Dr. Hirst said that he had to operate upon a large number of these patients every year. In the last three days three of the most desperate cases of puerperal sepsis were brought into the University Hospital. He has usually from four to six cases under observation.

Go back a few years in obstetrical practice, and you will see a great many patients who had "childbed fever," phlegmasia alba dolens and their complications, and they were considered unavoidable. Despite the great improvements in antiseptics, fever in the puerperal state is still seen. Strict asepsis in obstetrical work is practically impossible, owing, first, to the conditions that might have existed before we examine the woman, as the presence of gonococci, staphylococci, etc., and then to the anatomical relations, the close proximity of the anus, the excretions and the difficulty of making the vulva aseptic on account of the folds of the vulva and hairs.

It is admitted by all scientific workers that puerperal sepsis is due to the different streptococci, gonococci, staphylococci and to *Bacillus coli communis*. Then, when we admit the cause, we should use every effort to prevent the result. We should exercise the greatest care in our work in preparing the patient for confinement. We should see that she has had a general bath, with especial attention to the parts surrounding the vulva, that she should have on a clean gown, that the bladder and bowels are emptied. The bed should be prepared so that all discharges can be removed when the woman is cleaned up after the birth of child. A rubber sheet about four by six feet should first be placed on the bed, this to be covered over with a clean sheet; the use of the Kelly pad is advisable for two reasons, the ease with which it can be made aseptic, and its cleanliness, since it catches all discharges. If the rubber pad is not used, an absorbent pad should be placed next to the rubber sheet and covered over with the draw sheet; the top sheet should likewise be clean. Where I can direct the preparation of the bed, I like to have the sheets come to the room fresh from the laundry.

The Kelly pad should be thoroughly soaked in bichloride solution before being placed under the woman. Then, with the woman placed in the dorsal position, I have the nurse—or, in the absence of a competent one, do it myself—clip the long hairs from the mons veneris and labia majora, then sponge the external parts thoroughly with bichloride solution 1 to 2,000.

With the coat removed and a rubber apron on for a twofold purpose, to protect the clothing and to protect the woman from any germs that may have accumulated on your clothes in everyday work, with the sleeves well above the elbows, scrub thoroughly with soap, brush and warm water from five to ten minutes, where time will allow, then soak the hands thoroughly in bichloride solution, 1 to 2,000, for at least three to five minutes; careful attention should be given to the nails. I prefer the use of gloves, soaking

them thoroughly in bichloride solution of same strength. It is admitted that all cases of puerperal sepsis are caused from without, so we cannot use too much care in our first preparation. When you have gotten to the case late and have not time to make thorough preparations, the hands should at least be soaked in antiseptic solution, preferably bichloride solution, and gloves worn, taking due care not to make any more examination than is positively necessary, and by no means in the vagina until you have time to cleanse the hands thoroughly. The parts should be cleansed hurriedly with bichloride solution before making any examination. After preparations have been made, make a careful examination; do not allow the examining hand to come in contact with the unclean parts of the woman. If possible make a diagnosis at your first examination, then watch the descent of the head by making external examinations; in normal cases one or two vaginal examinations are all that is necessary. One mistake that we make is in examining the woman too often. It not only increases the danger of infection, but increases the woman's anxiety as to her condition. Of course, there are cases where this rule will not apply. When it is necessary for version to be done or forceps used, the hairs should all be shaved off from mons veneris and surrounding parts, then scrubbed thoroughly with soap, water and bichloride solution. A bichloride douche or lysol 1 per cent. should be given before delivery; this cleanses the vagina, and where lysol solution is used it acts as a lubricant. In normal cases of labor the douche is not advisable by any means, especially after delivery. After the child is delivered the placenta should be delivered by Credé's method; it should then be carefully examined to see that it is intact and that all membranes have been removed; then the external parts should be sponged off with bichloride solution 1 to 4,000 and a sterile napkin applied over vulva. This should be changed and the parts sponged off with bichloride or lysol solution every few hours. Where the forceps have been used an intra-uterine douche should be given, a bichloride 1 to 10,000 or lysol 1 per cent. solution being used. The danger from absorption is practically nil from this strength. The solution should never be stronger than this in the uterus.

In all cases, after the third stage of labor is completed, the perineum should be carefully examined for tears; where there is a tear of any consequence, more than the simple breaking of the continuity of the mucous membrane, it should be repaired at once, within the first six to eight hours at the longest. The woman should be turned crosswise in the bed; a sheet folded can be used very satisfactorily for leg-holders; then cleanse the wound thoroughly with antiseptic solution and approximate the torn parts carefully, being sure that you approximate muscle to muscle, etc. The instrument shops now carry a very satisfactory ligature, threaded in needles, sterilized and sealed in glass tubes; chromicized and plain catgut is the best suture material. The closed tear is much less liable to become infected than when it is left open. I saw a case of infection recently where the doctor had closed the torn perineum with plain ball cotton thread taken from a workbasket in the room; the case was seen by a third physician, who told the family that the trouble was caused by the perineum having been closed at all, that it should have been left open. I find men occasionally who contend that the woman is much more liable to become infected if the tear is closed. For my part, I much prefer taking chances with it carefully repaired, as it does not leave so much raw surface for absorption. In all cases where I have a tear I close it at once, in most cases anesthetizing the patient. In cases where forceps and instruments are used it is necessary that they be carefully sterilized; they should be boiled and used from the same vessel that they are boiled in, or placed in a sterile one in a 1 per cent. lysol solution. The ligatures can be reboiled along with the instruments where the ones referred to are used.

The woman should be watched carefully for the first five to seven days, the nurse should keep the parts thoroughly cleansed with a bichloride solution 1 to 4,000. Should the lochia become offensive or the temperature rise above 99° to 99.5° F. a vaginal douche should be given at once; unless the temperature reaches normal in a few hours a careful digital examination should be made, and especial care given to the possible retention of membrane and pieces of placenta. You should see that the bowels are well opened, and that the kidneys are acting normally. Where the vaginal douche does not reduce the temperature in a few hours, the dull irrigating curette should be used with great care, using very little force, for fear of puncturing the uterus. Bichloride solution 1 to 10,000 or lysol one per cent. solution should be used, using as much as two gallons at the time, and as warm as can be borne by the patient. Do not pack the uterus with gauze after curetting, as this retains discharges. I have done this and upon removal twenty-four hours later found that the odor from the gauze was worse than the original condition. Elevate the woman's head or place her in a sitting position for a few moments to allow the uterus and vagina to empty themselves of the solutions used. This should be followed by hot douches every three to four hours, using two gallons at a time; this aids involution of the uterus, besides being soothing to the patient. Where the intra-uterine douche has been given with bichloride solution follow this with normal salt solution, as this will dissolve the albuminate of mercury formed in the uterus. After this give due care to the breasts, as they sometimes cause fever from slight inflammation or occlusion of the milk

ducts. Should the temperature persist, the discharge remain offensive, the pelvic organs and lower abdomen become tender, this patient should we watched with care. The tubes and ovaries should be given especial attention, and the posterior cul-de-sac watched. One point on which I wish to lay stress especially is the making of careful digital examinations.

I was called ten days ago to see a young woman who had been confined three months previously; she had been in bed ever since confinement with enlargement and inactivity of the liver, acute Bright's disease, inactivity of the kidneys, typhoid fever and pneumonia. When I was called it was time to sign the death certificate, which I did two days later. Upon entering the room the odor was unbearable. I made an unsatisfactory digital examination; everything in the pelvis seemed solid. I removed something from the vaginia, which appeared to be decayed placental tissue. She had general peritonitis and was green from absorption of toxins; temperature 104.5° F., pulse 140, respiration 40. I told her husband that I was powerless to help her; she died about thirty-six hours afterward.

Where there is infection of the uterus it spreads to the surrounding parts through the lymphatics and through the tubes into the peritoneal cavity. Often with these mild cases of infection, with infiltration into the tubes, ovaries and pelvic tissue, this condition can be greatly benefited by using systematic hot douches every three hours, preferably lysol solution 1 per cent., about two gallons at the time. This will very often arrest the infection and aid resolution. Should you not be able to cause resolution the inflammation may become localized and form an abscess in the pelvis or some pelvic organ. Should these abscesses appear they should be opened through the vagina, a T-shaped drainage tube left in. I use the drainage tube in preference to the gauze because my results have been best with the tube; as previously stated, I have used the gauze, and upon removal after twenty-four hours find that the odor is worse from the gauze than from the pus that was first removed. Gauze not only does not drain well, but stops the flow of pus and débris. I have found in these cases that the temperature would rise until the gauze was removed and then drop in a few hours. Vaginal douches should be given every three to five hours to keep the pus washed away and stop absorption. Drainage tube should be left in for twenty-four hours, and if patient is doing well, forty-eight hours, then removed, boiled and replaced if necessary. Where the infection has been general, the patient begins to turn green, with quick thready pulse, temperature showing septic variations, the whole body bathed in profuse perspiration, with sweetish breath; these cases are desperate. The same local treatment should be kept up, rectal enemas of normal salt solution should be given one pint at the time, usually the woman can retain a pint every three hours. Normal salt solution should be given subcutaneously; under the breasts and under the skin of the thighs are the most acceptable sites. In the event you cannot wait for this, give it directly into the veins, from a quart to three pints at a time. Stimulants should be given as is indicated, in the form of whisky, strychnine and such heart stimulants. The bowels should be kept open and the kidneys acting normally. Rubbing the whole body with alcohol is beneficial and acceptable to the patient. Strictly liquid diet should be given. In the use of the normal salt solution, the nine-tenths of one per cent. solution should be given, as this is isotonic with human blood; the six-tenths of one per cent. is isotonic with frog's blood and may cause some solution of the hemoglobin. I have seen cases of septicemia where, after the use of the normal salt solution, the temperature would drop several degrees in a few hours, and the pulse come down from 140 to 100. Dr. Robert T. Morris speaks of the use of normal salt solution as "blood washing." It dilutes the toxins in the blood, and aids elimination through the kidneys and skin.

In May, 1904, I was called in consultation with Dr. G. D. Couch, of Hapeville, to see a Mrs. H., who had been confined four days previously; on the second day after confinement she developed a temperature ranging from 105° to 107° F.; this kept up for forty-eight hours when I saw her. There was tenderness in the lower part of the abdomen, an offensive discharge from the vagina. I made a careful digital examination, found the uterus large and boggy, and could feel what I took to be some small pieces of membrane. There was tenderness on each side of the uterus, and great tenderness over the body of the uterus on pressure. I advised immediate curettement, which was done at once with the patient thoroughly anesthetized. I used a dull irrigating curette. There was a small amount of débris removed. She had unavoidably been confined in a room where her husband had had smallpox a few weeks previously. After curetting her the temperature dropped to normal in a few hours, to rise again on the following morning. The second day after seeing her I opened an abscess through the right side of the vagina; two days later one through the left, and two days later one through the posterior cul-de-sac. Three days later I opened another at the extreme right of the vagina, she being anesthetized each time. Her temperature kept up all this time, and just here she began to complain of pain above the brim of the pelvis on the left side. By bimanual examination a small enlargement could be felt high up in the pelvis. In about three days this could be detected through the abdominal wall, which gradually enlarged. Then I advised that she be brought to Atlanta, which was done, and she was placed in the Tabernacle Infirmary. The following morning the abdomen was opened directly over this en-

largement, which was just above the brim of the pelvis. Upon cutting through the abdomen wall it was found that the mass was separated from the peritoneal cavity by adhesions. The left tube could be traced up to this mass, much thickened and enlarged. Upon opening the abscess it was found full of very offensive pus. The cavity was thoroughly flushed with salt solution, three rubber drainage tubes were left in, and dressings applied, patient placed in bed on her left side to keep up drainage. The external dressings had to be changed every few hours for the first few days. At this time I found another abscess between the bladder and the vaginal wall, which was opened and drained. This case was treated with the normal salt solution, as suggested. She was confined to her bed in the hospital two months and ten days, when she was discharged in good condition. I am informed that she is again pregnant.

Finally, the points that I wish especially to emphasize in this paper are: (1) The careful preparation of the bed and the woman before the birth of the child, with especial attention to the hands of the physician. Then the examination of the placenta and membranes. (2) After birth of child examination of perineum for tears, and if they are present repair them at once. (3) In case there is a rise of temperature you should start at once with treatment. (4) The importance of making careful digital examinations, the use of the dull irrigating curette early, where the temperature is not reduced by douches. (5) The importance of the normal salt solution to dilute the toxins and to aid absorption; the strength of bichloride solutions used. (6) The preference of tube over gauze drainage in these cases; the absolute avoidance of gauze in the uterus after curetting. (7) The importance of opening and draining the abscesses as they form in the pelvis or any pelvic organ.

A PLEA FOR SURGICAL INTERVENTION IN SUSPECTED MALIGNANT DISEASE OF THE ABDOMINAL CAVITY.

BY B. B. DAVIS, M.D.,

OF OMAHA, NEB.;

PROFESSOR OF SURGERY, COLLEGE OF MEDICINE, UNIVERSITY OF NEBRASKA; SURGEON TO IMMANUEL AND TO WISE MEMORIAL HOSPITAL.

The study of malignant disease is greatly simplified by the practical recognition of a few basic principles: (*a*) Primarily it is strictly a local ailment; (*b*) at a more or less early stage it infiltrates widely the surrounding tissues, affects regional glands or is conveyed to distant organs by metastasis, and thus ceases to be local; (*c*) the period of time a neoplasm has existed or its size is no evidence of the extent of its dissemination.

From these premises certain practical deductions may readily be made: (1) If at an early stage, while still strictly localized, the pathological tissue is entirely excised, the growth will not return; (2) if considerable infiltration has already taken place, or if the nearby glands are already affected, complete removal is only possible by very wide dissection, and even then success depends largely on chance; (3) after the disease is extensive, and especially after involvement of parts not susceptible of complete removal, or after the occurrence of metastases, the case is hopeless, and all that can reasonably be expected is to palliate and mitigate to a slight degree the intensity of the suffering. Outside of surgery nothing has been found of any value in the treatment of internal carcinoma or sarcoma. Occasional reports of X-ray cures of superficial epitheliomata do not in any way affect the discussion of abdominal malignant disease.

The foregoing forms the foundation of a few observations desired to be made concerning malignant disease affecting the intra-abdominal viscera. Successful removal is here possible in almost any situation if the operation is undertaken while the growth is still local. But it must be confessed that heretofore most of the cases of intra-abdominal malignancy have ended disastrously. The greater number of patients have died without any attempt at removal. A minority have been treated surgically. In many of these the exploratory incision has revealed quite impossible conditions and the surgeon has been constrained to close his incision without any effort at removal of the disease; or such a condition has been found that excision of the disease has been out of the question, but a palliative operation has been done, as a gastro-enterostomy for inoperable pyloric cancer; or the viscus invaded has been resected or removed and the patient has died of the operation, owing to the extent of the operation necessitated by its lateness, or to the weakened condition brought on by the long illness, or to a combination of the two; or finally, the operation is successfully accomplished, the patient makes a rapid convalescence, only to die in a few months or a year or two from recurrence of the neoplasm.

Only very rarely has the surgical procedure been carried out while the disease was still local and curable by local extirpation. This is not a fanciful picture, but represents the average of work being done by operators to-day.

The reason for the necessity of this discouraging admission is fourfold: (1) The patient is late in consulting a physican; (2) when consulted there is too often a tendency to regard all cases with intra-abdominal symptoms as due to errors of digestion and to prescribe pepsin, etc., without a serious effort to make an accurate diagnosis; (3) even when malignant disease is suspected, the results of surgical intervention in the past have been so disheartening that many physicians are yet loath to advise operation; (4) when operation is advised, such is the general hopelessness among the laity of relief by surgical means that they first try the X-ray or other

fad, and thus more valuable time is lost. Everything which tends to delay early radical treatment simply serves to perpetuate the gloomy feeling with regard to the treatment of this disheartening disease.

I may be too much of an optimist, but it is my opinion that if the attitude of the profession could be reversed a ray of hope might yet be made to fall on even such a dire malady as cancer. It will not come about by spasmodic effort here and there, but only by a general readjustment of views on the part of the profession at large. It will necessitate more alertness, a more general resort to careful painstaking diagnostic methods, a greater courage in advising the thing that reason dictates, and the substitution of a little optimism for the pessimism which now prevails.

A continuation of the too general practice of prescribing a little pepsin and hydrochloric acid, or other placebo, for every patient complaining of indigestion, without any physical examination or the use of laboratory aids, will never bring about any improvement in results. Every patient who consults a physician is entitled to the benefit of all the resources of modern science in order to clear up the diagnosis and give the correct advice or treatment. In view of the manifold lesions apt to occur within the abdominal cavity, it seems especially mandatory on the profession to make careful examinations whenever a patient complains of symptoms in this region. Such conscientious study of one's cases is only fulfilling the obligation of an implied contract.

Suppose that for a period all members of the medical profession should resort to the painstaking examination here recommended. It would bring about a revolution. Many things would be discovered among the old chronics not suspected. Patients hitherto treated in a routine fashion and deemed decidedly uninteresting, denominated bores or hysterics, would be found to possess pathological lesions of the greatest interest. Many of them would be found susceptible of complete cure, and we should be led to a much greater appreciation of the possibilities of modern medicine than ever before. Incidentally it would be the hardest blow that could be delivered at the osteopathists, Christian Scientists and other faddists, because myriads of patients heretofore unrelieved and forced to go elsewhere would be cured.

But, in spite of all the modern methods, clinical and laboratory, there are still great difficulties in making accurate diagnosis of early malignant disease when it affects the stomach, intestines or other abdominal viscus. Unfortunately most of our positive symptoms are late in the disease—too late to permit of the ideal treatment. In cancer of the pylorus, or pyloric end of the stomach, obstructive symptoms, coffee-ground vomit, palpable tumor, etc., do not make their appearance until so late in the disease that dissemination, or, at least, extensive infiltration, has already taken place and complete removal is rarely possible. The absence of HCl, and the presence of lactic acid is also a late symptom, and not always conclusive. The presence of the Eppler-Boas bacillus is of somewhat greater value, but even this is often misleading.

Therefore, if we would aid in bringing about an improvement in results we must not wait for such positive symptoms that all the patient's friends have already made the diagnosis, but operative intervention must be made before the diagnosis is absolutely certain. Several years ago I suggested that when, after careful examination of a person of middle or advanced age suffering from a comparatively recent or progressive gastric disease, and the use of the best modern dietetic and medicinal treatment for two or three weeks without bringing about improvement, a lively suspicion of cancer of the stomach is allowable.

In cases of this character an exploratory incision is likely to reveal cancer. Even when the incision is made on suspicion the disease has been found to be in a surprisingly advanced state, and the natural wonder has been why the clinical picture was not more positive. Sometimes, happily, the exploration will not reveal malignant disease, but a gastric ulcer, or adhesions which may be relieved by gastro-enterostomy, or by freeing the adhesions. Even if nothing is found that can be relieved by operation the case is cleared up and no harm will have been done by the incision. This last will be very rarely the case, as usually the conditions bringing about enough suspicion of malignancy to warrant the procedure recommended, if not caused by cancer will be found due to some gross surgical lesion.

In cancer involving the gall-bladder, the intestines, the body of the uterus, the same thing is true. By the time the disease has advanced to such a stage that a definite diagnosis is possible, it has probably progressed too far for successful surgical removal. The unexplained presence of blood and mucus in the stools, localized accumulation of gas, which appears to be due to inability to pass along the intestines freely, a rather abrupt onset of troublesome constipation, not relievable by ordinary means, all call forth a decided suspicion of malignant disease, and should not be lightly dismissed. To wait until a palpable tumor makes its appearance is usually to wait until the peritoneum or other tissue is involved and the dissemination is so great that permanent cure is out of the question.

One of the most satisfactory cases of cancer of the intestines I have ever had was in a man who came to me with a very large left inguinal hernia—the largest I have ever operated—the mass hanging down to the knees. The immediate cause of his seeking operation was recent pain he had experienced and constipation. On opening the sac the sigmoid flexure was found with a hard malignant ring involving three-fourths of the circumference. There was also a gland in

the mesosigmoid three-quarters of an inch in diameter and of that characteristic woody hardness with which we are all familiar. Nearly seven inches of the large bowel were resected, the ends united by suture, and the man is now in excellent health, two years after the operation. The pathologist reported this a columnar-celled carcinoma.

When the diagnosis is positive sometimes an operation is indicated, at least a palliative one, but here too often the disease is found to have progressed too far for successful removal.

There is still another type of case, unfortunately at the present time the commonest of all, where the disease has manifestly progressed too far to offer any hope of relief. There is extensive dissemination over the abdominal cavity, affected glands are to be found in the inguinal or cervical regions, or already metastases have made themselves apparent. In such cases it is better for the credit of surgery to resort to no operative procedure.

In intra-abdominal malignant disease, therefore, there are three classes to deal with: (1) Cases too far advanced for any operative procedures; (2) cases with a fairly clear diagnosis of malignancy and offering apparently a fair chance of relief by operation; (3) cases with only a well-defined suspicion of malignancy where an exploratory incision is confidently advised. This is the type of case offering much promise of successful operations and where a great stride in advance may be predicted if the profession can see its way clear to adopt the suggestion of advising an operation as soon as a strong suspicion of malignancy is found.

Let us not lose sight of the fact that when a patient dies of cancer of the abdominal cavity, there was once a time when it was localized, and could have been successfully removed and a permanent cure effected!

PRESIDENTIAL ADDRESS: THE INSANE IN CANADA.[1]

BY T. J. W. BURGESS, M.D.,
OF MONTREAL, CANADA.

GENTLEMEN: My first duty is to reiterate my thanks to you for having called me to this chair, a distinction I can attribute only to the fact that in honoring me you sought to honor, not me alone, but the Canadian members of the association. "No man is born without ambitious worldly desires," says Carlyle, and surely there could not be a more laudable ambition than to became the president of this, the oldest of American medical associations, a position of which Dr. John S. Butler said, on his elevation thereto, in 1870. "In my opinion, to be elected President of this association is the highest honor of the profession." Rarely, however, does gratified ambition bring peace of mind, and I, alas, have been no exception to the general rule. The thought of occupying a position that had been held by such intellectual giants as Woodward, Bell, Ray, Kirkbride, Butler and Earle, all members of the "glorious original thirteen," besides many other illustrious men, abashed me—made me fully conscious of my inability to fill it properly. Nor did the sense of my demerit lessen as the days rolled by. On the contrary, the long list of presidents, whose names are familiar to us because of their attainments in psychological medicine, loomed continually before my eyes, added to which the task of to-day's address haunted me like an ever-lengthening shadow. I had but one thought to reconcile me to the greatness your generosity had thrust upon me. It was that the kindness which prompted you to elect me as your president would be extended so far as to induce you to overlook my shortcomings, and that if, in the matter of the address, I could not, like my predecessors in office, clothe my thoughts in

> "Choice word and measured phrase, above the reach
> Of ordinary men,"

you would at least take the kindly will for the imperfect deed.

In my search for a topic upon which to discourse, I fully verified the words of Terence, "*Nullum est jam dictum quod non dictum sit prius.*" Everywhere I found the fields of medico-psychology so well harvested by my forebears that there was apparently nothing left for even a gleaner. Nevertheless, a subject had to be selected, and I finally concluded that, as the oldest medical officer connected with the insane asylums of Canada, in point of length of service, I could not do better than tell you something about the development of our Canadian asylum system, the status of the insane in our Dominion, and what, in my estimation, are some of our most crying needs for the betterment of those so justly styled "the most unfortunate of all God's afflicted ones."

Of the number or condition of the insane in Canada under the French regime, that is, prior to its accession to England in 1763, I have been able to learn little or nothing. Doubtless, their treatment differed in nowise from the cruelty shown them in all other countries at the same period. That they were not totally neglected is manifested, however, by the fact that, in 1630, the Duchess d'Aiguillon, niece of Cardinal Richelieu, founded the Hotel Dieu of Quebec for the care of indigent patients, the crippled, and idiots. As here employed, the term idiot probably refers to all forms of mental disorder, acquired as well as congenital, and the creation of this establishment is especially noteworthy inasmuch as it was not only the first move toward the proper care of the insane, but was the first hospital instituted in North America. Four years later, namely, in 1643, Mademoiselle Mance founded the Hotel Dieu of Montreal to meet the same requirements.

For well-nigh three-quarters of a century after the establishment of British rule, the con-

[1] Delivered before the American Medico-Psychological Association, at San Antonio, Texas, April 18, 1905.

dition of the insane in the various Crown Colonies, which now make up the Dominion of Canada, was deplorable in the extreme. Each county seems to have cared for its insane as best it could by confining them in almshouses and jails. The poor lunatic did not appeal to the sympathies of the public—a workhouse was good enough for him if harmless, a prison his proper place if dangerous. The thought that he might be cured, and that no effort should be spared to cure him, occurred to few, if any. Bereft of man's noblest attribute, the mind, lunatics were regarded as little better than brutes, and were too often treated accordingly. While falling short of the Napoleonic Code, published in 1804, which openly classed the insane with beasts, and ordered the punishment of those who allowed "the insane and mad animals to run about free," the law in Canada deemed them at least on a par with criminals. In proof of this witness an act, in force as late as 1835, which authorized any two Justices of the Peace, without any medical certificate, "to issue a warrant for the apprehension of a lunatic or mad person, and cause him to be kept safely locked in some secure place directed and appointed by them, and, if they deem it necessary, to be *chained*."

The first of the old British North American colonies to make special provision for its insane was New Brunswick, by the conversion, in 1835, of a small wooden building in the city of St. John, originally erected as a cholera hospital, into an asylum for lunatics. This institution, the first of the kind in Canada, continued in operation for a little over thirteen years, under the medical supervision of Dr. George P. Peters, a native of St. John, but a graduate of Edinburgh University.

Dr. Peters had no previous experience in the care of the insane, but, being energetic and deeply interested in the welfare of his charges, did exceptionally good work considering how he was handicapped. That he was in advance of his day, and fully recognized the importance of special training for the proper treatment of mental diseases, a fact so often lost sight of by governments and their appointees, is evidenced by his urging, through vainly, the legislature to get a physician from England, one trained in the best schools of psychiatry, to take charge of the new asylum. The difficulties he had to encounter were many, not the least being one that is equally common to most of us at the present day, that of finding suitable nurses. On this point he quaintly reports: "I find it very difficult to secure proper attendants, especially for the female patients. Those who apply for the place are coarse and ignorant, their only qualification for the position being good muscular development, and absence of all proper sensibility."

The following record, preserved in the Sessions of the Peace minute-book, gives a good idea of the results attained by Dr. Peters during the first thirteen and a half months of his incumbency. "Of the thirty-one admissions," it says, "there have been discharged—cured, six; improved, five; to friends, not improved, two; died, four. Of the remaining fourteen, one is much improved, two perceptibly improved and eleven without any visible improvement." Some of the details of the itemized accounts, contained in the same volume, are highly suggestive of the times and of the methods of treatment, in which blood-letting and restraint must have played a considerable part, and bathing and light been luxuries:

"W. McBay, for twelve hogsheads of water (for one month), one pound fifteen shillings.

"W. Hammond, for thirty pounds rush lights, ten pence per pound, one pound five shillings.

"Harvie and Allen, for eight tin bleeding cups and one tin pan, seven and sixpence.

"D. Collins (saddler), for three hand mufflers, one pound fifteen shillings.

"G. T. Ray, for twelve straight waistcoats, at twenty shillings each, twelve pounds."

In 1848, this temporary refuge, the pioneer Canadian asylum, was abandoned, the inmates, ninety in number, being transferred to the present institution, the erection of which had been begun two years previously.

Ontario, or, as it was then called, Upper Canada, was the next of the provinces to make a movement toward providing for its insane, the old and recently abandoned jail at York, now Toronto, having been fitted up and opened as a temporary asylum in 1841. Prior to this, numerous attempts had been made in the House of Assembly toward the creation of an asylum, the government going so far, in 1836, as to appoint a Commission to visit the United States for the purpose of obtaining information on the subject. The chairman of this Commission was Dr. Charles Duncombe, who afterward, during the rebellion of 1837, became the leader of the rebels in the western part of the province, and only saved his neck from the hangman's noose, on the defeat of the movement, by making his escape across the Detroit River into Michigan disguised as a woman; this, despite the fact that a reward of £500 had been offered for his apprehension. Dr. Duncombe's report is particularly interesting to us, because he therein gives an account of his visit to Worcester Asylum, Massachusetts, then under the superintendence of Dr. Samuel B. Woodward, who eight years later became the first president of this association, of which he had been also one of the originators. His institution was the one, of all those inspected, that best met the approval of the Commission, and the one, the general plan of which they advised should be followed. In concluding his report Dr. Duncombe thus interestingly outlines his views on the subject of lunacy and the object of the proposed structure: "The building is not designed for the cure of the ordinary diseases of the body, but 'to restore the disjointed or debilitated faculties of a fellow creature to their natural order and offices, and to revive in him the knowledge

of himself, his family and his God.' The subject of lunacy has been until of late years less perfectly understood than any other complaint known to our country that is at this moment successfully treated, but thank Heaven that the disease of an organ of the mind is no longer considered a crime subjecting the unfortunate subject of it to imprisonment, punishment and chains, and that with the exception of this Colony no other portion of America has their insane confined in their jails, and I am well satisfied this will not be the situation of these unfortunate persons longer than until their number and present cost of support is known, and the legislature have time to provide a suitable asylum for their relief."

The makeshift asylum, into which the old jail had been converted, was placed in charge of Dr. William Rees, who had long urged upon the government the necessity for such an establishment, and continued in use up to 1850. At that date the patients were transferred to the present Toronto asylum, which, for twenty-two years after, was the field of labor of the venerable Dr. Joseph Workman, to whose wisdom much that is best in the present system of caring for the insane in Canada can be traced.

Kingston Asylum, generally known as Rockwood Hospital, was the second asylum born in the province of Ontario. It had its birthplace in the stable of the old Cartwright mansion, which, in 1856, was fitted up for the reception of twenty-four female patients. Like its successor, the present structure, opened in 1862, it was originally designed for a criminal lunatic asylum, and as such the institution remained in charge of the Federal Government, an adjunct to the Penitentiary, until 1877. In that year it was purchased by the local legislature and became one of the ordinary provincial establishments.

London Asylum, the third Ontario asylum in point of age, was, when opened in 1859, originally located in the old military barracks at Fort Malden, on the Detroit River, and formed a branch of the Toronto institution, which had become congested. In 1870, the present hospital, at London, having been completed, the patients were transferred there.

Of the other five public asylums in Ontario, that at Hamilton was originally built for an inebriate asylum, but was never used as such, being utilized instead for the reception of the insane, and opened in 1870. Mimico Asylum was first occupied in 1890, Brockville Asylum in 1894, Cobourg Asylum in 1902, and Penetanguishene Asylum in 1904. The Cobourg institution, for female chronic patients, was created by the conversion of Victoria College, the scholastic headquarters of the Methodist community prior to federation with Toronto University, into a hospital for the insane; and the Penetanguishene Asylum, which is for chronics of both sexes, was formerly a reformatory for boys.

Ontario also possesses an asylum for idiots. It is situated at Orillia, where it had its inception, in 1876, in a building originally designed for a hotel. This structure was replaced by a new modern establishment in 1887.

In the Province of Lower Canada, now Quebec, the Quebec Lunatic Asylum, formerly known as Beauport Asylum, is the oldest of the institutions for the insane, the progenitor of the present structure having been opened, during 1845, in the old manor-house of the Seigneur of Beauport, which stood about a mile from the present establishment. Its creation was due to Dr. James Douglas, an uncle of my immediate predecessor in this chair, Dr. Joseph Morrin, and Dr. Charles J. Fremont, but it is now the property of the Sisters of Charity.

The second of the Quebec asylums, L'Hôpital St. Jean de Dieu, or, as it is usually called, Longue Pointe Asylum, is situated a few miles east of Montreal, and also belongs to the Sisters of Charity. It originated in a very humble way in 1852, its capacity at that time not exceeding twenty-five patients. This being found quite inadequate to meet the ever-increasing demands upon their charity, the Sisters, with the sanction of the government, determined to take up the work of caring for the insane on a greatly enlarged scale. The result was the erection of a new St. Jean de Dieu Asylum, which was opened in 1875. This institution was completely destroyed by fire in 1890, no less than seventy-five patients and five Sisters losing their lives in the conflagration. Undeterred by this disaster, the Sisters lost no time in beginning the erection of the third St. Jean de Dieu Asylum. This, the present establishment, which is fully up to date in construction and equipment, was opened in 1901.

The third Quebec institution, rightfully called the Protestant Hospital for the Insane, though generally spoken of as Verdun Hospital, was founded by a number of the charitably disposed Protestant citizens of Montreal for the relief of their co-religionists then confined in Beauport and Longue Pointe asylums. It was opened for the reception of patients in 1890.

Quebec has in addition two institutions which receive idiots as well as some aged and infirm paupers. These are L'Hospice St. Julien, located at St. Ferdinand d'Halifax, and Baie St. Paul Asylum, situated at the Baie St. Paul. Both belong to the Sisters of Charity, the former having been opened for the reception of idiots in 1873, the latter in 1890.

Prince Edward Island stands fourth, and Nova Scotia fifth on the list with regard to the date of beginning special provision for the insane. The hospital of the former dates back to 1847, and of the latter to 1858, since which time Nova Scotia has increased its accommodation for the mentally defective by the creation of a system of county asylums, and combined county asylums and poorhouses. An interesting point in connection with the Nova Scotia asylum is that

to it pertains the honor of having had its site selected by the well-known philanthropist, Miss Dix, of whom it is said in Tuke's "Dictionary of Psychological Medicine": "Although, in every country, men and women and the medical profession have been ready to promote the interests of the insane, the name of Dorothea L. Dix stands foremost among all. Her efforts in improving the condition of the insane were not confined to her native State of Massachusetts, but extended to other States and distant lands. Her life was devoted to their interests, and it is stated that no less than thirty asylums owe their establishment directly or indirectly to her persistent efforts."

The first Manitoba asylum, now located at Selkirk, was originally established in 1871, at Lower Fort Garry, in connection with the penitentiary. One of the old stone storehouses of the Hudson's Bay Company, formerly used for the confinement of Lepine, the notorious Louis Riel's Adjutant-General, was fitted up for the purpose. The second asylum, situated at Brandon, began work in 1891.

The year 1872 witnessed the birth of the British Columbia institution, when an ancient wooden building on the Songhees Indian Reserve, outside the city of Victoria, originally built for a smallpox hospital, was reopened to receive lunatics. The population having outgrown these primitive quarters, it was decided to erect a new aslyum on the main land, close to the town of New Westminster. This was done and the patients removed thereto in 1878.

Of the superintendents connected with the bygone struggles of these beneficent institutions much might be said, but the limited time at my disposal forbids the eulogiums they so justly deserve, even were my pen equal to the task. No words of mine could do justice to such men as Dr. Workman, easily "*primus inter pares*," and fittingly styled by Dr. Tuke, "The Nestor of Canadian alienists"; Dr. Henry Landor, whose rare qualities of heart and mind fitted him so eminently for his position; Dr. R. M. Bucke, to whom is due the introduction of the non-restraint system into Canada; Dr. W. G. Metcalf, who, by his sad and untimely death, added another to the goodly list of physicians who have perished at the hands of those whom they sought to benefit; Dr. J. R. DeWolf, who was foremost in the early care and treatment of the insane in Nova Scotia; Dr. E. E. Duquet, who died worn out by his labors in striving to reform the Longe Pointe Asylum, and Dr. A. Vallée, whose advanced views did so much to improve the Quebec Asylum. The blessed results of the labors of such men can never be fully estimated, their works being truly

"Deeds which are harvest for Eternity."

STATUS OF THE INSANE.

At the present time Quebec is the only one of the provinces of the Dominion in which there is no State institution for the care of the insane. Though vastly improved in every respect and much more strictly supervised by the government than when Dr. Tuke visited them, in 1884, and so graphically portrayed the then existing evils, the two largest hospitals, St. Jean de Dieu and Beauport, are still proprietary establishments, and, as such, still open to the criticism thus forcibly expressed by that distinguished alienist in his work, "The Insane in Canada and the United States," "Far be it from me to attribute to these Sisters of Charity any intentional unkindness or conscious neglect. I am willing to assume that they are actuated by good motives in undertaking the charge of the insane, that they are acute and intelligent, and that their administrative powers are highly respectable. Their farming capacities are, I have no doubt, very creditable to them. It is not this form of farming to which I have any objection or criticism to offer. In the vegetable kingdom I would allow them undisputed sway. It is the farming out of *human* beings by the Province to these or any other proprietors against which I venture to protest. . . . It is a radical defect —a fundamental mistake—for the Province to contract with private parties or Sisters of Charity for the maintenance of lunatics. Whatever may be the provision made by private enterprise for patients whose friends can afford to pay handsomely for them, those who are poor ought to have the buildings as well as the maintenance provided for them by the legislature. They are its wards, and the buildings in which they are placed should belong, not to private persons, but to the public authorities, with whom should rest the appointment of a resident medical officer."

No less pronounced in his condemnation of the "farming out" system is a later writer, one of our greatest authorities on all appertaining to insanity and the care of the insane, Professor Kräpelin. This world-renowned alienist says of it, in an article published some five years ago: "It is not only unworthy of the State, but in the long run it is also dangerous to entrust the care of such institutions to promoters, who are working only on their own responsibility, be they laity or clergy. The best ordinances of State supervision cannot do away with the danger which attends the transference of the insane from the care of the public officials to that of private individuals. Even if State inspection were well carried out, which cannot be guaranteed, only the more apparent abuses could be guarded against. The management of the institution would still be carried out in accordance with the particular views and wishes of those who were in charge and, as a rule, to the disadvantage of the patients."

Following the publication of Dr. Tuke's article, the Medico-Chirurgical Society of Montreal held a meeting at which, among others, the following resolutions were unanimously passed:

"That the 'farming' or 'contract' system

either by private individuals or by private corporations, has been everywhere practically abandoned, as being prejudicial to the best interests of the insane, and producing the minimum of cures.

"That in the opinion of this Society all establishments for the treatment of the insane should be owned, directed, controlled, and supervised by the Government itself, without the intervention of any intermediate party."

Spite of these and other vigorous protests the system remains unchanged, and before Quebec can be counted in the foremost line, where it ought to be, the Province must own as well as supervise its institutions for the dependent insane.

One outcome of the furore excited was, however, the founding of the Protestant Hospital for the Insane, an incorporated charitable institution, which, while paid by the Government for the maintenance of public Protestant patients, is safeguarded by the leading clause in its charter of constitution. This stipulates that the conduct of the establishment shall be vested in a board of management elected by the governors, and that all moneys received by the corporation, from whatever source, shall be expended upon the institution and its inmates. As a matter of fact, ever since the opening of the hospital, the per capita cost of public patients therein has not been less than fifty per cent. more than the Government allowance for their keep, the difference having been made up by the revenue derived from private patients and the bequests of the charitably disposed.

The Province of Nova Scotia, though possessed of as well managed a State asylum as could be desired, is yet behindhand in that it has, since 1886, sanctioned the erection of county asylums, and, in many cases combined county asylums and poorhouses. To these can be transferred the harmless insane from the provincial institution, and to them can be sent direct, idiots, non-violent epileptics and cases of chronic insanity refused admission on statutory grounds to the State Asylum. At the present time there are eighteen of these structures, which, according to the report of Public Charities of 1904, house sane adults, children, insane patients, imbeciles and epileptics. Each is governed by a committee, the immediate management being entrusted to a keeper and a matron, and there is a visiting medical officer attached. These establishments have been erected in pursuance of a plan outlined by Dr. Reid, formerly Superintendent of the Provincial Asylum, though a Nova Scotia medical friend of mine, well acquainted with the system, contends that it was invented by the devil. The scheme was necessitated by the pressing need of additional room for the insane, and the financial inability of the Province to undertake the erection of another public hospital. It is only fair to Dr. Reid, however, to state that this was but one of four alternative suggestions made by him, and that it was the one he considered the least desirable, although the cheapest way to provide the required accommodation.

That county care is cheaper I will not gainsay, but does it best meet the demands of humanity, which, after all, is the true standard to be adopted by any right-thinking community? That it does not seems to be the general trend of the most advanced scientific opinion, and the following resolution adopted at the sixth meeting of this association, held at Philadelphia in 1851, still holds good:

"Resolved, That it is the duty of the community to provide and suitably care for all classes of the insane, and that in order to secure their greatest good and highest welfare, it is indisputable that institutions for their exclusive care and treatment, having a resident medical superintendent, should be provided, and that it is improper, except from extreme necessity, as a temporary arrangement, to confine insane persons in county poorhouses or other institutions, with those afflicted with or treated for other diseases or confined for misdemeanors."

Not a few of the chronic insane are as difficult to manage as the acute, and such being the case, it is hard to imagine any system of county care where abuses will not creep in as a result of the desire to lessen the per capita cost and the absence of constant medical supervision. As practised in the State of Wisconsin it seems to be as well conducted as it is possible for such a system to be, and yet Dr. Burr, our worthy Vice-President, who is a just and honest man as well as a careful observer, after a personal inspection of the system there, published, in the October, 1898, number of the *American Journal of Insanity*, a scathing denunciation of its inefficiency.

Many of the worst horrors connected with the treatment of the insane during the last half century were consummated within the walls of county almshouses. In New York, where the practice of transferring cases which failed to recover in a certain time from the Utica Asylum to the county poorhouses was in vogue for nearly thirty years, and where the county asylum system flourished for over eighteen years, the abuses which seem to be inseparable from almshouse and county arrangement so aroused public opinion that both methods were abolished. By the passage of the State Care Act of 1890, an act which affirms that the dependent insane are the wards of the State, and that their interests and maintenance should be confined exclusively to the State, New York justly earned the proud encomium that, "The leading chapter in the (past) century's history of the care and treatment of the insane in America will be the humane and progressive record of the Empire State."

The State of New Hampshire has also lately recognized the injustice of this method of caring for the insane, and, in 1903, passed an act abolishing county care, and providing for the removal of all lunatics confined in county almshouses to the State Hospitals within a period of six years.

That those connected with and so best qualified to judge of the working of the Nova Scotia system are not themselves enamored of it may be judged from the 1903 Report of Public Charities. Therein, the inspector, Dr. George L. Sinclair, an alienist of repute and a former superintendent of the Provincial Hospital, says:

"The plan of county care adopted in this Province has many grave objections. In a properly equipped and well-officered local asylum, reserved for the exclusive use of insane or imbecile inmates, the objectionable features are fewest. The scheme of associating in one house both sane and insane persons is the most objectionable and unsatisfactory.

"Unfortunately our law permits this to be done, provided the building is made suitable for both classes and for both purposes to the satisfaction of the Governor-in-Council. The difficulties to be overcome to make such a plan of care unobjectionable pertain quite as much to the structure of the municipal mind as to that of the building.

"It is most unfair to the sane members of such a household, whose only affliction is poverty, to compel them to associate with the insane and imbeciles, who are not only irresponsible, but may be a source of positive danger to their companions in misfortune, and it is distinctly unjust to the insane inmates to attempt to care for them with the limited oversight and attention which the small staff of an almshouse can give.

"I have yet to find a single keeper or matron of an asylum to which the mental defectives are sent to associate with the paupers, whose experience in looking after the two classes is sufficient to give the opinion any value, who does not think the mixing of the two kinds of inmates most undesirable. When it is done there is either a dangerous amount of liberty granted the defectives or they are isolated and secluded to an extent that means positive neglect, and leads to distinct deterioration and the formation of bad habits. It cannot be otherwise. The staff of an ordinary almshouse usually consists of a keeper and a matron. The former has charge of the farm and the latter of the housekeeping. When at his work the keeper must either take the insane men with him or leave them at home. The first is often impracticable, and the second unsafe unless the patient is locked up. This more or less frequent seclusion always has an evil effect in causing the insane person to fall into bad habits. Sometimes most objectionable and severe mechanical restraints are used, and nothing but harm results."

In the Province of New Brunswick, it is much to be regretted that the Government, on account of the overcrowded condition of the Provincial hospital, is contemplating a resort to the Nova Scotia system. At the last session of Parliament legislation was passed providing for the examination of all patients therein by a Commission composed of the Medical Superintendent and two other doctors. When the work of the Commission, which began its labors in November last, is completed, a report is to be made to the Government with a view to the selection of those who, being supposed to be harmless, can be sent back to their friends or to the county almshouses. To carry out such retrograde legislation will be to sully the record of a Province which has heretofore always steadfastly declared against the incarceration of lunatics, even temporarily, in prisons or poorhouses—a Province which can boast with pride of having been the first of the British North American colonies to provide special accommodation for its dependent insane.

At present, in New Brunswick, perhaps the gravest existing defect in connection with the insane is the method, or rather lack of method, of commitment to the Provincial Hospital. The safeguarding of the liberty of the subject seems to be little heeded, and a patient can be conveyed to it with only a line from a doctor. No thought is given to advising the hospital authorities beforehand that a patient is coming, and often no history whatever of the case is furnished. The Medical Superintendent, however, informs me that this matter is to be remedied at once, and that the present year will see the manner of commitment more in consonance with the modes adopted in other civilized countries.

Ontario, as the wealthiest of the Provinces, has, of course, been able to outstrip the others, and in its care of the insane has always endeavored to keep up with the advance of science. Its asylums are State institutions in the fullest sense of the word. In the majority of cases the patients are maintained entirely at Government expense; in other cases, where able to do so without hardship, the friends are charged a rate that covers the bare cost of keep.

While all its hospitals are good, Rockwood is certainly the foremost, ranking to-day among the most advanced institutions for the treatment of the insane in America. Whether it be that its presiding officer has a more persuasive tongue and so can better influence the Government, I cannot say, but assuredly it has accessories that are elsewhere lacking, to-wit, a beautiful nurses' home and several small cottages for the segregation of tuberculous patients. The varieties of employment provided for the patients are there, as they should be, numerous and diversified, and physical culture classes are one of the features of the establishment. In addition, those who have a taste for music are instructed in it under a qualified teacher, and there is also a school modeled after that in the Utica Asylum. At Rockwood, too, it is worthy of record, was established Canada's first training school for asylum nurses, and the first separate building, or infirmary, on the continent, for the treatment of lunatics afflicted with additional ailments.

Prince Edward Island has a Provincial hospital for its insane, but idiots and imbeciles are

sheltered in the Provincial poorhouse, those who become dangerous being transferred to the insane hospital.

In Manitoba and British Columbia the asylums are State institutions and well conducted, though, at present, sadly hampered by the constant and pressing necessity of providing sufficient room, owing to the mass of immigrants that has been flowing into those Provinces during the last two or three years. The Manitoba hospitals receive imbeciles, but idiots are sent to the Home for Incurables, also a Provincial institution, located at Portage la Prairie. British Columbia has no special provision for idiots or imbeciles. When utterly unmanageable at home they are received into the insane asylum.

The Northwest Territories, having no hospitals of their own, by special arrangement with the Dominion Government, all cases of insanity occurring in those districts are cared for in the Provincial asylums of Manitoba.

NUMBER OF INSANE.

In 1901, according to the census of that year, there were in the Dominion of Canada 16,622 persons of unsound mind, being a ratio of 3.125 per thousand, or about one in every 319 of a population numbering 5,318,606 souls, exclusive of the unorganized territories. Of these 16,622 defectives, 10,883 were inmates of asylums or other institutions, a percentage of .642 under care.

The Provinces as regards the number of their insane stood as follows: Prince Edward Island, 361, a proportion of 3.496 per thousand; Ontario, 7,552, or 3.459 per thousand; New Brunswick, 1,064, or 3.213 per thousand; Quebec, 5,297, or 3.212 per thousand; Nova Scotia, 1,403, or 3.052 per thousand; Manitoba, 464, or 1.818 per thousand; British Columbia, 301, or 1.684 per thousand; Northwest Territories, 180, or 1.132 per thousand.

The following table shows the changes indicating increased custodial care, or otherwise, on the part of the several Provinces, in the decade extending from 1891 to 1901. By this it will be seen that there has been a marked advance in all with the exception of New Brunswick, which remains unchanged:

PROVINCES.	1891. In Asylum,	1901. In Asylum,
British Columbia	90 per cent.	94 per cent.
Manitoba	55 " "	77 " "
New Brunswick	52 " "	52 " "
Nova Scotia	36 " "	71 " "
Ontario	58 " "	69 " "
Prince Edward Island	38 " "	61 " "
Quebec	50 " "	58 " "
Northwest Territories (Housed in Manitoba Asys.)	..	58 " "
Canada	54 per cent.	66 per cent.

With respect to custodial care, British Columbia ranked first, having under care, at the close of 1901, no less than 94 per cent. of the total number of those mentally incapacitated. Manitoba came next, with 77 per cent. in safe keeping. Nova Scotia stood third, with 71 per cent. sheltered. Ontario was fourth, with 69 per cent. in asylums. Prince Edward Island was fifth with 61 per cent. provided for. Quebec and the Northwest Territories were equal, with 58 per cent. under care, and New Brunswick was eighth, with 52 per cent. housed.

INCREASE OF INSANITY.

In spite of the provision made for the care of the insane, from every Province comes the cry for additional accommodation. Year by year the number of lunatics, imbeciles and idiots to be supported and cared for by the State is being largely augmented, and it has become a burning question whether something cannot be done to lessen an evil which imposes upon the community an enormous load of taxation for the maintenance of a large and constantly increasing multitude of those mentally afflicted. Canada, in common with the rest of the civilized world, has of late years shown a decided increase in the percentage of her insane population. Of course it is easy to be led astray by statistics compared without just qualification. The very agencies created for the care of the insane lead to an apparent increase in their number. With well-appointed asylums, conducted on enlightened lines, aided by Government grants and private charity, hundreds of patients who might otherwise be uncounted, leave their homes to swell the enumeration of the insane. Still, with all allowance made for this, it is the consensus of opinion that insanity is on the increase in Canada as elsewhere. That such is the case is fully borne out by the census returns, which, though lessened in validity by the fact that the figures they furnish are in great measure dependent on voluntary information, are yet in this case a fair index of the true state of affairs, because any false statements made would be in the line of lessening the number of defectives. From this source we find that, while in 1891 there were 13,342 insane persons in a population of 4,719,893, in 1901 there were 16,662 in a population of 5,318,606, being an increase, in ten years, of nearly twenty-five per cent. in the number of lunatics, whereas the increase of the total population was less than thirteen per cent.

The causes of this increase are manifold. The methods of modern life and the modern race for wealth undoubtedly play an important part in it. Our high-pressure civilization does not come to us without attendant woes. With the change and increased comfort in the mode of life of the great bulk of the people, their susceptibilities have been augmented, and their nervous systems have been laid more open to the unkind influences of material and moral forces. But while these and other causes play a part in the production of mental disorder, it is a small one in comparison with that played by heredity. From time immemorial it has been recognized that the great predisposing cause of insanity is hereditary taint, and as time rolls on and we are able to make more careful

inquiry into the influence of hereditary predisposition, the truth of this old-time belief becomes more and more evident. Unfortunately, we are not in a position to say exactly what amount of the mental obliquity met with is due to transmitted weakness. The statistics of heredity vary widely, and this variation is chiefly in direct ratio to the prevarication practised by the relatives of the insane. Not one of us but is well acquainted with the way in which people, even in the lower ranks of life, endeavor by every means to keep us ignorant of what they consider to be a stigma on the family. Almost every authority on mental diseases has commented on this, one writer going so far as to compare the difficulty experienced in getting at the truth in such cases to that which might be expected in dragging from an erring woman a confession of her frailty. Why brain disease should be regarded as more disgraceful than disease of the lungs or any other organ of the body, or why the fact of insanity being in a family should be looked upon by the public as tantamount to an acknowledgment of criminality, is hard for us to grasp. Such, however, is the fact, and until the masses are educated out of such erroneous beliefs, friends will continue to lie about their antecedents most unblushingly. Often I have known cases where the relatives have positively asserted that there was no trace of insanity in their family history, and often I have afterward discovered that it had been well marked for generations. I well remember a lady, widely known for her Christian principles, coming to see me about receiving her daughter as a patient. A prognosis in the case was of importance, and I was asked to give as definite a one as possible. Naturally I asked as to any possible hereditary taint. My lady was firmness itself in her denials. In the course of further conservation, however, she happened to mention that her brother, who had been very fond of the insane girl, was dead, and added, "Perhaps it's as well after all that he is." It struck me at once that there must be something behind this expression of opinion, and my question, "Why so, Madam?" elicited the answer, "Well doctor, you see for over a year before my brother shot himself he was always worrying about Mary's future welfare." Needless to say the hospital registers showed heredity as a definite predisposing factor in the case.

But it is unnecessary that I should dwell upon the question of heredity as a cause of the increase of insanity. It and the marriage question were fuly and ably discussed by Dr. Blumer in his presidential address delivered at Washington two years ago. I shall but strengthen, if that be possible, what was then said, by a quotation. It is from an address on the prevention of insanity given by Dr. G. F. Blandford, as President of the Psychological Section of the British Medical Association, in 1894. On that occasion Dr. Blandford stated: "I have long been of the opinion that insanity is to be prevented chiefly by limiting the propagation of this most fearful disease through the union of affected persons. I am convinced that the only way to really diminish and finally stamp out insanity is by so educating public opinion, that those who have been insane or are threatened with insanity, shall, in the face of such public opinion, abstain from bringing into the world children who must certainly contain in them the potentiality of insanity, and so will hand on the heritage from generation to generation till the race dies out."

(To be Continued.)

MEDICAL PROGRESS.

MEDICINE.

Bright's Disease.—Bright's disease, according to A. C. Croftan (*Journal A. M. A.*, June 24), is a toxemia presumably of intestinal, and, by implication, of hepatic origin, involving, primarily, the cardiovascular apparatus, and secondarily, many organs of the body, including the kidneys. Causal treatment, therefore, in his opinion, must be directed toward the digestive disorders that underlie most causes of the disease. In some cases, however, there are, he believes, obscure metabolic perversions, hereditary or neurotic, it may be, that we do not understand, and this class is less manageable and its treatment is necessarily only symptomatic. Symptomatic treatment is not, however, the conventional treatment of the kidneys, but the treatment of the heart and arteries. When nephritis is established, it of course calls for treatment, but nephritis may not occur till late in the disease. The general measures of maintenance of the nutrition by regulated diet and the avoidance of nervousness, care, worry and fear are naturally of paramount importance. Croftan advises the use of intestinal antiseptics, sulphocarbolate of zinc, sodium glycocholate and organic peroxides, a number of which are sold under various trade names, and which, he thinks, are useful in small doses, together with bismuth as a test for the presence of sulphur compounds in the feces. When the stools are not colored black by bismuth sulphide, it is an indication that the intestinal antiseptic is given in sufficient amount to check the putrefaction of albumin, and in most cases the indican and other aromatic urinary ingredients also will have disappeared. Small doses of digitalis, one drop of the tincture, t.i.d., are useful in rendering the heart less susceptible to the disturbing stimulation of circulating toxins, and may be given without danger of impairing the power of the heart to respond to larger doses in emergency. Schott's exercise treatment is very useful for strengthening the heart in Bright's disease when myocardial changes threaten, and far better than large doses of digitalis or other cardiac tonics. For reducing blood pressure nitroglycerin, or better, erythrol tetranitrate, is the orthodox remedy and can be kept up for a long time. Continuous vasodilatation, lowering blood pressure in the kidneys, reduces the albuminuria and enables the renal epithelium to regain its tone and to resume its functions. Other measures that aid are hot baths, rest in a warm bed and judicious life in a warm, dry climate, all favoring relief of arterial tension and rest to the heart. Croftan condemns kidney decapsulation as irrational in Bright's disease. In acute nephritis underfeeding is advisable, but in chronic cases the daily amount of feeding, expressed in caloric values, should

be inversely proportionate to the presumed duration of the nephritis. There is also no reason why a mixed diet may not be allowed in these cases, excluding only such foods as produce substances difficult of elimination by or irritating to the kidneys. A milk diet also is good in the acute disease, but injurious in chronic cases, and the excessive water drinking so often advised, he states, is irritating to the kidneys and injurious to the overtaxed cardiovascular apparatus. Sweating a nephritic patient may be of some value in relieving the patient of excess of water which the kidneys can not dispose of, but giving much water at the same time is irrational. The restriction or withdrawal of chlorides, on the other hand, is both practically and theoretically useful.

The Manner of Infection in Cerebrospinal Meningitis.—A valuable pathological study, based on a series of 30 autopsies, has been made by WESTENHOFFER (*Berl. klin. Woch.*, June 12, 1905). The results of his investigations seem to show that the point of entrance for the infectious germs is the posterior nasopharynx, and particularly the pharyngeal tonsil. The meningitis is at first invariably a basilar process and centers in the region of the hypophysis. It takes place in a lymphogenous manner. The involvement of the cranial cavity is analogous to the inflammation of the mucous membrane of the accessory sinuses connected with the nasopharyngeal space. A meningitis of this type never, or at least very rarely, occurs by the extension of an inflammatory process from the ethmoid cells. The writer claims that both adults and children who happen to be attacked by this disease show distinct evidences of the so-called lymphatic diathesis. The disease is due to the inhalation of the infectious organism and its prophylaxis is essentially hygienic. The meningococcus Weichselbaum-Jäger is found in the majority of cases, although it is by no means decided that it is solely and alone the cause of the disease. The fact that many other cocci are found with this coccus, either alone or in a mixture, makes it probable that all of these bacteria play only a secondary rôle in the etiology of the disease and that the real etiological factor has not yet been discovered. This seems to be analogous with the streptococcus infection in scarlatina.

Quinquaud's Phenomenon.—Recently Quinquaud described the following symptom as characteristic for alcoholism: The fingers of the patient to be examined are spread out and then placed perpendicularly upon the palm of the physician. After several seconds a decided crepitation will be felt by the latter, if the test is positive, even where the joints are absolutely normal. M. HERZ (*Münch. med. Woch.*, May 30, 1905) has investigated the symptom in a large number of cases and concludes that the crepitation does not come from the joints but results from slight lateral motions of the tendons in their sheaths, set up by the involuntary muscular contractions so common in alcoholics. The symptom is present to a slight extent also in normal individuals.

Medical Phases of the Immigration Legislation.—V. G. HEISER (*Med. Rec.*, June 17, 1905) says that the act of 1891 was the first under which immigrants suffering from certain mental or physical conditions were absolutely excluded, and the law provided for the first time for the medical examination of all arriving aliens. The medical features of the immigrant legislation consist of two simple divisions, the first for those suffering from afflictions for which they are absolutely excludable and the second for those suffering from conditions which may cause them to be likely to become a public charge. From year to year it has been found desirable to augment the list of affections that come under both divisions of the law, and the last act pertaining to immigration, passed in 1903, still further increased the list of absolutely excludable diseases. In discussing the maladies on the absolutely excludable list which give rise to the greater number of rejections, the author says that trachoma easily ranks first, and favus is also of importance. Leprosy, active syphilis, and cases of tuberculosis with bacilli in the sputum, are also on the list. Epileptics, idiots, and the insane are specifically mentioned by law. The second class of diseases is a very long one and includes such conditions as valvular disease of the heart, hernia, chronic rheumatism, nervous affections, malignant tumors, defective eyesight, senility, etc. Persons suffering from temporary conditions are cared for until well in hospitals at the expense of the transportation company bringing them in. The author is in favor of the enforcement of the medical clauses of the immigration law in the Philippines, both from a humanitarian and a practical standpoint.

Menstrual Jaundice.—A few cases of jaundice recurring with every menstruation are reported, and there is a tendency to look upon this condition as a separate disease. L. METZGER (*Münch. med. Woch.*, June 13, 1905) has observed and previously described a case and now is so fortunate as to give the autopsy reports, as the patient died of an intercurrent disease. A calculus was found wedged in the common duct which seemed to obstruct this passage completely, yet during life probably permitted the escape of sufficient bile to prevent stasis. With the congestion of the abdominal organs incident to menstruation, a true biliary stasis set in, so that some of the bile was readily absorbed by the lymphatics and icterus developed. Probably most cases reported depend on a similar cause, though there are no other autopsy records.

Intestinal Peristalsis.—ISAAC OTT and J. F. ULMAN (*Journal A. M. A.*, June 17) have studied the effects of various agents on the intestinal movements, confirming Ott's earlier findings that adrenalin arrests the pendulum movements and causes relaxation of the longitudinal musculature, and that splenic extract increases the peristaltic action both in frequency and force. Infusion of the pancreas was found to relax the muscles and slow the movements of the intestine, at the same time increasing the force of the contraction. Experiments were also made with other animal extracts, ovary, testes, parotid and mammary glands, pituitary, thyroid, brain and spinal cord, but they had no marked effect on intestinal peristalsis. The thymus seemed occasionally to increase its force. Sodium citrate increased the force of the contraction, which was slowed, weakened, and made irregular by the addition of calcium chloride, thus agreeing with MacCallum's observations. It is suggested, therefore, that calcium is indicated, in agreement with MacCallum's and with Loeb's theories of the action of the calcium ions, in persistent diarrhea of nervous and hysterical cases. A series of experiments were made testing the effects of various drugs, atropine, eserine, nicotine, muscarin, pilocarpine, strychnine, curare, morphine, etc., on intestinal peristalsis and also on their antagonistic action to each other, which are discussed in detail, especially their relations to the nervous supply of the intestine, and the conclusion is deduced that the automatic movements of the bowel are not myogenic, but are dependent, as shown by Magnus, on Auerbach's plexus. The action of certain organic bodies, bile, albumoses, peptones, leucin, tyrosin, was also tested; they all increased the force, and most of them also the frequency of the intes-

tinal movements. It is evident, the author remarks, that the products of proteid digestion are active stimulants of peristalsis. A good digestion predisposes to regular evacuation of the bowels, and this accounts for the habitual constipation of dyspeptics.

The Preservation of the Urine.—A large number of experiments (140) with different preservatives in urines of various compositions have been made by J. B. Ogden (*Boston Med. and Surg. Journ.*, June 22, 1905), as the result of which he concludes that boracic acid is the most practical urinary preservative when used in the proportion of 5 gr. to 4 oz. of urine. Formaldehyde solution should only be used by the physician or a responsible person. It should be remembered that one drop of the solution will preserve about a pint of urine for a week and that a drop can be used in 4 oz. of urine without harm. Other substances than these two should not be used, as they either interfere with chemical tests and microscopical examination or are ineffectual as preservatives.

NEUROLOGY AND PSYCHIATRY.

The Prevention of Shock.—Assuming that surgical shock is due to the functional impairment or even exhaustion of the vasomotor centers through afferent impulses set up by trauma, exposure, etc., G. W. Crile (*Journal A. M. A.*, June 17, 1905) discusses the means of its prevention, as well as that of hemorrhage, in various surgical procedures. Aside from the impulses mentioned, there are a number of important accessory causes to be reckoned with, he states, including psychic emotions, such as fear, hemorrhage, cold, acute and chronic infections, anemia, cachexia, etc., and age and sex. One or more of these is met with in every case. In operation on the head he emphasizes the importance of giving particular attention to circulatory conditions, of reducing to a minimum the exposure and manipulation of the meninges and the brain, and of having as complete control of the blood pressure as possible. He has clamped the carotids in 41 cases without unfavorable effects, and thinks it a valuable method of controlling hemorrhage in certain cases, together with the head-up posture and the use of the pneumatic rubber suit. In laryngeal operations, the danger of cardiac collapse can be avoided, he says, by previously giving a physiologic dose of atropin or by the local use of cocaine. In minor intrathoracic operations, when there is hampered respiration and seriously impaired circulation, Crile advises local anesthesia, and if further measures are needed they can be carried out later, after the patient's forces are recruited, under surgical anesthesia. The supreme importance of the respiratory action on the circulation must be kept in mind, as well as the danger of interfering with the large venous trunks. In abdominal operations, shock is in direct ratio to the trauma and exposure. In all time-consuming, exacting technics, he advises, no special contraindication existing, the use of morphine-ether anesthesia: either during the abdominal incision and the exploration and development of the operative field, morphine alone, with slight or no ether accessory during the technic proper, and ether again in closing the abdominal wound. The region around the diaphragm is much more shock-producing than the lower abdominal tract, and he cautions the anesthetizer against being misled by the expiratory moan in these upper abdominal operations and overdoing the anesthesia. In anemia, cachexia and acute infections, the available vitality must be most carefully estimated and methods safely within its limits be adopted. The prevention of shock in operations on the extremities is narrowed down to two or three simple propositions, the minimum loss of blood and the least manipulation and force, and the "blocking" of the nerve trunks by intraneural injections of cocaine or eucaine. Crile summarizes his views as follows: "Every tissue and organ has a more or less individual shock-producing value and must be individually considered. The amount of shock produced by a given trauma varies according to the amount and special quality of its nerve supply and the number and intensity of the afferent impulses originated by the injury or operation. Cocaine or eucaine may wholly 'block' these shock-producing impulses. When one or more of the accessory causes of shock are present the highest possible tax is laid on the surgical judgment of the operator. A precise technic offering a minimum of exposure and trauma, grafted on a comprehensive grasp of all the factors entering into the operative consideration, are the ideals for which we must strive."

Neurasthenia Among the Laboring Classes.—Excellent facilities for the study of this subject are presented in one of the large German sanitaria, which have been studied by Leubuscher and Bibrowicz (*Deut. med. Woch.*, May 27, 1905). It was formerly believed that this complaint was relatively infrequent among this class, but this conception must now be revised. This may, of course, be due to the fact that the lower classes are now under more systematic medical observation, at least in Germany, than formerly, but the writers are rather inclined to the belief that it is produced by our changed social conditions. The work itself and the conditions under which it is performed are different. Either greater excitement or extreme monotony characterizes it. The struggle for existence often induces longer hours of work, and another important rôle is played by the disparity which exists between the intellectual equipment of the workmen, especially in the large cities, and the actual value of his work. Thus, the typesetters, often fairly well educated, pursue an occupation which is not only fatiguing but monotonous. Among those workmen where manual labor is of such a nature as to be productive of some degree of enjoyment, neurasthenic conditions are rarely to be found. The majority of cases were noted between twenty-five and forty-five years of age.

The Hypochlorization Method of Treatment for Epilepsy.—This method, also known as the "salt poor diet," has been in use at the Massachusetts Hospital for Epileptics for several years, and consists of the substitution of sodium bromide for the chloride in the patient's food. The claim is made that the bromide salt is rapidly absorbed and becomes part of the body tissue when administered in this way, and only about half the usual quantity is necessary. A. Morton (*Boston Med. and Surg. Jour.*, June 15, 1905) reports on 24 patients who had been on this treatment for two and a half years. The diet consisted mostly of milk, eggs, bread and butter, gruel and soups, to which enough sodium bromide was added to amount to about 15 grs. per day. Sodium chloride was not, however, entirely excluded. The results were encouraging, the number of attacks decreased markedly and the patients were much quieter. Later on about one hundred other patients were put on the same treatment, who were getting a plain mixed diet. The greatest decrease in the number of convulsions occurred when the

women were taking about 35 grs. daily, but they objected to the salt and the ordinary sodium chloride was then mixed with it. An immediate increase in the convulsions was noted, although the number was still below the average seen with the regular diet. The writer concludes that this method controls the convulsions and requires only about one half the amount of bromide usually given. It has little or no effect on the general nutrition of the patient. It is apt to cause constipation. It does not furnish enough salt to supply the patient's craving. It may be used with success with intelligent patients, but is practically useless in the middle grade of epileptics. A modified salt poor diet, in which about equal parts of sodium chloride and bromide are used in the food, may be used to advantage with idiotic and demented patients if their diet can be controlled absolutely. Bromism was found to be comparatively rare.

THERAPEUTICS.

Radium in Cancerous Growths.—REPMAN presented two patients before the Society of Neuropathologists and Psychiatrists at the Moscow University (*Prakt. Vrach*, March 26, 1905), one of whom had a cancerous ulcer at the inner angle of the right eye. The treatment began December, 1903, weekly sittings, duration one hour. The bromide of radium was used; improvement was noticed after every application. For some reason the patient discontinued treatment after six weeks with the result that the condition became worse and the edges of the ulcer that were in a fair way of cicatrization reopened again. Treatment was instituted again with the result that the ulcer that resisted obstinately treatment for five years is now healed completely. The second case was that of a cancer of the breast for which the patient was operated on twice—nine and three years ago. In this case applications were made three times a week, and after twenty-six sittings the tumor seems to have disappeared and the patient regained perfect control of the shoulder-point (tumor located under left clavicle).

Relation Between Chemical Constitution and Diuretic Action.—Among the large number of diuretics, not the least important are caffeine and its numerous homologues. It has seemed almost imperative that a careful comparison of these bodies be made, with the idea of linking the diuretic effect to some particular molecular group or aggregate of groups. P. BERGELL and P. F. RICHTER (*Zeitsch. f. Exp. Pathol. und Therapie*, Vol. 1, No. 3) compared a group of compounds which are hemalogues of caffeine, in which one of the three methyl groups is substituted by an ethyl radicle. These are, therefore, three isomeric compounds having a purin nucleus. Caffeine is trimethylxanthin, and the other compounds are ethyltheobromin, ethylparaxanthin, and ethyltheophyllin. All of the three latter have a marked diuretic effect, but ethyltrophyllin has an effect less than that of ethyltheobromin. In substituting the ethyl-radicle and other alkyl radicles, such as propyl, butyl and amyl, the authors find that these all have a diuretic action, but this is not as marked as that of the ethyl compounds. The length of the side-chain diminishes the diuretic effect.

Rectal Injections of Large Doses of Sodium Salicylate in Cerebrospinal Meningitis.—A. SEIBERT (*Med Rec.*, June 17, 1905) believes that the administration of large doses of sodium salicylate, given by rectum to avoid gastric disturbances, forms the most satisfactory plan of treatment for this disease. Tapping the spinal canal by lumbar puncture may be of great value in some cases by relieving pressure, but it is not curative, and injections of antibacterial fluids into the spinal canal never reach the organisms they are intended to destroy. An effective remedy for cerebrospinal meningitis must travel the same road which the infectious germ has taken through the blood current. Salicylates have been used before in this condition, but in doses that are entirely too small. Five cases are described in which the use of large doses of the drug appeared to exert a very powerful curative effect. According to the age of the patients, sodium salicylate was given by rectum in fifteen grain doses dissolved in a tablespoonful of water, at intervals of from one to eight hours, the salicylization being gradually reduced as improvement followed. In one case, that of a boy aged four and a half years, who had had the disease for seven weeks some months previously and presented numerous sequelæ such as contractures, hemiplegia, strabismus, etc., very remarkable improvement followed the treatment, though it was begun only at so late a date. In a tuberculous case the salicylate did not appear to be effective. The author urges those who have charge of large numbers of cases of the disease to give a trial to this plan of treatment which he is convinced is of value in all cases where serous, not purulent, exudate forms.

Treatment of Inoperable Cases of Malignant Disease of the Orbit.—C. S. BULL (*Med. Rec.*, June 24, 1905) says that while malignant disease of the orbit which has apparently not originated in or involved the adjacent sinuses should be extirpated by the knife as soon as possible, the consensus of opinion seems now to be that when the neighboring sinuses are involved a complete removal of the growth is impossible, a recurrence of the growth is certain to appear, and with each repetition of the operation the return of the disease is hastened, and the life of the patient is by just so much shortened. On the other hand, in view of what we actually know of the action of the X-rays, it would seem not only wise, but our duty, after such operation by the knife as may be necessary, to expose the parts a certain number of times to the X-rays, in order, if possible, to destroy isolated cells or aggregations of cells in the neighboring parts which cannot be reached by the knife. It is stated on good authority that there has been a marked diminution in the death rate following operations on patients so treated. The author's experience, based on his own cases, has satisfied him that the X-rays are of value in removing the pain so constantly complained of, and he, therefore, believes that the treatment is to be recommended in inoperable cases because it relieves much of the patients' suffering, and thus may prolong their lives. It would seem that the more recent and superficial a malignant growth is, the more rapid and favorable are the results from X-ray treatment, but it takes time to prove the ultimate good results. The author presents the detailed reports of ten cases from his own private practice, in which the X-ray treatment was employed after excision by the knife. Of these ten cases, two were very much improved if not apparently cured, and of these two one was an epithelioma and the other a carcinoma. The remaining eight cases, in which no demonstrable effect was produced by the X-rays, were all sarcomata. In all but one of these the pain was more or less effectually relieved. No untoward results of the action of the rays were observed in any of the cases.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 19, 1905.

THE PHARMACOPOEIA OF 1900.

On September 1, 1905, the Eighth Decennial Revision of the Pharmacopœia of the United States of America becomes the official guide to physicians and pharmacists of this country.

The present edition has been unduly delayed. The reasons are not far to seek, but not the least was the untimely death of Dr. Charles Rice, chairman of the Revision Committee, at the very outset of the labors of the Committee on Revision.

It has been a standing reproach to the medical profession in general that they have taken little interest in this important work, but fortunately this is fast becoming a matter of history, and the time we hope may not be far distant when the Pharmacopœia will be a living part of every practitioner's armamentarium. The flagrant features of the patent-medicine evil, so far as it is fostered by the physician himself, will cease to exist when he is better acquainted with this book.

The present edition represents in the aggregate an immense amount of labor. No one who has not served on the Revision Committee has the slightest conception of the gigantic task involved in putting this work through, and the profession little realizes the debt that it owes to the sacrificing members of this committee. To utilize it to the full is to express in small measure the sense of that obligation.

It is impossible to more than indicate some of the important additions and changes that are here found when compared with the edition of 1890. We hope to present from time to time some of these to our readers. A few of the more striking features may be mentioned and attention further called to a useful Bulletin of the Public Health and Marine Hospital Service No. 23, under date of August 1, written by Drs. Reid Hunt and Murray Galt Motter on the changes found in the new edition.

We would call particular attention to two most important changes, viz.: Tincture Aconite is now 10 per cent., having been reduced from 35 per cent., and Tincture Strophanthus has been increased to 10 per cent. (formerly 5 per cent.), thereby creating a source of possibly grave error on the part of either prescriber or dispenser, unless the prescriber plainly states which tincture he desires, by appending the title U. S. P. 1900 (or U. S. P. 1890, should he desire the stronger preparation). These remarks apply equally to several of the other tinctures, notably:

	Per Cent. Now.	Per Cent. Formerly.
Belladonna leaves	10	15
Cannabis indica	10	15
Colchicum seed	10	15
Digitalis	10	15
Gelsemium	10	15
Hyoscyamus	10	15
Lobelia	10	20
Calabar bean (Physostigma)	10	15
Stramonium	10	15
Veratrum	10	40
Syrup ferrous iodide	5	10

Tinctures Nux Vomica, Opium and Opium deodorized, remaining as before, 10 per cent. These changes are in accord with the recommendations of the Brussels conference as to uniformity of strength of potent remedies.

Among other changes which will prove of interest, the admission of Phenacetine, Sulfonal, Trional, Aristol, Urotropin, are to be noted. They should be prescribed for by their official names.

Several new galenical preparations are important: Cataplasm of Kaolin, Elixir, Glycerole and Syrup of the Phosphates of Iron, Quinine and Strychnine, Emulsion of Turpentine, Antiseptic Solution, Compound Solution of Cresol, Solution of Sodium Phosphate, Compound Laxative Pills (A. S. B. and I.), Tincture of

Gambir Compound (to replace Tinct. Catechu Co.), as well as several others.

For the first time, and a highly commendable innovation, dosage is admitted to the Pharmacopœia under the following distinct declaration. "That neither this Convention, nor the Committee of Revision created by it, intends to have these doses regarded as obligatory on the physician or as forbidding him to exceed them whenever in his judgment this seems advisable." Anti-diphtheritic serum, and also Desiccated Suprarenal Glands and Desiccated Thyroid Glands, are new.

Several changes in nomenclature are manifest, Acidum Arsenosum and Acidum Chromicum becoming Arseni Trioxidum and Chromii Trioxidum. The name Acidum Carbolicum has been dropped, "Phenol," the more correct chemical name, replacing it.

Cocaine, Morphine, and Quinine Hydrochlorates now become Hydrochlorides, and Sodium and Zinc Sulphocarbolates are now respectively Sodium and Zinc Phenolsulphonate.

The cumbersome nomenclature of the fluidextracts is simplified and they are now all written "Fluidextractum," thus avoiding the possibility of an error on the dispenser's part should the "Fluidum" be omitted by the prescriber.

These constitute but a few of the important modifications; of the refinements of tests, standards for purity, simplification of assay processes, standardization of potent remedies, etc., we cannot at this time speak. The work is a notable one, and the Committee of Revision is to be congratulated on the completion of their task. The Eighth Decennial Revision is an honor to its compilers.

NEWER IDEAS ON THE FUNCTIONAL TOPOGRAPHY OF THE BRAIN.

In the quarter of a century that has elapsed since Fritsch and Hitzig first worked out the localization of motor functions in the cerebral cortex, although but a comparatively small part of the convexity of the hemispheres of the cerebrum has been explored, the facts discovered have certainly been of incalculable value from the viewpoints of diagnosis and treatment. The attention of investigators has been mainly riveted on the cerebrum, and to this has been accorded, at the expense of other parts of the brain, an influence altogether too predominant in the activities of this organ. For it appears in the light of the most recent investigation that other parts of the brain are likewise the seat not only of important motor functions, but also of the highest psychic activities.

It is well known that among the lower animals deprivation of the cerebrum does not abolish some of the very complicated motor mechanisms. Thus, in birds the centers that control the intricate movements of the eyeball are located in the corpora quadrigemina. A number of observers, among whom may be mentioned Sherrington, have noticed that in lesions or destructions of the cerebrum a well-marked muscular rigidity occurs. This is supposed to originate from centers situated in the mid-brain, which are normally the source of motor impulses and whose activity is under the inhibitory control of centers situated in the cortex. This form of muscular rigidity is observed in many diseases involving the cortical region of the cerebrum and the path leading to and from it.

F. H. Thiele (*Journal of Physiology*, July 13, 1905) has discovered in the posterior part of the optic thalamus, centers which, he believes, control the coordinated movements of walking. The nervous impulses emanating from these centers are independent of the pyramidal tracts, for the complete degeneration of the latter does not affect the functional efficiency of these centers. There are other centers in the optic thalamus which exert an inhibitory influence over the motor cells in the spinal cord.

This same observer also maintains that the cerebellum is the seat of important motor mechanisms. The sum total of the scant knowledge which until quite recently has been garnered from the study of the functions of the cerebellum, has been that this no insignificant part of the cranial contents exercises a coordinating influence over muscular contractions, or, in other words, contains the centers of equilibrium. This knowledge has been derived chiefly from clinical observation. Thiele has found that the cerebellum through its peduncles governs the skeletal muscles and is capable independently of producing movements, particularly those of the trunks and girdles. The author concludes from his experiments that movements of great complexity, such as those of progression, can be carried out in the absence of the cerebral cortex altogether. It is noted that the muscular mechanisms centered in the optic thalamus are of

wide spatial distribution and employ the limbs of both sides and the trunk, while the cells in the cerebral cortex control only limited groups of muscles.

Of still greater interest are the results of the experiments recorded by G. Pagano (*Arch. Ital. de Biol.*, May 10, 1905). This author was able to map out distinct areas in the cerebellum, and to show that these are in relation with movements of definite parts of the body. Although the results of his work leave room for considerable amplification, he has actually succeeded in proving the existence of cerebellar localization. This has already been foreshadowed by other observers, notably by Weir-Mitchell, thirty-six years ago, by Nothnagel, and by Ferrier.

The author's experiments were performed upon dogs, and his technic was so novel as to deserve mention. In order to excite the cerebellar cortex, he injected into it small quantities of a 1 week solution of curare. The dogs were not under the influence of any anesthetic. These injections were shortly followed by contractures of definite parts of the animal's body, particularly of the limbs. In this way the author was able to map out distinct motor areas of the vermis, or the median lobe of the cerebellum, and of the contiguous parts. The character of the movement differs markedly from that obtained by a similar stimulation of the cortex of the cerebrum. In the latter case the curare causes clonic contractions of the limb. In the cerebellum, the stimulation causes a steady contraction or attitude, which is most frequently one of adduction or retraction of the limb.

The movements evoked by stimulation of the cerebellum differ also from those produced by stimulation of the cerebrum, in being chiefly homolateral. In the former case, as in the latter, there is a gradual merging of one area into another. One remarkable series of results was obtained by stimulation of the anterior extremity of the vermis. This gave rise to unmistakable psychical manifestations in the animal. It became possessed of maniacal fury, which was intensified by the slightest tactile, visual, and auditory stimuli, such as a breath, a gesture, or a whisper. This condition of the cerebellar cortex, which has thus been proved to be the seat of psychic centers, has been termed a veritable psychic strychninism. This is soon succeeded by epileptiform convulsions, then by a period of quiescence, and at last by death. There is no doubt, therefore, that the anterior part of the vermis contains centers whose stimulation leads to a state of mental exaltation.

That the cerebellum shares with the cerebrum the distinction in being the seat of psychic activities might have been inferred from previous observations on animals suffering from cerebellar lesions, in which vertigo and mental apathy had been noted, and in human victims of disease of the cerebellum, in which a certain intellectual decadence had been frequently observed.

One important difference between the motor centers of the cerebellum and those of the cerebrum is that the former are deeply situated, while the latter are placed near the surface. The question arises as to whether the cerebellum is normally capable of initiating mental processes, however subordinate these may be, or whether it produces a functional exaltation of centers situated elsewhere, or whether the phenomena of psychic excitation are the result of stimulating acoustic paths which are intimately connected with the cerebellum. The answer to this question awaits future investigation.

SUGGESTIONS IN TUBERCULOSIS.

In the midst of the present reduction in the mortality from tuberculosis there are certain features that are not near so encouraging as might be expected from the improvement of statistics. Notwithstanding advances in knowledge, and especially with regard to the early diagnosis and management of tuberculous cases, not a few persons suffering from tuberculosis fail to have the disease process stopped by treatment even when carried out very effectually, but go on to increasing lesions and ultimately to fatal termination. Not infrequently it is said with regard to these patients that they lack resistive vitality. This is, however, an entirely hypothetical explanation, and so indefinite as to give no help to the practitioner. There is a growing feeling, moreover, in the minds of many specialists in tuberculosis that there are specific types of the disease which run very different courses from others, some of which are comparatively mild in character, while others are decidedly virulent.

Not that the element of individual resistance can be entirely eliminated in the study of tuberculous patients. Every one who has had much experience with tuberculosis can recall cases in

which the infection was traceable from one individual to another, and yet ran a very different course in each.

It has been the custom, especially of late years, to consider that the more virulent forms of human tuberculosis were more closely related to bovine tuberculosis than to other forms of the disease. If the observation of Dr. Woods Hutchinson, reported at the recent meeting of the American Medical Association, should be confirmed by others, and the suspicion of the nature of the affection observed be justified by subsequent observers, this opinion must have added credence. At the State Sanitarium not far from Portland, Oregon, Dr. Hutchinson has had under observation some eighty patients. Of these considerably more than one-third suffered from a very severe form of tuberculosis, which went on rapidly to a fatal issue. Nearly all of these patients have been associated for a considerable period with the care of cattle on the mountainous ranges of the State. Notwithstanding their outdoor life at considerable altitudes, they had acquired this virulent form of tuberculosis, the bacilli of which proved, on careful investigation, to be of the short, thick variety of the microorganism which is often seen only in connection with bovine tuberculosis.

Whether there are intermediate types of the tubercle bacilli lying between the human and bovine forms, yet virulent for man, is, as yet, under discussion. It seems probable, however, that many of the individual peculiarities of the disease could be best explained by means of some such variation of virulence. It has been noted over and over again that certain persons do not do well at the sea level, while others suffering from apparently similar forms of tuberculosis are unfavorably affected by altitudes. Whether there may not be some difference in the type of microorganism accountable for this remains to be investigated. It would certainly be of the greatest possible help in the treatment of tuberculous patients if, by means of the microscope, it could be recognized whether altitude or sea level were the best climatic condition for such patients from the very beginning, as actual observation is the only source of knowledge in this matter, and in this way at times very valuable time is lost at a stage of the disease when every day counts as regards the ultimate fate of the patient.

On the other hand, a very curious reflection is emphasized by some of the cases reported in the Northwest. It is well known that our American Indians, notwithstanding their outdoor life in tents, succumbed very promptly to tuberculosis in very large numbers whenever exposed to the disease. Tent life has become such a shibboleth in the treatment of tuberculosis by the outdoor method that it is surprising that this Indian experience has not made more physicians and patients realize that it is not the outdoor life alone, but the coordination of all proper hygienic conditions, that constitutes the essence of the modern successful sanitarium method of treating tuberculosis. The Indians were lacking in nutrition and in hygienic precautions against reinfection, hence the enormous death-rate. Undoubtedly, however, there was besides this a lack of resistive vitality.

In civilized communities the fact that, as the Germans say, we are all of us somewhat tuberculous, a fact that is demonstrated by the finding of tuberculous lesions in the lungs of more than three-fourths of those who die from other diseases and come to autopsy, seems to furnish to most of us a definite protective immunity against the disease, not absolute but relative, yet of sufficient power to enable us to resist serious invasion even after infection has taken place.

It has been suggested that in the Northwest those who have been living outdoor lives out of contact with tuberculous patients have lost something of this immunity of civilization, and so seem to suffer from tuberculosis in the virulent form exhibited by the American Indian. All of which would seem to be an added argument against those who would be foolish enough to make elaborate efforts to prevent the establishment of sanitaria in the vicinity of cities for the treatment of tuberculosis with the idea that the only thing that is to be feared with regard to this disease is the possibility of infection. The problem is by no means so simple as this, and much remains to be known before even its terms can be properly stated. Meantime this oldest of diseases presents some most fascinating aspects for investigation.

Yellow Fever.—The Marine Hospital authorities assure us that they will have control of the fever situation in the South within the next month. In view of the few new foci being discovered, we trust that their optimism may not be rudely shaken

ECHOES AND NEWS.

NEW YORK.

To Avoid Typhoid.—Commissioner Darlington of the Health Department has put into a pamphlet certain information for the benefit of persons who wish to avoid typhoid fever. "Don't eat oysters in the months when typhoid is prevalent," says the pamphlet. "Neither is it good to bathe at beaches near where sewers empty. The primary rules of hygiene should be observed and carbolic acid used as a disinfectant around bathroom." It is advisable to have all well water in Brooklyn boiled. It is safer to boil all drinking water.

Improving Nassau Hospital.—Mrs. William K. Vanderbilt, Jr., has stated that she will provide a children's ward diet kitchen, dressing room and more private rooms for the Nassau Hospital at Mineola. The hospital was established through the efforts of a number of prominent residents of Nassau County and the members of the Meadow Brook and Rockaway colonies, who some years ago gave a horse show and a series of races in order to raise money for it. The improvements have already been begun. The addition is being built at the west end of the hospital. It will be about the size of the present building.

Filtration Figures.—In Health Commissioner Darlington's report to the Mayor on the question of filtration of the city's water supply, there are various comparisons of healthy cities with filtered water, with nearby towns, in which such precaution has not been taken. The most striking of these comparisons is that of Hamburg and Altona, adjoining cities, both of which take their water from the Elbe. Altona's supply is filtered. Hamburg's was not, previous to 1893. On the chart based on the statistics of thirteen years ago, in Dr. Darlington's report, the location of typhoid cases in these two cities is indicated by black dots. East of the dividing line, where the site of Hamburg is shown, the paper is black with dots. On the other side these marks can be easily counted at a glance. There is no question in Dr. Darlington's mind but that the water supply of New York should be filtered. The water sheds which supply Manhattan and Bronx extend over 360 square miles and a part of this area is within Connecticut, over which the State and city have no control. Concerning the cost of filtration, the Commissioner says that the estimates of the Commission on Additional Water Supply show that a suitable covered slow sand filtration plant can be built for the entire Croton supply of about five hundred million gallons daily for about $17,000,000 (at present wages and prices of material), with a total annual cost of operation, including interest, sinking fund, depreciation, etc., of about $900,000. The work could be completed within two years.

General Rules for Prevention of Mosquitoes.—The yellow fever scare at New Orleans has had one good effect, at least. It has caused the widespread publication of hygienic rules that ought to be observed by every owner or tenant of houses and lands throughout the country. Accepting the theory that the plague is transmitted by means of the mosquito, this advice has been tabulated and given out by the New Orleans health authorities:

"Clean out every place where water stands.

"So dispose of old tin cans, bottles, or what not, that rain cannot possibly be retained.

"Watch your roof gutters.

"Empty your rain barrel of water every week, or screen it closely with fine-meshed wire on top.

"Change the water every day in a drinking pan for dog, cat, or bird.

"Watch the watering trough near your stable.

"Fill a hole in a tree with soil packed tight, or with cement.

"In other words, get rid of, or coat with kerosene, all stagnant, standing water, and you will get rid of mosquitoes.

"If you have a playing fountain, put little fish, like minnows or goldfish, in the water, and they will eat the mosquito larvæ.

"If you have a sluggish brook or a stagnant pond near your house, spray kerosene or coal oil on the surface; this makes it impossible for the 'wigglers' to breathe when they come to the surface, and they die. The coal oil application is only necessary at the edges, and is good only so long as the oil film is unbroken."

Bearing in mind the assertion that New York is nearly as likely to suffer from the plague as New Orleans, if sanitary measures are neglected, these articles in the hygienic creed are worth preserving.

The Brooklyn Typhoid Situation.—To ascertain the causes of the prevalence of typhoid fever in Brooklyn, and particularly in the Bath Beach, Bensonhurst, Borough Park, and Bay Ridge sections, the Health Department is giving great attention to the water supply, on which, it is thought, a large share of the responsibility will fall. A house-to-house inspection of the Thirtieth and Thirty-first Wards is being made by six Sanitary Inspectors. Their object is to find out to what extent the residents are taking their drinking water from the public sources of supply, and to what extent from wells and cisterns. An investigation is also being made as to the quality of the water supply from all sources. Reports on all the phases of this investigation will probably be received by the Health Commisioner by Monday or Tuesday. The local physicians admit that typhoid is now almost epidemic in the Bath Beach and Bay Ridge districts. It was learned that for the five weeks ending last Friday forty-eight cases of proved typhoid were reported from the Thirtieth Ward alone. This record has since been growing steadily worse, and up to the present time about 300 cases have been reported, and the end is not yet. The principal causes of infection found by Dr. Berry were bathing in Gravesend Bay, overflowing cesspools, defective sewers, stagnant pools, into which the drainage of surounding districts is being collected, and wells and cisterns exposed to pollution. And his principal recommendations embody the following propositions: Prohibition of building new cesspools, inspection and enforced cleaning of existing ones, appeal for the improvement of roads, and the installation of sewers in the Bath Beach district, and for the improvement of the sewers of the Bensonhurst district; closing of public bathing establishments along the shore from Fort Hamilton to Ulmer Park, the placing of signs in conspicuous places warning the people of the danger of bathing in the bay along that district, the maintaining of a more rigid standard of cleanliness in regard to stables and general sanitary conditions in the ward. Dr. Henry V. Walker, the Chief Inspector, reports that the recomendations can not be carried out without the amendment of the present sanitary code. What is particularly wanted is a rule forbidding the establishment of new cesspools without permission from the department. Much of the trouble is the rapid growth of the Bath Beach and Bensonhurst districts, making it impossible to keep sanitary improvements on a level with the increase of population. The result is that in many houses the

same conditions exist which prevailed before the region had changed from a rural to an urban community.

PHILADELPHIA.

Duty Neglected.—Assistant Medical Inspector H. L. Sidebotham has been asked to tender his resignation. The Department of Health took the step after being satisfied that the inspector was wilfully neglecting his duties. One of the duties of the inspector was to make daily visits to certain schools; these he failed to make, but handed in a manufactured report each day.

Jail Overcrowded.—Lawyers, whose clients are suffering from the overcrowded condition of Moyamensing Prison, have pointed out that an epidemic of one kind or another may arise as a result. In order to corroborate their views and to give them better grounds upon which to work in bringing about relief these attorneys have obtained certificates from many physicians attesting to the conditions.

Young Doctors Receive License.—Shortly after the examinations, which took place in the latter part of June, there was a rumor current that the candidates for license to practise medicine under the old school would be re-examined owing to a change in the questions after they had been delivered to the examiners. The matter must have been settled in an amicable manner. Of the 466 candidates 320 passed, 56 failed, 4 were expelled for cheating, 4 withdrew and the decision was reserved for 82. The announcements were made in Atlantic City, where the papers were examined.

Benefit for Frankford Hospital.—While the politicians in the center of the city are playing a mild game of war the politicians of the northeastern section of the city are playing exciting games of baseball. The Republicans and the Democrats of Frankford have each organized a baseball team and since the organization occurred last year the one team is called the "Roosevelt" and the other the "Parker." The proceeds of the game will be given to the Frankford Hospital, consequently there was a large attendance. The proceeds are said to amount to several hundred dollars.

Bequests.—The will of Emma C. Harris, in disposing of an estate valued at $150,000, provides that it be held in trust for her two daughters and her grandchildren; but should the grandchildren die and not leave heirs the following institutions will be recipients: Episcopal Hospital, $25,000; the Home for Crippled Children, $5,000; the Home for Colored Crippled Children, $1,000; the Woman's Hospital, $2,000; the Philadelphia Protestant Episcopal Mission for two homes for consumptive men and women, each $25,000; the St. Christopher's Hospital for Children, $1,000; the Philadelphia Society for Organizing Charity, $2,000; the Franklin Reformatory Home, $2,000.

CHICAGO.

Report of Visiting Nurses' Association.—During the last month this association has cared for 853 patients and made 3,717 visits, besides caring daily for fifteen sick babies at the Fresh Air Station at Augusta and Noble streets.

Impure Milk in Illinois.—Milk conditions in Illinois towns outside of Chicago are causing a flood of complaints in the office of the Pure Food Commission. Because of the cramped facilites of the smaller cities they cannot exercise such close supervision as is possible in Chicago, and the milk now sold in some places is denounced as "rank poison." Formaldehyde is being used freely by country milk dealers, according to complainants.

GENERAL.

Diphtheria Epidemic at Port Republic.—The prevalence of diphtheria at Port Republic, N. J., has caused several of the surrounding towns to establish quarantine regulations. The disease became epidemic two weeks ago. Last week a camp meeting started in the town grove, but the health authorities feared it would help to spread the contagion and ordered it stopped.

Tropical Disease Experts Coming.—Among the passengers on board the Cunard Line steamship Campania, which sailed for New York last Saturday, were Major-Surgeon Ronald Ross and Dr. Rubert Boyce, professors in the Liverpool School of Tropical Medicine. Professors Ross and Boyce are going to New Orleans to assist the authorities there in dealing with the yellow fever outbreak.

Marine Hospital Physician Takes the Fever.—Dr. D. T. D. Berry, of the United States Marine Hospital Corps, in charge of the yellow fever work at New Orleans, was taken down last Friday with yellow fever. He has worked in the yellow fever epidemics in Cuba and was supposed to be an immune. He had charge of the inspection service in the Italian district. Dr. Berry was appointed from Virginia.

Typhoid in Washington.—The typhoid fever situation in Washington is growing worse. Since July 1 200 cases have been reported, of which 240 are now under treatment. A year ago to-day only seven cases were reported, making a total of 193 cases from the preceding July 1. A hopeful feature of the situation is that the new filtration plant is being put into operation. Water was started through two of the filter beds last week, and other beds will be put in commission as rapidly as finished.

Cumberland Valley Medical Association.—The third annual meeting of the Cumberland Valley Medical Association will be held at Holly Inn, Mount Holly Springs, Pa., Tuesday, August 29, 1905. The following program has been arranged: Address of welcome by James Evelyn Pilcher, M.D., of Carlisle, Pa.; address of President by V. Milton Reichard, M.D., of Fairplay, Md.; "A Case of Diaphragmatic Hernia of Twenty-one Years' Standing," by J. Bruce McCreary, M.D., of Shippensburg, Pa.; "Medical Lessons of the Far East," by James Evelyn Pilcher, M.D., of Carlisle, Pa.; "Our Relations to the World at Large," by Chas. F. Palmer, M.D., of Chambersburg, Pa., and a paper, subject to be selected, by Augustus C. Maisch, M.D., of Hagerstown, Md.

Big New Lake for New Jersey.—Next to the Great Meadows that lie between the Passaic and Hackensack Rivers in Hudson and Essex counties, the most prolific mosquito breeding grounds are the Great Piece Meadows, Hatfield Swamp, and the Troy, Whippany and Melapards Meadows that stretch along the Passaic River from Little Falls, in Passaic County, almost up to the city limits of Morristown. It is proposed to drown out the mosquitoes of this vast expanse of marshland by covering it with water and making another lake for New Jersey that will rival Hopatcong, in size and natural beauty. Petitions signed by all the rich residents of the two counties urge the State to supply the water. A lake covering the meadows and marshes named would be fifteen miles long and six or seven miles wide. The surrounding country is the most picturesque in the State, and the petitioners say that the lake would soon be fringed with beautiful new settlements that will add many millions to the material wealth of the State.

National Standard Dispensatory.—A new edition of this standard work will be ready September 1, the date when the United States Pharmacopœia goes into effect. By authority of the Convention it will contain every article in the new U. S. P., as well as the explanations and instructions necessary to understand and apply the brief statements to which the official guide is restricted. The National Standard Dispensatory is a new work, a distinct improvement upon anything of the kind hitherto published. Its authors, Dr. H. A. Hare, of Philadelphia; Prof. Charles Caspari, Jr., of Baltimore, and Prof. H. H. Rusby, of New York, are all men of the highest eminence in their respective fields, and are all members of the Revision Committee of the U. S. P. They have carefully matured its plan so as to render the maximum service to both professions it interests, namely, Pharmacy and Medicine. It not only covers the new U. S. P. as aforesaid (and the chief foreign pharmacopœias as well), but the scarcely less important domain of the unofficial drugs and preparations so largely used. It offers full information regarding the pharmacognosy, the pharmacy, and the medical action and uses of all substances used in Pharmacy and Medicine at the present day. Pharmaceutical methods and products are covered, with descriptions of the most improved apparatus and tests.

Medical Society of the Missouri Valley.—The eighteenth annual meeting of this association will be held in Council Bluffs, Iowa, on Thursday and Friday, August 24 and 25, under the presidency of Dr. S. Grover Burnett, of Kansas City. The Grand Hotel has been selected as headquarters, while the sessions will be held in the auditorium at Lake Manawa, a beautiful resort near the city. This will afford a cool and comfortable place to enjoy the scientific program, which will be much appreciated. The evenings will be devoted to the various forms of amusement found at this park. Following is a list of the papers already promised: Discussion on Diabetes, led by Dr. LeRoy Crummer, of Omaha; Discussion on Pulmonary Tuberculosis, led by Dr. J. W. Kime, Fort Dodge, Iowa; Carelessness in the Use of the Curette, Herman E. Pearse, Kansas City, Mo.; Treatment of Patients after Intra-Abdominal Operations, Daniel Morton, St. Joseph; Practical Facts About Hernia, L. A. Todd, St. Joseph; Four Cases of Essential Anemia and Their Differentiation, W. O. Bridges, Omaha; Some Observations on Carcinoma of the Large Intestine, A. P. Condon, Omaha; Clinical Importance of the Diplobacillus of Morax-Oxenfeld, Harold Gifford, Omaha; The Prevention of Deformity, J. P. Lord, Omaha; Bodily Weight as a Factor in Prognosis in Nervous and Mental Disease, Frank Parsons Norbury, Jacksonville, Ill.; Some Non-Septic Causes of Fever after Labor, Mary Strong, Omaha; The Pharmacology of Antipyretics, A. L. Muirhead, Omaha; Ectopic Gestation, with Report of Cases, O. Beverly Campbell, St. Joseph; Paper, W. O. Henry, Omaha. A cordial invitation is extended to the profession.

Mosquitoes in London.—A plague of mosquitoes, says the *London Mail*, is widespread in London. A few years ago they were almost unknown, or made their appearance fitfully in the neighborhood of the docks and Fleet street, coming, it was supposed, among the rolls of paper. This summer they are being found all over the metropolis, and in many places have given considerable work to the medical practitioners and the hospitals. They are extremely plentiful along the line of docks. The lower part of the Thames valley seems full of them, and a suggestion is made that those brought from abroad on ships have found a congenial breeding place in the low-lying, marshy ground on the Essex shore. At the Poplar Hospital, recently, it was stated that they had many cases there every day, men, women, and children being alike victims. There have been for years past many patients treated at this hospital for mosquito bites, but this summer they are more numerous than ever. The dry, hot weather has favored the insects, or made them, so to speak, strong on the wing. They are now wandering far from their breeding places, and not a suburb is free from them. The West End has suffered but little from the plague, but they have made their appearance in force in the western, southern and northern suburbs. They are especially abundant in the neighborhood of Muswell Hill, where hundreds of cases are treated by the local doctors daily. Alexandra Park, Hornsey, Wood Green, and Bowes Park swarm with them. Their clear, ringing buzz, unlike that of any other insect, is heard nightly, and hundreds of people are suffering seriously from their punctures.

The Boston Day Camp for Consumptives.—An open air day camp for consumptives, said to be the first of its kind in America, and similar to those in Berlin, has been opened by the Boston Association for the Relief and Control of Tuberculosis. One of its marked features is its availability, for the camp is within two miles of the State House—located near the reservoir on the top of Parker Hill, Roxbury, the highest point of land in Boston. Except in the case of the indigent, a small fee is required from those who receive the benefits of the camp. Only early cases, where there is hope of cure or decided improvement, are taken. The camp consists of several tents in an apple orchard on the old Brown estate adjoining the reservoir property. Last week there were thirty-six patients present with the chances that another week would see the tents used to their full capacity (fifty). The patients coming in the morning are met at Roxbury by a conveyance which takes them up the hill to their destination. It is as a day camp that the undertaking is a pioneer in this country. The treatment consists of good, wholesome food, rest and continuous outdoor life. Each patient on arriving is given a luncheon of eggs, milk and bread. The mid-day meal consists of meat, vegetables, bread, butter, milk, and dessert. Another luncheon is given late in the afternoon. Games and newspapers and books are provided, the women bringing their sewing, and a large recreation tent is there for stormy weather. Lectures are to be given at intervals by leading physicians of Boston—lectures that will tell them how to properly ventilate bedrooms, how to eat and how to avoid communicating the disease to others. Dr. David Townsend, of Brookline, and Dr. Gardner W. Hall, of Boston, visit the camp daily, together with General Secretary Alexander M. Wilson, of the association. Dr. Edward O. Otis, Dr. Frederick I. Knight and Dr. Herbert C. Clapp, the association's consulting physicians, have had much to do with originating the camp.

Yellow Fever Infection Sources.—The epidemic of yellow fever at New Orleans, writes the *Evening Post*, has served to draw attention to sanitary conditions in Central and South American countries from which the disease might have been brought. In North America, outside the United States, yellow

fever has been reported at four places in Mexico, three places in Honduras, at Belize, British Honduras; at Guatemala, and at Panama, Colon, La Boca, Corozal, Empire, and Paraiso, on the Isthmus of Panama. San Pedro, Honduras, is the only one of these places in which an extensive prevalence is recorded. South American reports received since July 1 show the continued presence of the disease in Venezuela, Ecuador, and Brazil, the latest reports indicating 85 cases, with 11 deaths between May 27 and June 11, at Rio de Janeiro. July reports from outside the Western Hemisphere do not indicate the presence of yellow fever elsewhere than in Senegal, Africa, and Santa Cruz de Teneriffe. The general health report from the Isthmus of Panama, however, is not very encouraging. The Marine Hospital surgeon stationed there reports, under the dates of July 18 and 22, as follows: "Week ended July 17, 1905: In the two municipalities of Colon and Cristobal, which together have an officially estimated population of 9,932, the mortality has been very high for the first half of July. From July 1 to 13, inclusive, there has been officially reported 38 cases from the following causes: "Fever 3, pernicious fever 3, malaria 5, yellow fever 1, dysentery 2, diarrhea 4, tuberculosis 1, tetanus 2, beriberi 2, pneumonia 2, pleuritis 1, pulmonary inflammation 1, epilepsy 1, nephritis dropsy 1, athrepsia 1, yaws 1, unknown 4. Classified according to nationality, as follows: Native 14, Jamaica 13, United States 3, France 3, Spain 2, England 1, Canada 1. These figures would show an annual death rate of over 90 per thousand. These statistics are compiled by the health officer from the reports of deaths made to the alcalde of Colon, and they show the same lack of care and display the same ignorance which characterized such statistics in former years. Comparison of the reports with the records of the Colon Hospital show that of the total deaths, 16 occurred in the hospital. The certificate of death is furnished the authorities by the hospital, but the occasional change or difference in the diagnosis cannot be explained. Malarial fevers have been very prevalent, and every section of the town, in fact, every house, swarms with *Anopheles*. The hospital records show an increase from 33 per cent. of all admissions in May to 50 per cent. in June. This does not include the out-patient department. It often occurs that patients, after an attack of yellow fever, return to the hospital with a severe malarial infection."

How the Pharmacopœia is Published.—Prior to the 1890 edition, the Committee on Revision of the U. S. P. sought a publisher as would an individual author of a new book. The Convention of 1890 made a new departure and instructed the Committee on Revision to secure the copyright for the revised Pharmacopœia. A contract was made with one firm to print the book and with another to act as selling agent. The Committee on Revision realized a good profit, which was used in covering the expenses of the work of revision and paying the members a small honorarium. The convention of 1900 inaugurated a new plan by adopting a constitution and by-laws and taking steps which resulted in securing papers of incorporation for the United States Pharmacopœial Convention. The constitution provides for a Board of Trustees of five (with the President of the Convention and Chairman of the Committee on Revision as *ex officio* members) in addition to the usual Committee on Revision. To the Board of Trustees is intrusted the transaction of all business, including the publication of the manuscript prepared by the Committee on Revision. The work has now reached that point where some idea can be given of the magnitude of the undertaking. The printing began in June, 1904, and progressed steadily until June 17, 1905. At that time, an imperfect sample copy was printed in order to obtain measurements for the size of cloth and leather sheets to be used in binding. The first complete unbound copy was furnished June 24. Then followed cloth-bound copies. The first edition consisted of 10,000 copies. This was printed in two runs, the first of 2,000 copies and the second, two weeks later, of 8,000 copies. This division of the edition was made in order that the Chairman of the Committee on Revision could be notified of typographical and other errors discovered in the 2,000 copies and have the corrections made in the plates before the 8,000 copies were printed. The Chairman states that no serious errors were discovered, but, of course, it was desirable to correct typographical errors, even as small as the omission of a bracket or an apostrophe. The second edition of 5,000 was ordered bound, July 21. A third edition has been printed and will be bound as soon as the distributing agent can give an idea of the styles of binding desired. Of course, corrections have been made in the plates for each edition as fast as errors were pointed out to the Chairman of the Committee. The different editions are designated by the serial letter on the printed conpon in the front of the book. "A" designates the first edition of 10,000, "B" the second edition of 5,000, "C" the third edition of 5,000. The fourth edition will bear the letter "D." It is estimated on good authority that at least 20,000 copies will be sold before January 1, 1906. The Board of Trustees will use the profit on these volumes in paying the expenses already incurred and, as soon as possible, send the members of the Committee on Revision checks for the honorarium voted by the Board of Trustees at the annual meeting in May and announced in the report of that meeting. Errors in the Pharmacopœia should be reported without delay to Professor Joseph P. Remington, No. 1832 Pine Street, Philadelphia, Pa., so that corrections can be made in the plates before another edition is printed. Criticisms and suggestions for the next revision should also be mailed direct to Professor Remington. Requests for permission to use portions of the text of the Pharmacopœia in commentaries, works of reference, text-books and other similar publications should be made direct to the Chairman of the Board of Trustees, Charles E. Dohme, Baltimore, Md. Neither the Board of Trustees nor the Committee on Revision members have anything to do in their official capacity with the National Formulary. This work is published and revised by the American Pharmaceutical Association, of which Charles Caspari, Jr., Department of Pharmacy, University of Maryland, Baltimore, Md., is the General Secretary. The Convention to arrange for the ninth decennial revision of the Pharmacopœia will be called by the President, Dr. Horatio G. Wood, for May, 1910.

OBITUARY.

Dr. Seth D. Boggs, a well-known physician of the Bedford District, Brooklyn, N. Y., died suddenly last week. He was fifty-three years old and was born in Brooklyn. Dr. Boggs was a graduate of the College of Physicians and Surgeons.

Dr. CLARKSON CROSBY SCHUYLER died at Plattsburg, N. Y., last Wednesday, aged fifty-five years. He was born in Troy, and was surgeon of the Troy Hospital for fourteen years. He was one of the best known physicians in Northern New York. He was appointed State Forest Commissioner in 1893 by Governor Flower, serving two years. He was a member of many medical and other associations.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, held at San Francisco, Cal., July 5, 6 and 7, 1905.

(Continued from Page 322.)

A Summary of all the Cases of Fracture of the Spine (244) Which Were Treated at the Boston City Hospital from 1864 to 1905.—Dr. H. L. Burrell, of Boston, contributed a paper on this subject, in which the author presented the following conclusions: (1) "That fractures of the spine may well be divided into two classes; *first,* fractures of the spine with injury to the cord; and, *second,* fractures of the spine without injury to the cord. (2) That it is not best to decide what the treatment of an individual case of fracture of the spine should be from the statistics, because the lesion varies so widely. (3) That in many cases of fracture of the spine it is impossible to state primarily whether the cord is crushed or pressed upon by bone, blood, or exudate, except by an open operation. (4) That only by the persistence of total loss of reflexes, complete insensibility to touch and pain, and motor paralysis below the level of the lesion can total transverse destruction of the cord be diagnosed. (5) That if pressure on the cord is allowed to remain for many hours, irreparable damage to the cord may take place. (6) That unless it is perfectly clear that the cord is irremediably damaged, an open operation to establish the condition of the cord and to relieve pressure is imperative as soon as surgical shock has been recovered from. (7) That in certain cases of fracture of the spine, when the cord is not injured, but is liable to injury from displacement of the fragments of a vertebra, rectification of the deformity and fixation of the spine may be used. (8) That if the cord is crushed, no matter what treatment is adopted, there will of necessity be a high rate of mortality.

Suture of the Spinal Cord Following a Gunshot Injury Involving Complete Severance of the Structure.—Dr. George Ryerson Fowler, of Brooklyn, N. Y., reported the case of A. E., aged eighteen years, clerk, born in America, single. The patient was admitted to the Brooklyn Hospital on April 28, 1903. He gave the following history: He suffered from pneumonia several years ago. Four years ago, while working at a machine, his left hand was caught in the latter, and so badly crushed that it became necessary to amputate four fingers. He had gonorrhea six months ago; no discharge at the present time. Shortly before admission he was shot in the back, his assailant using a 38-caliber revolver, at a distance of about thirty feet; the shooting took place somewhat from the right side. He suffered severely from shock, and paralysis of the lower extremities occurred at once. The bullet wound was located one and a quarter inches to the right of the median line and on a level between the tenth and eleventh dorsal spines. He was found to be paralyzed below the waist; sensation was absent over all of both lower extremities, and over the abdomen as high as one inch above the crests of the ilia on the sides, and about halfway between the symphysis and the umbilicus in front. Bladder and rectum were also paralyzed. The bowels moved involuntarily and irregularly, and without the volition or cognizance of the patient. There was considerable twitching of the muscles of both legs, especially the toes. Operation, May 9, 1903. Ether anesthesia. An incision was made, six inches long, over the spines of the vertebræ, the middle of the incision resting upon the eleventh dorsal spine. The laminæ of the tenth, eleventh and twelfth vertebræ were removed by the chisel. The bullet was found lying transversely between the severed ends of the cords, concealed from view by a large blood clot. A very narrow, ragged, and contused strip of dura, scarcely more than one-sixteenth of an inch in width, remained intact. The blood clot was carefully sponged away and the bullet removed. The ends of the cord were then sutured with three fine chromicized catgut sutures, the dura being included in the sutures. No special difficulty was experienced in drawing together the ends of the cord and closing the defect, the latter representing in width the diameter of the 38-caliber bullet. The dura was further secured with a number of sutures of fine catgut, and a drain consisting of a half dozen narrow strips of oiled silk protective introduced. The skin incision was sutured with silkworm gut. On May 30 the following note appeared on the hospital record: "Wound healed, upper line of anesthetic area from one and a half to three inches lower than before operation. Twitching of toes of both feet and occasional clonic muscular spasms of the flexors and extensors of the thighs; the patient says his 'feet jump on him.' Can feel when the bowels move, but is without control of the rectum. Can feel distention of the bladder with urine, but is without control." The main points of interest in this case related to the possibility of regeneration of the spinal cord following a destructive lesion. Prior to the report of Dr. F. F. Stewart's case, in which Dr. R. H. Harte sutured the cord after it was severed by a bullet, it was the opinion of the majority of investigators that such regeneration in man was impossible. Mikulicz, of Breslau, endeavored to demonstrate the possibility of a successful regenerative process in the lower animals following section of the cord, but without result. Spiller and Frazier found that after division of a posterior root in the dog, followed by immediate suture, regeneration occurred, and that regeneration into the cord did not occur. In Dr. Fowler's case, twenty-six months after the injury, voluntary motion was practically lost in the affected area. The patient was able to stand when supporting himself by the hands resting upon an apparatus, and to make some locomotion by swinging movements in a special frame on wheels. The bladder and rectum control was doubtful, to say the least, the former acting automatically. The patient had the sensation that the bladder and rectum were about to empty themselves, and if the urinal or bedpan were brought to him promptly soiling was prevented. The amount of urine passed in this manner probably averaged more than a pint in the twenty-four hours. The urine was sometimes voided during sleep. Sensation was practically abolished in the entire affected region, with the exception of an area about five inches in length extending down the outer side of the right thigh, where some sensation was present. He was not able to correctly distinguish between heat and cold. Tactile sensations were recognized, but were usually referred to a point two or three inches distant from the point

touched. Marked rigidity and spasticity of both legs rere present. Patellar reflex exaggerated; Achillis reflex marked. Ankle clonus present on one side and absent on the other. The reaction of degeneration was absent. Bed sores developed in the third month; these extended to the muscles and were six months in healing. The skin showed but slight, if any, evidences of trophic disturbance. A final and important comment was suggested in comparing this case with the Stewart-Harte case, namely: The Stewart-Harte case was operated on three hours after the injury, while in Dr. Fowler's case upward of ten days had elapsed before consent to interfere operatively was obtained. The prolonged separation of the divided ends of the cord and the presence of the foreign body had, in all probability, an influence in preventing a complete regeneration of the cord, as occurred in the first case, provided, of course, that regeneration did actually occur. While the case in hand was, therefore, not as striking in many of its features as the Stewart-Harte case, the author thought it presented some points of interest, and for this reason was offered as a contribution to the literature of the subject.

The Surgical Treatment of Intraspinal Tumors.—Dr. Richard H. Harte, of Philadelphia, said that the science of spinal localization was now so well developed that it usually was not difficult to determine with accuracy the location of an intraspinal growth. What was usually understood by the term tumor of the spinal cord was an extramedullary but intraspinal growth like a sarcoma, a fibroma, or a myxoma, giving no evidence of its existence except by the symptoms of medullary pressure which it produced. There had been found records of 92 operations for spinal tumors, among which number 43 patients died, a total mortality of nearly 47 per cent. The nature of the tumor was recorded in 88 of the reported cases. It was sarcomatous in two-fifths of the whole number (37 cases); adhesions, thickenings, etc., hold second place, with 11 cases; then came echinococcus, 8 cases; fibroma, 6 cases; syringomyelia, 5 cases; endothelioma, 4 cases; psammoma, 3 cases; cyst, 3 cases; fibromyxoma, 2 cases; osteoma, 2 cases; and one each of myeloma, lipoma, lymphangioma, dermoid cyst, primary and secondary carcinoma, and one tumor of bone whose nature was not stated. The author reported an interesting case of paraplegia from Pott's disease in which he resorted to laminectomy, with great improvement. With very few exceptions, he said, it was impossible to determine the nature of the tumor before operation. He reported a case of dermoid cyst of the spinal canal on which he operated, followed by recovery, the patient being a girl, seven years of age. Of 82 cases in which the region of the spine affected was given, the upper dorsal region was involved in 33 cases, or over 40 per cent. The tumor was found in the lower dorsal region in 24 cases, in the lumbosacral region in 14, and in the cervical region in 11 cases. the cause of death was given in 28 cases. One-half of these were due to shock and hemorrhage, or to infection and meningitis, there being seven fatal cases under each of these categories. Eight patients died from exhaustion, three from recurrence of malignant growths, two from hypostatic pneumonia, and one from bed sores and sepsis.

As regards the technic of the operation, it was the same as when employed in traumatic cases.

Tuberculous Conditions of the Spine Requiring Surgical and Mechanical Relief.—Dr. De Forest Willard, of Philadelphia, stated that the principal surgical measures employed for the relief of spinal caries were laminectomy for paraplegia; forcible immediate straightening of the kyphosis; forcible gradual straightening; erosion of carious bone; wiring of spinal processes; evacuation of pus accummulations; long continued fixation of the column; and hygienic measures to prevent the necessity for operative interference.

Complete, methodical and long-continued fixation of the spine in the position of hyperextension, with healthful surroundings in the sunlight, were the prime factors in securing new ossific deposit necessary to replace the carious bone. Laminectomy for paraplegia was advisable only after long continued and patient treatment along the above-named lines from one to two years, since the prognosis, especially in children, under these conditions was favorable, and good powers of locomotion might be confidently expected. The operation was justifiable in selected cases where loss of motion and sensation were progressively worse and the symptoms threatened life. If the tuberculous masses within the spine could be removed, and if extradural pachymeningitic deposits or pus could be taken away, improvement might be expected, and in many cases relief occurred. The operation had a mortality of about 25 per cent. from immediate shock; 36 per cent. within a month, while one-half the cases died within the next year, their lives being probably shortened by the operative procedures; cases of non-improvement and death equaled nearly 65 per cent. Forcible immediate straightening of the kyphosis was an unsurgical and dangerous proceeding; it was liable to re-awaken the tuberculous disease and to weaken the column. Forcible gradual straightening by supporting the kyphotic area upon a pedestal was a valuable agent in relieving deformity. The weight of the shoulders and pelvis could thus be utilized as straightening forces, and the weight of the column thrown upon the posterior arches. In this position it was permanently fixed by plaster-of-Paris. Complete erosion of the carious bodies of the vertebræ was an uncertain operation, in the dorsal region requiring section of ribs, with danger of wounding the pleura. Wiring of the spinous processes had never been sufficiently tried to demonstrate its helpfulness. Spinal abscesses which contained only liquefaction of caseation should be aspirated. When true pus formed, thorough aseptic drainage was advisable.

Tumors of the Spinal Cord.—Dr. J. Collins Warren, of Boston, read a paper on this subject in which he reported three cases of tumor of the spinal cord operated on with good results.

Spina Bifida.—Dr. James E. Moore, of Minneapolis, Minn., read a paper on this subject in which he presented an analysis of 385 cases treated by excision. A careful study of these reported cases, illustrating the experience of many surgeons, justified him in drawing the following conclusions: "(1) Operation upon children of very tender age is scarcely worth while because it is accompanied by so large a mortality rate, and because it does not stop the progress of progressing cases. (2) Patients five or more years old can be operated upon safely. (3) Patients with large or rapidly growing tumors, with hydrocephalus and with paralysis or deformities of the extremities are not cured. Finally all we can hope to accomplish by operation for spina bifida is to relieve the patient of an unsightly and annoying tumor after he has survived the dangers of the affliction *per se*."

Exophthalmic Goiter Treated Surgically.—Dr. Thomas W. Huntington, of San Francisco, Cal., said that during the past three years he had treated surgically nine patients suffering from exophthalmic goiter. In each instance partial ablation of one or both lobes of the thyroid was done, and one patient was subjected to three operations successively. Seven were females, and two were males. The ages ranged from twenty-eight to fifty-six years the average age being forty-two years. In five patients the development of symptoms of Graves' disease was associated with pre-existing enlargement of the thyroid. Two of these were cystico-colloid. In four the development of characteristic symptoms was simultaneous with glandular hypertrophy. All of these were colloid. In the five cases where the exophthalmic condition developed secondarily, pre-existing glandular hypertrophy was noted during a period of six, ten, thirty-four, thirty-five and thirteen years respectively. In this series exophthalmic symptoms had been noted one, two, three, two, and two years prior to operation, the average being one and four-fifths years. Duration of symptoms in the primary or pure Basedow cases prior to operation was two years, three months, two months and one year, the average being seven and one-quarter months. In this series eight patients survived the operation and were now living. One patient died on the twelfth day. The eight living patients were carefully watched and their status definitely recorded up-to-date. The author gave a detailed account of each case as it occurred. A wider experience in this particular field had increased his faith in the value of surgical interference in carefully selected cases, and in conclusion he repeated what he wrote in an earlier communication, namely, the argument for early operation in malignant disease applied here with equal force. Extirpation should be undertaken before destructive changes had occurred, before the function of important organs was seriously, perhaps permanently, injured, and the patient's vitality lowered by chronic thyroid intoxication.

A Review of Five Hundred Cases of Gastro-Enterostomy, Including Pyloroplasty, Gastro-Duodenostomy and Gastro-Jejunostomy.—Dr. William J. Mayo, of Rochester, Minn., stated that this included all the cases operated on by Dr. Chas. H. Mayo and the writer during fourteen years in which an incision was made in both intestine and stomach, and plastic union established to increase gastric drainage. The death-rate gave every case dying in the hospital without regard to the cause of death or the length of time after operation. Of pyloroplasty there were twenty-one cases with no deaths, and seven re-operations. Pyloroplasty had only a small field of usefulness. Finney's gastro-duodenostomy, 58 cases, four deaths, two from other causes at a late date; only one death in the first forty-six. The author stated that there was a large field of usefulness for this operation in narrow stricture following healing of ulcers, but it was less useful in unhealed ulcers. Of gastro-jejunostomy there were four hundred and twenty-one cases; benign, 307; death-rate, 6 per cent. Last 140 cases, four deaths. Malignant, 114; death-rate, 18 per cent. In the last 40, including radical operations for cure of cancer, 5 per cent. Murphy button, 157 operations, 139 anterior, and 18 posterior. This was the operation of choice after pylorectomy and partial gastrectomy. McGraw ligature, 36 operations. This was the operation of choice by the anterior method in gastro-jejunostomy for inoperable cancerous pyloric obstruction. Two hundred and twenty-eight posterior suture operations. Robson's bone bobbin, 16 operations, with one death. Mikulicz operation, transverse incision, 43 operations, with four deaths and four secondary operations. Moynihan operation on 9 inch loop, 53 operations, with three deaths; 7 re-operated for chronic bile regurgitation within fifteen months. Roux-Doyen operation, 48 cases, two deaths, two secondary operations. Operation of choice was the Moynihan-Peterson without a loop; made by suture within 3 inches of the origin of the jejunum and obliquely on the posterior wall of the stomach with the inferior margin at the greater curvature near the junction of the pyloric end with the body of the stomach. Last 80 gastro-jejunostomies for benign disease, only one death.

A Simple Aseptic Surgical Technic.—Dr. Dudley P. Allen, of Cleveland, Ohio, related observations which were based upon a series of 377 bacteriological examinations of the hands, made at the close of operation, and upon the clinical results obtained in 3,500 cases. The bacteriological investigations were conducted in five series. In series "A" the cleansing of the hands was with soap and water, scrub brush and nail cleaner. The hands were then sterilized in Harrington's solution. In operating the hands were encased in rubber gloves in which was sterile water. Twenty-six observations were made by taking cultures from the hands at the close of operation. In each case the cultures were negative. In series "B" the washing of the hands was as in series "A." Twenty-four observations showed that cultures were negative in each case. In series "C" the washing was as in series "A" with the addition of thorough subsequent washing in 70 per cent. alcohol. In 42 observations the *Staphylococcus pyogenes albus* was found in eight cases, or in about 20 per cent. The conclusion reached was that alcohol was not efficient as a disinfectant and did not prevent the development of bacteria within the rubber gloves containing no germicide but simply sterile water. From these observations it would seem probable that if bacteria developed upon the hands sterilized by alcohol, when in gloves containing simply sterile water, they would develop in the same manner upon the hands prepared in the same way if encased in dry gloves with powder as the hands became moist with perspiration. In series "D" the hands were prepared as in series "C" and then washed in a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. Sixty-four observations were made. All were negative except one. In this were found the *Staphylococcus pyogenes albus*.

In series "E" the hands were washed as in series "A" and then thoroughly washed with a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. One hundred and two observations were made. The Hay bacillus was found in one case.

In series "F" the hands were washed as in series "D" and then cleansed in a solution of bichloride of mercury, 1-3,000, and encased in gloves containing the same solution. Seventy-five observations were made. The *Staphylococcus pyogenes albus* was found in a single case.

The clinical observations were made upon a series of 967 laparotomies. Of these 687 were clean and 288 were septic before operation. There were 2,533 operations other than laparotomies. This gave a

total of 2,139 clean operations. For the purpose of study the clean cases only were taken, since the question of asepsis evidently could not be studied in cases septic before operation.

Tables were presented by the author showing the results obtained in all of the various series of operations as in hernia, varicocele, varicose veins, and laparotomies of all kinds and other miscellaneous operations. The results showed from the whole series of 2,139 clean operations but two deaths from sepsis. Erysipelas developed but once. Stitch abscess occurred in 58 cases, or in about 2.25 per cent.

The method of cleansing the hands finally adopted was to wash them thoroughly with soap and water, using the scrub brush for the palms of the hands, but slightly upon the backs of the hands and never upon the arms, the object being to avoid irritation of the integument. The nail cleaner was used only beneath the nails and not around the bases of the nails. The hands and arms were then washed in a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. The belief of the writer was that the continued action of the solution of bichloride of mercury in the gloves was a fundamental safeguard in preventing the development of bacteria within the gloves during operation. That this was true in practice was shown by the results obtained in the large number of cultures taken at the close of operation.

The conclusions reached from the various series of cultures and clinical cases were, first, that Harrington's solution, although efficient, was undesirable, since it caused marked irritation of the hands and arms. Second, that washing of the hands and arms should not be too violent, and that the use of the scrub brush should be confined to the hands. The arms should be washed by rubbing with gauze or a towel. The use of the nail cleaner about the base of the nails was unnecessary. Alcohol was not adequate as a germicide when used upon the hands. That a solution of 1-5,000 bichloride of mercury, used after washing to disinfect the hands and arms, and then used in the rubber gloves, was thoroughly satisfactory in protecting against the development of bacteria within the gloves during operation. That the rubber glove was a guarantee of safety, not only to the patient but to the operator himself, when operating upon infected wounds. That a mask over the face was not necessary.

Intussusception.—Dr. Maurice H. Richardson, of Boston, Mass., reported a case of intussusception in a boy aged four years. Vomiting and pain, with intestinal obstruction and a tumor in the left abdomen, suggested very strongly the diagnosis. The operation showed an invagination of the small into the large intestine, so firm that reduction seemed impossible. The child's condition was so bad that an enterostomy was performed, in the hope that a cure would be effected by spontaneous sloughing of the invaginated gut, life meanwhile being maintained through the enterostomy. Unfortunately, the child died at the end of eighteen days; the immediate cause of death being a purulent bronchitis. At the autopsy, no trace of the intussusception could be found. A careful search through the literature showed no case of spontaneous reduction of an intussusception in which the chain of evidence was absolutely complete. In this case, the diagnosis made before operation, and demonstrated before the staff of the Massachusetts General Hospital and a large audience, was unassailable. The lesson taught by this case would seem to be that greater efforts should be made for reduction, either by hydraulic or air pressure through the rectum or by manipulations after the abdomen had been opened. In the reader's experience, however, the results have been fatally compromised by just such efforts. It seemed, therfore, questionable whether in view of the great rarity of spontaneous reduction and of the almost universal failure of the milder palliative measures, one will ever be justified in selecting any but those operative measures which, undertaken at the earliest possible moment, cannot fail to remedy completely and effectively the disease.

Constriction of the Duodenum Below the Entrance of the Common Duct and Its Relation to Disease.—Dr. A. J. Ochsner, of Chicago, read a paper with this title. In a series of cases operated for the relief of cholecystitis it was found that there was frequently present a constricted condition of the duodenum just below the entrance of the common duct. This was usually accomplished with dilatation of the duodenum above this point.

The dissection of a number of cadavers demonstrated the fact that there was present a marked increase in the circular muscular fibers of the duodenum beginning at a point from one to three cm. below the entrance of the common duct and extending for a distance of one to four cm., forming a broad sphincter. It seemed likely that this sphincter had much to do with the physiological function of the duodenum, facilitating the mixing of chyme with bile. It also seemed likely that this sphincter served the purpose of establishing a condition of rest in this portion of the alimentary canal in case of irritation of the biliary or pancreatic ducts. The paper was fully illustrated and the author gave a tabulated list of fourteen cases of dilatation of the duodenum which he had met with among his patients operated for the relief of gall-bladder disease.

Perforation of the Gall-Bladder.—Dr. Archibald MacLaren, of St. Paul, Minn., read a paper on this subject in which he reported ten cases, and said that gall-bladder perforations were comparatively rare, especially if observations were confined to ruptures due to violence, ulceration and gangrenous inflammations. But if we added to these the cases of cholecystitis, in which inflammatory products had evidently escaped from, or passed through, the wall of an inflamed gall-bladder, even though we may not find the perforation itself, the number of cases was considerably increased. Such abscesses about the gall-bladder either in the free peritoneal cavity or in the neighboring liver tissues were rare as compared with appendical abscesses; but were not uncommon and unquestionably should be included when studying perforations of the gall-bladder. Fistulous passages between the gall-bladder and duodenum, stomach or colon were, of course, due to perforation of the gall-bladder. Most perforations of the gall-bladder occurred in neglected cases where gall-stones had been known to exist for long periods of time and where the patient had had ample warning through many attacks of biliary colic. Of Robson's 539 operations on the gall-bladder and bile ducts, 25 of these cases could be fairly said to be perforative in character. Dr. Mayo in 328 cases found 16 perforative cases. Dr. Ochsner in 48 cases operated upon found one perforation. He had operated upon 80 gall-stone cases, 9 of which were perforative in character and one post mortem, making a total of 10, which seemed a large proportion

as compared with other lists of cases already on record. There were eight recoveries and one death. In this fatal case he believed that the result would have been the same even though the gall-bladder had been removed because with gangrene of the gall-bladder and neighboring liver tissue, and especially in the presence of a localized abscess, any operative work which disturbed the abscess wall would only have spread the infection and lessened the chance of recovery. He believed that in any perforation case which had gone on to the formation of a localized abscess, the wisest course was to open and drain the abscess, waiting until a later time to deal with the gall-stones or the disease of the gall-bladder.

Dr. Emmet Rixford, of San Francisco, read a paper in which he discussed the subject of excision of portions of the chest wall for malignant tumors and reported cases upon which he had operated.

Officers.—The following officers were elected for the ensuing year: President, Dr. Albert Vander Veer, of Albany, N. Y.; Vice-Presidents, Dr. James E. Moore, of Minneapolis, and Dr. John C. Munro, of Boston; Secretary, Dr. Dudley P. Allen, of Cleveland, Ohio, re-elected; Treasurer, Dr. Geo. R. Fowler, of Brooklyn, N. Y., re-elected; Recorder, Dr. Richard H. Harte, of Philadelphia, Pa. Cleveland, Ohio, was selected as the place for holding the next annual meeting, the time for which is to be fixed by the Committee on Annual Meeting.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-sixth Annual Meeting, held at Portland, Oregon, July 11, 12, 13 and 14, 1905.

(Continued from Page 324.)

SECTION ON STOMATOLOGY.

First Day—July 11th.

Chairman's Address.—After transacting the regular business, the Chairman delivered the annual address. She said the oral cavity bears an important relationship to medicine and surgery. Many pathological conditions of the mouth are due to constitutional causes, and many constitutional disturbances are directly due to neglect of the mouth and teeth and consequent auto-intoxication. Many gastrointestinal diseases and respiratory affections are due to infections of the mouth. Tuberculosis of the tonsils in children, adenoids and mouth breathing are all antecedents of phthisis. Proper care of the oral cavity will lessen stomatitis, gastric and intestinal outbreaks in public institutions. This should emphasize the necessity of a dental staff for all public institutions. The mouth should be very carefully sterilized before operations, otherwise infection and very serious results may follow. Parotitis has been known to follow laparotomies. Deformities of the jaws and teeth are often the cause of indigestion and disturbances of nutrition, due to interference with mastication. Decay of the teeth and pyorrhea may cause deformity by allowing the teeth to change position. The Jewish children have much better teeth as a rule than the Gentile children. The percentage of carious teeth is vastly greater among the Gentiles. The care and development of the teeth in childhood are most important. Nerve end degeneration is often the cause of carious teeth.

Dr. Eugene S. Talbot, of Chicago, said the average dentist does not see anything in relation to his specialty but the mechanical side. Within the last few years he thought certain men in this country had demonstrated that there is hardly a pathological condition of the mouth that is not due to some constitutional cause. Perhaps the most important point in regard to a paper like that is the treatment and care of the mouth during the development of the child. It has been shown that almost all of the deformities and pathological conditions of the mouth can be produced by a want of proper nourishment; that the first period of stress is probably the most important period in the development of the child, and deformities of the jaws, irregularities, etc., are apt to occur when the tissues begin to form. It has also been demonstrated that another cause of defect which has already been stated by the Chairman—*i.e.*, nerve end degeneration—has much to do with the development and disease of the teeth. Another important point, and one upon which great stress should be laid, is that of proper care of the teeth and of the mouth. The fact has been developed that in the specialty of stomatology, as well as other specialties in medicine, auto-intoxication and mouth infection are important causes of disease, and the time has arrived when if the specialty is to take rank with the other specialists of medicine, these three important points must be considered.

Dr. M. I. Schamberg, of Philadelphia, said he was much pleased to hear the Chairman make reference to the pernicious practice of retaining abscess teeth until they had passed beyond the acute stage. Another feature of the Chairman's report was the introduction into the public schools of an examining corps of dentists, who would not only examine, but endeavor to treat and handle many abnormalities presenting themselves early in life. In Philadelphia there has recently been established a corps of medical examiners. He feared, however, it would be some time before dental examiners would be placed in the public schools, but from what he has been able to learn there are very few children in the schools whose teeth are not badly neglected. It shows the necessity for a united effort of physicians and dentists throughout the country.

Dr. Marshall said that if absolute oral cleanliness could be had that it would only be two or three generations before dentists would be a scarce article in the profession. He believed that if the teeth and mouth were kept absolutely clean oral disease would disappear. Diseases of the mouth are usually diseases of neglect. The mistake of not beginning early enough with children is made.

In his army experience he had seen many soldiers coming from the Philippines. The majority of these men are from the lower walks of life and have very little education—certainly no idea of hygiene except what is taught them after they come into service. They know absolutely nothing of the care of the mouth; probably never even owned a tooth brush. It is a part of the duty of the United States to teach these men the use of the tooth brush. Those coming home from the Philippine Islands frequently have salivary deposits all over the teeth, the gums badly inflamed, and many of them suffering from pyorrhea. Some of these men are sent home with dysentery or diarrhea. It has been his fortune to be able to strike a line of treatment with these men which has been exceedingly beneficial. In those suffering from diarrhea, a thorough cleansing of the mouth, putting upon a proper tonic and giving good

mouth washes to keep the mouth clean and tone up the tissues, has produced wonderful results in many cases. Some have been under treatment for four or five months; others eight or ten months, and usually become well finally.

A symposium of dental education was read, consisting of the following papers:

A Common Ground for Medicine and Dentistry.—Frank L. Platt, of San Francisco, read this paper. He said the goal of both professions is practically identical, embracing all honorable means for the relief of suffering and the care and prevention of disease. It is the endeavor of the honest physician to prevent epidemics, and of the dentist to prevent dental disease. Prevention of disease is given a greater and more valuable scientific triumph than its alleviation and cure. More attention should be paid to the study of dental diseases in the medical colleges, and to diseases associated with the teeth in dental colleges. Both professions should unite in instructing the patients as to the value, care and preservation of the teeth. Syphilis, tuberculosis, etc., have much to do with the condition of the teeth.

The Physician as a Dentist.—Calvin W. Knowles, of San Francisco, in his paper said that a dentist should not only be a dentist but a medical graduate as well. Too much attention is paid to the mechanical side of dentistry and too little to the medical aspect. The affections of the teeth are not given sufficient attention in our medical colleges. He was firmly convinced that a chair of Stomatology should be established in our medical colleges. He was also inclined to the belief that a more extensive mechanical course would be very beneficial. It is only by having a more thorough knowledge of the subjects almost exclusively confined to dentistry that the physician will be able to determine in time to conserve the best interests of the patient, where the services of the physician end and those of the dentist begin.

Physician's Duty to the Child from a Dental Standpoint.—Alice M. Steeves, of Boston, in her paper said that the general practitioner has vast opportunity for dental missionary work among the children because of his relationship to the family. He should instruct the mother as to the care of the child's teeth from the appearance of the first white pearl, explaining to her the necessity of giving as much—yes even more—care to these first teeth than should be given to the permanent teeth. These first teeth should receive the attention of the dentist as soon as a cavity appears, and should not be removed until such time as they have fulfilled their mission. Internal medicine is important in this connection because of the relation of the mouth to normal digestion, and because of the effects of various medicines upon the teeth; laryngology is important because of the importance of a healthful condition of all the mucous membranes of the head. The textbooks on diseases of children should give more explicit consideration to the mouth and its relation to disease, and esthetic perfection.

Medical Relations of Certain Conditions of the Mouth.—Dr. L. Duncan Bulkley, of New York City, in his paper said that the mouth is actively concerned in the first step in digestion, and therefore in the processes of life and health. Although subject to continual irritation from various foreign substances, and although the seat of many varieties of microorganisms, its tissues show remarkable powers of healing after surgical or other injuries. The normal alkaline secretion varies with different conditions of the system. The saliva has an important function, but the average person eats too hurriedly and bolts his food too rapidly to give it a chance to act on the food. The saliva has a beneficial effect in sea sickness. If the patient be instructed to thoroughly chew some dry toast or crackers, thoroughly moistening it with the saliva, and eschewing all other food and water, in the majority of instances a recovery will ensue. It is becoming more apparent that decayed teeth are the cause of dyspepsia in many instances, and that purulent discharges in the mouth are often the cause of systemic disturbances. Syphilitic conditions of the system are more frequently evidenced by the condition of the mouth than is generally supposed. In gout and rheumatism there is increased acidity and a consequent gingivitis and pyorrhea. Chancres are found in all parts of the mouth and on the tongue. The most frequent cause of lesions within the mouth is syphilis.

In the discussion Dr. Vida A. Latham said that her experience has been in the last few years that the conditions of the mouth and teeth are based almost entirely upon systemic conditions. One of the great objects of the section work is to bring forth as much as possible specialists who have had large experience in diseases of the body, and try to show a relationship between the system and the teeth and adjoining structures. To her mind syphilis has much more to do with the conditions of the mouth than other extensive infections, possibly excepting tuberculosis. She had seen cases in her own practice where syphilis has been contracted, where the teeth before infection had been in splendid condition and afterward discoloration, decay and erosion have been quite severe, and interstitial gingivitis resulting in pyorrhea alveolaris, with wasting of the alveolar processes. In the last two years she had had two patients with gonorrheal infection of the mouth. The infection was thought to come from the fingers. These cases were unusually peculiar. There was marked inflammation with much pain, —the teeth became loose—there was a greenish slimy condition of the gums, and there was in these two cases slight fever.

Dr. M. I. Schamberg, of Philadelphia, said that all appreciate the number of pathological conditions of a systemic nature that manifest themselves in the mouth. During the past year he had seen one case of lupus, several cases of carcinoma of the mouth, and in one case the main interest lay in the early diagnosis. The dentist referring the case to him sent it because he was rather doubtful as to the condition, and a microscopical examination of the growth, which was very slight at the time, was made, and it proved to be an epithelioma, which was treated by the X-ray with good results. Several cases of syphilis of the mouth in various stages have come under his care during the past year. The last case happened to be an initial lesion immediately posterior to the superior central incisors. The case had gone on with a wrong diagnosis for three weeks, both the physician and the dentist failed to discover the cause of the lesion, and the condition was bad. He found a very pale, macular syphilide upon the abdomen. The mouth lesion had been masked by the application of caustics and other forms of treatment. Such cases show the necessity for thorough insight into medicine generally. It shows also

that the general practitioner is too frequently derelict so far as studies of the mouth are concerned.

Dr. L. M. Rhein, of New York, said that last year in evidencing his interest in the examination of the oral fluids for diagnostic purposes, he had occasion to take exception to the name saliva as applied, as being misleading. There are in the mouth the submaxillary glands, the sublingual glands and the parotid glands. It is true they are the salivary glands of the mouth, and they give forth a large per cent. of the fluid that circulates in the mouth, but there is added to that all of the eliminative secretions of the mucous follicles, which add materially to this fluid. Up to the present, this portion of the fluid has had no recognition given to it as having any of the function that pertains to salivary glands. The main portion of the medical profession have had no education as to what the normal physiological condition of the mouth is, and consequently when they examine an abnormal mouth they are at sea in regard to making a proper diagnosis either of what may be wrong, or as to whether it is even abnormal as distinguished from physiological. The trained stomatologist has opportunities for the minute and careful observation of what he sees in the mouth that so educates his sense of perception between the various conditions that it places him in a peculiarly fortunate position as regards diagnosis. The tendency of the papers presented to us has been more or less to bring us to a realization of the value that a general medical education will give to the man who practices in the region of the mouth. There is no gainsaying also another fact that is apt to be overlooked, and that is the absolute thoroughness of the work.

Dr. Bulkley, in closing the discussion, said that this subject is an immense one, and the fact that others have reached the same point of view on this subject is interesting. Stomatology as a term is of very great advantage, and if that can be introduced everywhere he thought it would be a step in advance. If the section had been called "Dentistry" he would not have read a paper. American dentistry is recognized all over the world. There are many cases of pyorrhea alveolaris which it would unquestionably be folly to send to a physician. In those cases which have been under his care he had used peroxide of hydrogen freely. Undoubtedly in these cases the first item is proper surgical treatment and perfect dental cleanliness. On the other hand, why does a patient have this condition? It is not from the parasites in the mouth. He did not believe in putting down so many diseases as have been attributed to bacteria. Just think a moment what tuberculosis was about fifteen years ago. Who ever thinks of trying to cure it now with tuberculene, etc.? Sunlight and fresh air are the best treatment. Thirty years ago Andrew Clark, one of the greatest physicians in the world, said: "Do not pay so much attention to the lungs; look after the stomach."

Second Day—July 12th.

Dentistry of To-morrow.—Dr. H. P. Carlton, of San Francisco, in this paper said that dentistry is the only specialty of medicine not universally requiring the degree of doctor of medicine. Dentistry and medicine have been separately studied, and this he considered was a great error. The dentist and the physician do not know enough of each other's work. The mechanical aspect of dentistry appealed to those first studying; it has been made a trade rather than a science. The relation of physiology, pathology and bacteriology necessitates an entirely different attitude, and is rapidly bringing the child dentistry back to the parent medicine. Many diseases are best studied in the mouth. The training of dentists should be under scientific teachers—men who devote their time to the study of medical education, rather than those with a busy practice. The technic of dentistry appears only as a small branch of a work in which all should share. The merely mechanical dentist is not competent to judge problems of diseases of the mouth, which may often be simply an indication of general systemic disturbance. Faulty dental conditions may cause faulty nutrition, etc., which could not be diagnosed by a merely mechanical man. The dental specialist of the future must be a broad diagnostician; must interpret what he sees in the mouth in connection with his general medical education. The same preliminary training should be required whether a student expects to practice general medicine, surgery, dermatology, ophthalmology, dentistry, etc. When this is accomplished, what will become of the dentist? The practical life demands division of labor, and the natural ability of the individual will bring about the proper division. This will not only prepare great men for great things, but little men for greater things than would otherwise have been possible. He who takes up the mechanical side has a broad field. Dentistry requires the highest type of mechanical ability; broad mental training makes a better dentist. "We live not only to be wage-earners, but for our country, our nation and science."

What Will Probably be the Educational Standard for the Coming Decade.—Dr. C. C. Chittendale, of Madison, Wis., in his paper spoke of the advisability of lengthening the college course to four years, and of requiring a degree of doctor of medicine.

These papers were discussed by Drs. Frank L. Platt, of San Francisco; M. L. Rhein, and others.

Surgical Bacteriology of the Mouth.—Dr. A. H. Levings, of Milwaukee, Wis., read this paper. The bacteriology of the mouth, he said, should play an important rôle. Here local manifestations of many diseases are found: influenza, smallpox, syphilis, scarlatina, measles, scurvy, etc., in some of which the specific organism may be found in the oral cavity. The frequency and variety of germs found is of interest. A great variety of germs gain entrance to this cavity, and the natural warmth and moisture, as well as the organic matter frequently present, make it a favorite seat for growth of bacteria. For the purposes of investigation, a variety of types of mouth may be distinguished thus: (1) Clean, (2) ordinary, (3) filthy, (4) tobacco chewer's, (5) mouths with distinct pathological processes.

The first group of bacteria studied comes from clean mouths, with well preserved teeth. To obtain these the mouth is washed with normal salt solution and the washings used for plating. In all cases a hanging drop showed thousands of bacteria; micrococci were found in all. Most frequently one finds staphylococci. In fifteen out of twenty a micrococcus test was made, while in six cases sarcina were discovered. All shapes and sizes of bacilli were discovered. These produced colonies too numerous to mention. Large numbers were acid producers, many gas producers and many species of putrefactive bacteria were found. In filthy mouths there is frequently some pathological process such

as scabies, suppuration, or ulceration. The pneumococcus was present in 10 to 30 cases. Tobacco chewers' mouths are more filthy than ordinary filthy mouths. Tobacco has no influence upon the growth of bacteria.

In ordinary conversation 235 colonies were counted as expectorated. After one minute of conversation at a distance of five feet during forced expiration 105 colonies developed. In one-half a minute at a distance of five feet and forcible expiration 102 colonies. At a distance of 15 feet after five forcible expirations 15 colonies were obtained. On plates exposed at a distance of five feet and coughed at forcibly five times, with one thickness of gauze, 156 colonies developed; with two thicknesses of gauze 35 colonies; with three thicknesses 8 colonies. Scrubbing with water and tooth-brush reduces colonies from thousands to a few. If the mouth is well rinsed and antiseptic then applied, a sterile solution is practically obtained.

Dr. Marshall, in his discussion, said that experience in handling fractures of the jaw shows that about ninety per cent. of all compound fractures of the jaw separate. He had operated upon those cases without any more disinfectant than washing out the mouth; but had learned that if the mouth be not thoroughly cleansed the wound will be troublesome, and salivary deposits will form. In his work in the Presidio, in San Francisco, he had found that the mouths of the soldiers were in a most deplorable condition. He had some placards printed and put in front of the dental chairs: "Clean Teeth Do Not Decay" and others, "Do Not Ask the Dentist to Treat Your Teeth Until You Have Brushed Them." It was surprising how many of those who had been with us some time improved. Many of them had never owned a tooth-brush.

The Treatment of Suppurative Affections of the Face and Neck Emanating From the Mouth.—Dr. M. I. Schamberg, of Philadelphia, Pa., in this paper said that early in the history of medical science men began to follow Nature's method of cleansing. Unaided, the vital forces will ultimately throw off pus. For a long time the use of poultices was considered proper treatment. Now the method of prompt evacuation is practised as soon as the presence of pus is determined. There is no place where a scar is more in evidence than on the neck and yet how often does it occur. Unfortunately relief from pain is often obtained by the application of heat in dentalgia. A large proportion of diseases of the neck and throat emanate from the mouth, evidently due to the fact that diseased teeth may be present, and transmit disease to the deeper structures. It is true pus organisms may gain entrance through wounds, ducts of glands, etc., but these are unusual. Suppurative parasites and other deep-seated disease are usually handled intelligently by the general surgeon. Often patients present with swollen faces, necks, and suppurative foci in the superior and inferior maxillary regions, the etiology of which is often obscure. A careful examination of the mouth often reveals the dental origin of the difficulty. A successful treatment of any suppuration is dependent upon recognition of the etiological factor; a putrefying pulp in a tooth may be evidence of its presence. To properly treat suppurations taking place about the face and chest, regard should be given mouth conditions. Sometimes where the lymphatics have been involved, the glands are so badly overworked that they broke down. Suppuration of neck in two cases seen by writer was so extensive as to suggest Ludwig's angina. In fact, in most if not all of Ludwig's anginas the avenues might be sought for in the mouth. Treatment is prevention and proper care of the mouth and teeth. If all mouths were to receive a reasonable amount of intelligent care in the hands of a competent dentist, supplemented by patient's oral cleanliness, many suppurative conditions about the head and neck could be avoided.

Etiology of Teeth Corrugations.—Dr. G. Lennox Curtis, of New York, said that peculiar spots, opaque markings, lateral corrugations, resembling rings, are often found in teeth. They were not always present in all of the members of the same family. Sometimes they are lateral, sometimes longitudinal. One cannot always find these markings on teeth and nails of same individual at same time. He believes that their presence points to an abnormal and interrupted changes in nutrition when the enamel is soft and impressionable. He concluded that the principal causes of corrugations upon the teeth are intoxication from absorption of ptomains, etc., from intestinal fermentation. These interfere with normal functional activity, clog emunctories, pollute the blood stream and produce substances called rheumatic fibrin. Fibrin may also be due to prodromal stage of disease. Some claim that leucocytes produce fibrin. He elaborated his opinions at great length and illustrated with many unique observations.

Dr. M. H. Fletcher, of Cincinnati, said in discussion that the markings on the nails are an established guide to physicians and he had always understood they were looked upon as being especially indicative of disorders of the alimentary tract; however, it is a known fact that any acute wasting disease which so reduces the assimilative processes of the body that destructive metabolism is present for a period of one or more days, will show transverse corrugations in the nails, the number, size and depth of these being determined by the severity and length of time that destructive metabolism is present. Pneumonia, pleurisy, or an acute attack of any kind will show these markings as surely as derangement of the alimentary tract.

THIRD DAY—JULY 13TH

To What Extent are Teeth Necessary to the Human Being?—Dr. M. H. Fletcher, of Cincinnati, in his paper said that nature offers considerable variations from an average standard, and still preserve a good state of health. The physiology of perfect function is so rare that it is hypothetical. It is the physician's endeavor to restore a patient to an average state. In patients in whom all the teeth are lost, great benefit may be derived from artificial ones, yet if they are not good, many of them are injurious to the mouth. Some artificial teeth are only valuable for cosmetic reasons, and appearances are not to be ignored. The insertion of a poor crown to replace lost teeth, however, brings trouble. Good molars properly opposed do more good work than substitutes. Grinding can be replaced in present stages of civilization by chemicals and by cooking. The actual necessity for teeth in the civilized race, he said, is almost nil. His superior intelligence allows him to choose his food. The saliva is merely a moistening fluid, and it is soon replaced by the gastric and the pancreatic juice. In examining men for military service, he

must have four sound double teeth on each side, or he is rejected. The loss of two-thirds or eight back teeth will not debar entrance and the back teeth include bicuspids. If the front teeth remain and double teeth are gone, rejection is demanded. Artificial teeth are not considered a substitute for natural ones in the army. Not much choice in army rations, which no doubt is taken into consideration by the examiner. The demands of health are more properly met by choice and selection of foods and proper preparation. There is danger to the patient from unkept artificial teeth and badly fitting plates.

In the discussion Dr. Talbot said that the first point in the paper is that man can get along without his teeth. The dentist believes that it is possible for a man to live without teeth; the second point is that modern dentistry, due to uncleanliness in the insertion of bridges, has as much to do with disease as any one thing. The collection of germs about ill-fitting crowns is more detrimental to the mouth than no teeth. In the lower vertebrates teeth are necessary, not only for chewing, masticating, but for prehensile purposes. As man rises in evolution the jaws and teeth are of less importance until at the present time it is questionable whether teeth are necessary. He has believed for years that man could get along without teeth. There are plenty of cases on record where men have lived for ninety or one hundred years where they have been without teeth for fifty or sixty years. Methods of preparing foods nowadays do not require mastication, and the jaws are shortening.

Dr. Platt, of San Francisco, said that while it is possible that man may live without teeth, he did not think it is a good plan for him to do so. He is heartily opposed to eating prepared food that is easily digested, and said he was opposed to vegetable diet and health foods. He had had patients who have taken up this mode of living and they are all losing their teeth. All show evidence of malnutrition.

Fatal Oral Pathological Conditions.—Dr. G. V. I. Brown, of Milwaukee, Wis., in his paper said: First, early recognition is essential to the prevention of grave results from comparatively simple, incipient conditions; second, extremely carefully differential study is necessary to distinguish between comparatively unharmful and other pathologic states that may be almost or quite hopeless from the point of view of prognosis; third, by the time the more serious cases come to the attention of the surgeon or general practitioner of medicine, it is frequently too late for successful treatment, and having developed one form or another of serious disease, the simplicity of its origin is too commonly never recognized; fourth, one of the reasons this is so is because dentists who have constant supervision of the mouths of their patients do not recognize the serious nature of the affection promptly enough; and, on the other hand, want of familiarity with the detail of diagnostic symptoms of mouth diseases on the part of the general practitioner prevents him from making a diagnosis that would be of untold value. Interstitial gingivitis, or so-called pyorrhea alveolaris, the various forms of stomatitis, neuralgic pain, malposed teeth, inflammatory and suppurative processes, including necrosis of the maxillary bone, and contracted dental arches are every day matters in the daily routine of the average dental practice. Malignant growths, tic douloureaux, mascular tic, facial paralysis, neurasthenia and other neurotic manifestations are constantly numbered among the hopeless cases of practitioners of medicine. That there is a chasm, but poorly bridged between these two, the better covering of which would save many lives and incalculable suffering, can hardly be questioned.

"The Ossification of the Lower Jaw," by Edward Fawcett, of Bristol, Eng.; "Anchylostomiasis and Tongue Pigment," by T. M. Russell Leonard, of Grenada, British West Indies, and "The Roentgen Rays in Dentistry," by M. Kassabian, of Philadelphia, were read by title.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirtieth Annual Meeting, held at Niagara Falls, May 25, 26 and 27, 1905.

The President, Emilius C. Dudley, M.D., of Chicago, in the Chair.

The Society held its sessions at the Cataract House.

An address of welcome was delivered by Dr. Carl G. Leo-Wolf, of Niagara Falls, which was appropriately responded to by Dr. Ely Van de Warker, of Syracuse.

Accidental Rupture of the Non-Parturient Uterus, with Report of Cases.—Dr. George W. Jarman, of New York, had seen five cases of accidental rupture of the non-parturient uterus. These were detailed. To draw some deductions from his own cases and those reported by others, it seemed to the author (1) that the operation of invading the cavity of the uterus should not be regarded lightly, and that the same care in the details of asepsis should be carried out as in a laparotomy. (2) That great care should be used in the introduction of steel dilators, and at no time forcing them into the cavity of the uterus. (3) That as one's experience in gynecology increased, the use of the uterine sound decreased, and the fingers more and more frequently took the place of the curette to remove secundines from the uterus. (4) That sterile water was the best fluid for irrigating the uterine cavity. (5) That if a rupture or perforation of the uterine wall occurred, it was better to perform a laparotomy and assure one's self of the safety of the patient than to hope that no untoward results would ensue. (6) That if one could not be certain of the asepsis of the curettage, it was better to use a small drain through the vagina, and a slightly elevated posture of the patient, than to regret its non-use after the development of septic peritonitis. (7) That in properly conducted cases observed soon after the accident there should be almost no mortality.

Dr. A. Palmer Dudley, of New York, had perforated the uterus four times. In one case, after introducing the instrument into the uterus, he withdrew what he supposed was a fungous growth or secundines, but which proved to be eight inches of the small intestine. The intestine was passed back through the opening made in the uterus, and the patient let alone. She had since borne two children.

Dr. Herman J. Boldt, of New York, said it was not always that a perforation of the uterus caused serious trouble. Great discrimination should be used in those cases in which there was danger. In all instances of criminal abortion, where there was any suspicion that infection had taken place, the abdomen should invariably be opened. He had perforated the uterus a number of times, and had seen it perforated by others. In other instances of perforation of the uterus, the physician should do nothing except perhaps insert a small piece of gauze through the cervix, let the patient alone, and he believed the majority of cases would recover.

Dr. Eugene Boise, of Grand Rapids, Mich., reported two cases of perforation of the uterus, one of which occurred in 1871. The physician in attendance passed a sound clear up to the handle. Nothing was done, and the patient developed no symptoms. In the other case the uterus was perforated with a curette; the cavity was thoroughly washed out, the patient put to bed, without anything further being done, and she made an uninterrupted recovery.

Dr. Fernand Henrotin, of Chicago, had seen five cases in which the uterus was perforated. One was accidental. One was the result of the work of an abortionist, and on opening the abdomen, the patient being septic nine days after the supposed operation, he found a bougie nine inches long in the abdominal cavity. The patient recovered after undergoing a severe trial.

Dr. Andrew F. Currier, of New York, agreed with the previous speakers that in many of the cases in which perforation of the uterus had occurred no damage would result if the intestine had not been withdrawn. If there was a mere puncture of the uterus, if the woman was not septic, it was safe to leave her alone and do just as little manipulation as possible. But supposing the uterus was in a soft, friable condition, one was presented with the alternative of either closing the perforation or of removing the uterus. In many cases the removal of the uterus was preferable, and more than likely would result in more benefit to the patient than the mere closure of the hole. The key to successful treatment was complete drainage, and if there was already a condition of sepsis in the uterus, and one simply closed the wound, he was by no means sure that the sepsis would not continue. Therefore, in cases of that kind it would be prudent to remove the uterus, leaving the wound in the vagina open, and establishing free drainage.

Dr. A. Lapthorn Smith, of Montreal, did not think it was the curette which was responsible in most cases for perforation of the uterus. He confessed to having perforated the uterus about six or eight times. He had no fear of the result if the parts were thoroughly aseptic.

Dr. Clement Cleveland, of New York, had perforated the uterus with a sharp curette on one occasion when he was talking to his class about the carefulness with which the instrument should be used. The patient was to be operated upon for a lacerated cervix and lacerated perineum. He postponed this operation, put the patient to bed, and no bad results followed. The Society should exercise its influence toward eliminating the sharp curette from the bag of the general practioner, or else it should be relegated to the junk heap. It was fraught with the greatest harm to future women if it was used in the careless way it was to-day.

Dr. William E. Moseley, of Baltimore, said both the dull and sharp curettes had their place. Personally, he first introduced the dull instrument for diagnostic purposes, and then the question as to whether the dull or sharp curette should be used depended upon the character of the tissues one had to deal with. There were some cases in which there was more danger of perforation of the uterus from the use of the dull than from the sharp curette.

Dr. William H. Wathen, of Louisville, did not think the dull curette had any place in the surgery of an experienced gynecologist. The man who could not use a sharp curette without injuring his patient had better refer his cases to someone who could. Occasionally, he admitted, cases were reported where the uterus had been perforated by experienced operators. Curettage should be done by the sharp curette, or decidual remains should be removed by the finger, if possible.

Dr. Ely Van de Warker, of Syracuse, N. Y., stated that uterine curettement was attended with more or less danger, and should be confined to the hands of good gynecologists, and rarely ever or never done by the general practitioner.

Dr. Seth C. Gordon, of Portland, Me., said occasionally he had pushed a sound through the uterus, but by leaving the patient alone he had not seen any harm result.

Dr. Philander A. Harris, of Paterson, N. J., had perforated the uterus twice, once through the corpus posteriorly and once anteriorly. The perforation posteriorly was done by the curette, and the one anteriorly by his dilator. With his present dilator there was a device attached to it which registered the exact number of pounds exerted by the operator in dilating the cervix.

Dr. T. A. Reamy, of Cincinnati, Ohio, had perforated the uterus with a sharp curette within the past two years. He curetted a woman a short time ago, whose condition was such that his consultant was in doubt as to whether there was cancer of the body or the result of a chronic endometritis. The speaker in curetting the uterus rather thoroughly perforated it. A pelvic abscess resulted from the perforation, which was opened, and the patient made a good recovery.

Dr. Emilius C. Dudley, of Chicago, stated that within five weeks he perforated a uterus with a curette. The uterine wall was not more than the thirty-second of an inch thick, due to a localized pathological condition. A considerable quantity of bloody fluid was found in the cul-de-sac of Douglas, which was sponged out, the abdominal cavity flushed out with salt solution, and after closing the wound in the uterus with a purse-string suture, the abdominal wound was closed, and the patient made a good recovery.

The Treatment of Retroversion of the Uterus by Shortening the Uterosacral Ligaments.—Dr. Arthur W. Johnstone, of Cincinnati, stated that the first step in either retroversion or prolapse was due to a stretching of the uterosacral ligaments. This was proven by clinical experiences and a study of the comparative anatomy of the subject. This stretching was most commonly due to a low grade of infection spreading to these ligaments from the uterus or other contiguous structures, that made them lose their tone. A few cases were due to direct violence. The operation consisted in shortening the uterosacral ligaments through the vaginal incision. The uterus was replaced and prolapse cured. Shock was *nil*, and convalescence smooth.

A New Plan of Procedure in Retro-Uterine Displacements.—Dr. E. E. Montgomery, of Philadelphia, stated that retrodisplacements of the uterus more frequently demanded restoration to normal position than any other form of displacement. Nature's forces should be imitated as far as posible in relieving malpositions. The Alexander operation and its modifications were in this line of procedure. Its usefulness was limited to the uncomplicated and mobile uteri in which operative interference was least demanded. The majority of the intra-abdominal operations on the round ligament employed the best part of the ligament in their manipulation and left unaffected its weakest portion. The various operations of ventrofixation and ventrosuspension were departures from the normal, placed the uterus in abnormal relations and rendered painful and difficult the performance of its normal functions. The vaginal procedure required considerable dissection, were ineffective in restoring normal relations, and were to that degree to be condemned. The operative procedure, he would suggest, was a combination of operative procedures employed by Gilliam, Ferguson and Simpson. It permitted of treatment of diseased ovaries and tubes, left the uterus a freely movable organ, supported it by normal elastic

and muscular structure capable of undergoing evolution and involution, and, finally, afforded no opportunity for the formation of unfortunate adhesions.

Arteriosclerosis of the Uterus as a Factor in Uterine Hemorrhage.—Dr. Palmer Findley, of Chicago, read a paper on this subject, in which he gave a résumé of all cases, and reported four new ones. The writer dealt exclusively with the so-called essential or idiopathic hemorrhages, the cause of which was not definitely determined. He argued that arteriosclerosis of the uterus was not the prime factor in bringing about these obscure hemorrhages. In his opinion muscular insufficiency was the underlying cause, and the sclerosed vessels were but contributing factors. He drew the following conclusions: "(1) Metritis, as a primary lesion and independent of infection, is not accorded the consideration which the frequency of its occurrence and its clinical significance would warrant. (2) The muscular fibers of the uterine wall have an important function in controlling the caliber of the blood vessels, and hence in regulating the blood supply to the uterus, as evidenced in the relaxed condition of the uterine wall during menstruation, in post-abortion, and post-partum hemorrhages, and in the free bleeding which accompanies curettage when the uterus has relaxed under the irritable influence of the curette. In all these conditions the hemorrhages are controlled by the contractions of the uterus. (3) Any event which lowers the muscular tone of the uterus may occasion an abnormal loss of blood into the endometrium and uterine cavity. (4) Prominent among the factors which contribute to muscular atony in the uterus are the wasting diseases, anemias, and acute febrile diseases, which are not infrequently accompanied and followed by uterine hemorrhages as the result of weakened support to the vesical walls. (5) Fibrosis uteri is a far more common cause of muscular insufficiency. The building up of connective tissue in the uterine wall at the expense of the muscular elements is the result of long-continued passive congestion, which in turn is due to numerous general and local lesions, such as an incompetent heart, obstructions in the lungs, liver, kidney and spleen, abdominal swellings, varicose veins of the pelvis, and uterine displacements. (6) The walls of the blood vessels share in these hyperplastic changes, in that the media and adventitious coats of the vessel are thickened. In this manner the elasticity of the vessel walls is impaired, and if the lumen of the vessels is not narrowed by contraction of the vessel walls, and thickening of the intima, there will be added reasons for various engorgements of the uterine wall and capillary oozing at the endometrium. In such cases the prime factor in the causation of uterine hemorrhages is the muscular incompetency; the thickened vessel walls and the remote embarrassments to the circulation are but contributory factors. (7) This condition of the vessel walls is to be distinguished from the arterio-obliterans of the normal senile uterus, in which the vessels are partially or wholly obliterated by the thickened intima. In such cases hemorrhages do not occur, for the season that the blood supply is greatly diminished. (8) In none of the recorded cases were hemorrhages seen to come from ruptured blood vessels, nor were aneurysms of the arteries seen in the uterine wall. On the contrary, the escaped blood was farthest removed from the sclerosed vessels, and more evidently capillary. We are therefore not justified in ascribing the hemorrhages directly to the sclerosed vessels. (9) The diagnosis can only be made by first excluding all other possible causes, such as polyps, carcinoma and fibroids. (10) Hysterectomy has been frequently resorted to after repeated curettements have failed. Palliative methods—rest, ergot, styptic applications to the bleeding surface, and finally tamponading the uterine cavity—may be resorted to, but have repeatedly failed."

Postoperative Vomiting.—Dr. Eugene Boise, of Grand Rapids, Mich., said it was assumed as proved that there was a vomiting center from which all impulses toward vomiting were sent. These impulses might be received through various channels. The conditions that led to postoperative vomiting were numerous. They might be grouped as (1) those conditions pertaining to the anesthetic; (2) those pertaining to the general condition and surroundings of the patient; and (3) those pertaining to the stomach. The anesthetic caused vomiting (1) by its direct irritant action on the vomiting center; (2) by causing a toxemia, and (3) by saturating the secretions of the stomach. The conditions pertaining to the stomach were (1) chronic, such as atony, dilation, chronic disease of the mucous membrane, etc. (2) Acute, as saturation of the tissues and secretions of the stomach by the anesthetic. Treatment must therefore be preventive as well as curative, involving greater care in the preparation of the patient. Four things must be kept in mind: (1) The abnormal irritability of the vomiting center; (2) the condition of the stomach; (3) the condition of the blood; and (4) the condition of elimination. Treatment must be adapted to the conditions found. Theoretically, the indications were to obtund the sensitiveness of the vomiting center; to neutralize, if possible, the irritant character of the anesthetic, to cleanse and soothe the stomach; to keep the patient quiet in order to avoid circulatory disturbances; to aid elimination, and to support the patient and nourish the irritated nerve centers by rectal feeding when indicated.

Dr. A. Lapthorn Smith emphasized the necessity and importance of preliminary preparation of patients. Careful attention should be given to diet, to getting the bowels thoroughly cleaned out, so as to reduce the amount of vomiting after operation to a minimum. He advocated the drinking of large quantities of hot water by patients to wash out the ether that had been swallowed during its administration. Hot water taken in this way amounted to the same thing as gastric lavage.

Dr. Matthew D. Mann did not believe the character of the anesthetic had as much to do with vomiting as the amount of the anesthetic. The more deeply a patient was anesthetized, the greater the amount of anesthetic used, and the longer time it took the patient to get rid of it, the more the vomiting center was irritated. For three years he had been using ether, preceding it by chloride of ethyl. He had done an operation, lasting forty-five minutes, with two or three ounces of ether, when preceded by chloride of ethyl. Since following this method, vomiting had been greatly reduced, and in many instances the patients had not vomited at all.

Dr. A. Palmer Dudley said that if operators considered the preparatory measures mentioned by Dr. Mann, there would be less reflex action on the part of the stomach in postoperative work.

Dr. Andrew F. Currier thought the preliminary administration of chloride of ethyl, or nitrous oxide, as had been his custom recently, was much more satisfactory than the prolonged and irritating effects which came from the first stage of anesthesia through the administration of ether alone. One could lay down as a principle that given a very careful administration of the anesthetic and a small quantity, one would have much less trouble afterwards from vomiting.

Dr. C. C. Frederick agreed with Dr. Mann as to the preliminary use of chloride of ethyl, followed by ether or chloroform. For a year and a half or more he had begun anesthesia with chloride of ethyl, getting the

patient under its influence rapidly, then changing to ether or chloroform. Vomiting was much less by this combination.

Dr. Arthur W. Johnstone attributed the great decrease in the amount of vomiting after operations largely to careful preliminary preparation of his patients.

Dr. Daniel H. Craig, of Boston, did not consider eserin in any sense a specific against postoperative vomiting, but he thought it had the same effect on cases of postoperative vomiting as gastric lavage, whether resorted to before the patient left the table, or later. The effect of small doses of calomel given before operation, or divided doses of it after operation, was the stimulation of normal peristaltic action. With lavage the stomach was emptied. Eserin had no effect on the motility of the stomach itself, but it did in reestablishing or preventing stoppage of intestinal peristalsis. Eserin did the work far more efficiently than divided doses of calomel, which necessitated giving the patient medicine by the mouth at a time when she was nauseated and unprepared to take it.

Dr. Malcolm McLean, of New York, said one should give as little of the anesthetic as possible. Anesthetics should be given by men who were skilled in this work. By giving a preliminary anesthetic, such as chloride of ethyl or nitrous oxide, the preparation was such that when ether or chloroform was given, large toxic doses of it were not carried through the circulation so as to poison the patient in the postoperative stage.

Dr. George Gellhorn, of St. Louis, stated that for about a year he had employed as a preliminary the hypodermic injection of scopolamine-morphine, about an hour before operation. This combination arrested secretions from the mucous membrane of the mouth and throat. He gave scopolamine and morphine in the proportions of $^1/_{150}$ of a grain to $^1/_4$ of a grain of morphine. The effect was that the mouth and throat were absolutely dry and remained so during the operation, and the amount of ether used was materially minimized.

Dr. Reuben Peterson said his experience had been different from that of Dr. Gellhorn in the use of morpine and atropine. He had used this combination for years, giving about one-sixth of a grain of morphine and $^1/_{150}$ of a grain of atropine, about three-quarters of an hour before the anesthetic was given. Before he used these drugs there used to be excessive secretion; there was gurgling, so that the mouth and throat had to be swabbed out; but since their use this had almost entirely ceased. He had not attributed the absence of vomiting to the use of these drugs entirely, but to thorough preliminary preparation of the patient, and to better methods of administering chloroform and ether.

Dr. Edward P. Davis said that the remarks made concerned patients with whom there had been abundant time for preparation. One was obliged sometimes to operate upon emergency cases, as ruptured ectopic gestation. In these postoperative vomiting might be very depressing and dangerous. What could be done to prevent it? While the patient was on the table, and before the operation was quite completed, intravenous saline transfusion or injection would prevent postoperative vomiting as well as prevent shock

Dr. Fernand Henrotin said that one of the most important factors in the reduction of vomiting, as well as in the reduction of shock and of making a patient's recovery reasonably smooth, was washing out the stomach. For a little over a year he had been resorting to quick anesthsia with nitrous oxide preparatory to the administration of ether, using as little of the anesthetic as possible, immediately washing out the stomach thoroughly after every operation, and giving a hypodermic injection of eserin before the patient was taken off the table. The use of this combination had made an immense difference in the results of his general operative work.

Dr. J. Wesley Bovee thought the proper procedure was to prepare patients as well as the conditions would permit, and do it with proper discrimination. Then came the proper administration of the anesthetic, giving as little as possible of it, and steadily, not irregularly. After the administration of the anesthetic he had found the administration of oxygen for fifteen to twenty minutes to be the most satisfactory of anything he had used. He objected to the use of morphia because there were so many cases of renal complication in which the use of this drug would handicap the operator.

SYMPOSIUM ON THE RELATION OF THE APPENDIX TO PELVIC DISEASE OR TO PREGNANCY.

The Relation of the Appendix to Pelvic Disease.—Dr. Reuben Peterson, of Ann Arbor, Mich., read a paper on this subject in which he presented the following conclusions based upon the clinical and microscopical study of 85 appendices removed during the course of operations for pelvic disease: "1. In the first series of 200 cases, reported last year by him, a little over 50 per cent. of the appendices were found microscopically to be normal. In the present series 49.3 per cent., or practically 50 per cent., were found normal. The same microscopical classification was adopted as last year, namely, (1) negative; (2) chronic inflammation; (3) doubtful significance; (4) former inflammation; (5) acute inflammation; and (6) periappendicular inflammation. The only change in the classification was that groups 1 and 3 were practically united, and with the exception of two cases were placed in the negative group. This was a minor detail of classification, however, as in each series the appendices in both groups were considered normal. 2. In both series practically one-half of the removed appendices were microscopically normal, while the remainder showed evidences of acute or chronic inflammation, or the results of former inflammation. 3. The average length of 79 appendices was 9.99 centimeters. In the first series the average length was 8.25 centimeters. 4. The appendix was found adherent in 20 out of the 85 cases, or in 23.4 per cent. This was 5 per cent. higher than in the last year's series. But both series show that the appendix was adherent twice as frequently in those cases where microscopic examination showed past or present disease. A certain proportion of adherent appendices were, however, perfectly normal microscopically. 5. Abnormalities in shape were noted in 27 out of the 85 cases. The appendices were found to be club-shaped, constricted, or bent upon themselves in 10 of the 27 cases, yet microscopically such appendices were normal. Hence the same conclusions arrived at last year held good for the present series. Mere shape of the appendix cannot serve as an index of its normality or disease. Appendicitis may be club-shaped, constricted, or bent upon themselves, and yet be perfectly normal. 6. There were fecal concretions noted in 14 out of the 85 cases. This gave a percentage of 16.4, and was double that noted last year. This might be explained by the more accurate observations made in the present series of cases. It did not take into consideration microscopic concretions, but only the palpable forms. In 7, or one-half the cases, the appendices with fecal concretions were normal, hence, as noted in the first series, their existence did not denote disease. 7. Exactly 50 per cent. of the 34 patients in the present series with chronic disease of the appendages showed accompanying disease

of the appendix. 8. The following conclusion would hold good for both series: In chronic disease of the appendages adhesions of the accompanying appendices are present in nearly 50 per cent. (47 per cent., second series) of the cases where microscopical examination shows the latter to be diseased. In a certain proportion of cases, however, although the appendix may be adherent, it is also perfectly normal. 9. Of the 17 normal appendices accompanying chronic diseases of the appendages, 9 were noted as changed in shape, or contained fecal concretions, hence in chronic disease of the appendages, the appendix, which is club-shaped, constricted, or contains fecal concretions, is not necessarily diseased. 10. There were 21 cases of uterine fibromata among the 85 patients. Of these, 48 per cent. had accompanying disease or evidence of former disease of the appendix. The percentage was in the first series practically the same. 11. There were eight cases of large ovarian cystomata in the second series. Of these, 50 per cent. had accompanying disease of the appendix."

Inflammatory Conditions of the Appendix Accidentally Brought to Light in Pelvic Operations.—Dr. Hunter Robb, of Cleveland, Ohio, stated, in a paper on this subject, that of 370 appendices removed and examined microscopically, 103 were normal; 46 showed signs of a chronic, and one of an acute, appendicitis. In 88 cases there was an hypertrophy of the subperitoneal or internal coat, or of both coats. In 66 cases the changes were of doubtful significance; in 36 the lumen was occluded; in 16 dilated; in 12 the appendix contained concretions; in one case the appendix was cystic and had undergone myxomatous degeneration; in one case no lymphoid tissue was present. Conclusions: "(1) In a large number (in his series, 323 out of 370) of pelvic cases no inflammatory changes in the appendix were found even microscopically. (2) When one finds a normal appendix in conjunction with disease of the pelvic organs, it is improbable that the latter condition has been brought about by a perforation of the appendix which had afterward healed. (3) On the other hand, an old periappendicitis and adhesions might often be looked upon as the result of a septic infection, originating in and spreading from the organs of generation. (4) An appendix which looks abnormal microscopically does not always show inflammatory changes on microscopical examination. (5) Nevertheless, when the removal of the appendix adds very little to the gravity of the abdominal operation, for the benefit of the patient it should be taken away. (6) In his series of 370 cases there were four deaths; but a careful analysis shows that the fatalities should in no instance be attributed to the appendix removal."

Appendicitis in Its Relation to Pregnancy.—Dr. Henry C. Coe, of New York, stated that his experience had led him to believe that many mild cases were overlooked, or were mistaken for other affections—adnexal disease, pyelitis, colitis, etc. In view of the tendency to obstinate constipation and intestinal toxemia, one would expect to find that appendiceal complications were not infrequent during pregnancy. Moreover, many women with a history of former attacks became pregnant, when all the conditions favored recurrences, though they were usually of a mild type. Eight illustrative cases were cited from the writer's private practice, four patients recovering without operation, two being operated upon at the third and fifth months, without interruption of the pregnancy, while the remaining two were carried through the puerperium and submitted to operation later. Dr. Coe then discussed the symptoms, diagnosis, differential diagnosis, prognosis and treatment. The writer's views coincided practically with those of Pinard, namely, to treat appendicitis in the pregnant female according to the same rules as in the non-pregnant. In mild cases carry the patient to term, if possible, and operate as soon as convenient after the puerperium, if the trouble persisted. With the persistence of local pain, and if an induration was felt, operate as in any other case. Perforation and abscess formation called for immediate operation, rapid work, as little handling of the uterus as possible, and free drainage. Accouchement forcé, previous to operation, as recommended by Marx, was not approved by the writer. Since the toxemia of pregnancy was often of intestinal origin, as in appendicitis, careful attention should be paid to the regulation of the bowels by the use of laxatives, high enemata, restricted diet, the drinking of large quantities of water, etc.

(To be Continued.)

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Regular Meeting, held March 20, 1905.

The Scope and Problems of Surgical Physiology.—This paper was read by Dr. Crile, of Cleveland, Ohio. Surgery in its early days had been, he said, anatomical and empirical; but it had been wholly transformed by the origin and development of pathology and bacteriology. Physiology in its surgical relations was now, however, coming to the fore as it was more and more realized how often surgical treatment rested on an understanding of surgical physiology. A stoppage of respiration for instance due to reflex inhibition was a very different phenomenon from a similar stoppage due to obstruction, and demanded therefore a different sort of surgical interference. Respiratory arrest could be caused by strong traction on the tongue and a knowledge of this physiological fact might relieve anesthetizers of embarrassment who, in their efforts to produce respiration, might, in their ignorance of physiology, be defeating their own purpose. The reflex effects of peritoneal manipulations were often overlooked and the reflex expulsion of intestines, through an abdominal wound, was often blamed on the anesthetist when it was due really to peritoneal irritation. The surgical physiology of the circulation was of the utmost importance and yet it was very incompletely understood. Often life itself and more often still immediate operative results depended on the proper care of the circulation. Independent of anesthesia the mere handling of tissues might impact or even throw out of function completely the vaso-motor centers; and a proper knowledge of the facts would make efforts to afford these centers efficient support more intelligent. The result of an operation is equal to the sum of the insults caused the tissues; and blocking of certain of these insults, by intraneural cocainization has minimized or even abolished shock after even such serious procedures as double thigh amputations. The mere opening of an appendical abscess under cocaine with an extensive curative operation later when the procedure could be carried on within physiological limits was a good example of the safety of operative physiologic progression. Many of the facts of compensation by one organ for another were quite unknown and yet a knowledge of them would be most important for surgical treatment. The nature of protoplasmic response to changed environment, determination of minimum circulatory requirements for each organ, discovery of practical methods for helping organs over a surgical crisis, the whole question of physiology of the lymphatics, of the surgery of thrombosis and embolism, of shock—here were problems almost untouched. The intricate problems of brain localization in human beings

were still to be developed. And might it not be possible by cocainization to effect functional detachment of the medulla to protect it from injurious surgical stimuli? There had been hitherto a surgical fear of the heart; yet perhaps in the future operations on the valves might not be impossible. Our knowledge of the pulmonary circulation was infantile; surgery of the stomach had but just been opened and the suprarenals, thyroid and pituitary body had been almost untouched.

Dr. Howell said that thirty years ago, when Ludwig and Virchow were doing their work, the association between medicine and physiology had been intimate. With the prominence of pathology and bacteriology, however, the two had been somewhat divorced; but it was gratifying to see surgeons again coming back to physiology. The problems in surgical physiology were, however, very difficult ones and were not to be thought of as simple; for they depended, ultimately, on physiological fundamentals and these were difficult for even specially trained physiologists to master.

Partial Occlusion of the Aorta.—Dr. Halsted reported some experimental work done by himself and Dr. Sowers on this subject. Ligation of the aorta had been tried fourteen times in human beings and had always been fatal. The early experimental work on the subject had been done by Pirogoff, but, on account of his septic technic, it had not been successful. Dr. Halsted used for ligation a metal band which could be gradually tightened until obliteration was complete. Contrary to what might be expected, no gangrene of the lower extremities occurred; but Stensen's phenomenon (paralysis of the extremities due to anemia of the cord) was present. As a rule in time the circulation became completely shut off; but just before this occurred an equilibrium was apparently established between the blood above and that below the ligature and there were evidences that in some cases the pulse reappeared below after having disappeared. No evidence of clot formation was seen nor was there any endothelial proliferation in the arterial wall—which was normal except for atrophy. In certain cases the metal band cut through and lay within the vessel; and in one or two cases a semilunar diaphragm formed within the aorta. Contrary to the experimental findings of Lister, no endothelial proliferation took place.

The Blood Pressure in Different Parts of the Arterial Tree.—Dr. Dawson reported a study of this subject which was undertaken to determine the changes undergone by the systolic, the diastolic and the mean pressures in passing from the heart to the periphery. The aortic-cephalic, the aortic-brachial and aortic-femoral systems of the dog were studied—a canula being introduced into the aorta and then into the successive parts of each of these systems moving toward the periphery. The various blood pressures were read in each of these situations. An unexplained initial rise occurred near the heart—the pressure measured at a point nearest the heart being slightly lower than at a point a little distal to that.

Heart-Block in Mammals.—Dr. Erlanger reported experimental work done in regard to heart-block in mammals. Complete heart-block was said to be present when the auricle and ventricle were beating with two independent rhythms and, though a well known phenomenon in coldblooded animals, had never been produced in the mammals. Dr. Erlanger's experimental work started with a study of a case of Stokes-Adams disease in the Johns Hopkins Hospital. It was found, by careful pulse tracings, that the auricle and ventricle in this patient were beating with differing rhythm. The administration of atropine had the usual effect on the auricular beat; but the ventricular beat did not change, the ventricle being thus shown to be uncontrolled by the vagus. The accelerations were, however, shown to be acting in both auricle and ventricle. During the attacks the ventricles stopped but the auricles continued to beat, and all these phenomena led Dr. Erlanger to the conclusion that the Stokes-Adams disease was ultimately heart-block. He then set about trying to produce this condition in dogs, and was finally able to accomplish this by placing a specially devised hook-clamp between the auricle and ventricle and compressing with it the auriculo-ventricular muscle bundle of His. The study of the case and the further experimental work on dogs showed conclusively that every case of Stokes-Adams disease (the rhythm in the neck vessels different from the rhythm at the heart, being one of the features described by Stokes) was in reality an instance of heart-block, and a study of all the cases in the literature which have been well observed and by adequate methods confirmed this idea. All the symptoms, Dr. Erlanger said, could be explained by a lesion of the auriculo-ventricular bundle of His and there seemed to be neither need nor warrant for calling in the cardiac nerve centers to explain the condition.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held February 22, 1905.

The President, James M. Anders, M.D., in the Chair.

The Pasteur Treatment for Rabies Administered at the Patient's Home.—Dr. Myer Solis-Cohen in this paper said that the treatment might be administered at the patient's home, and reported the following case: A man and his son were bitten by a dog whose medulla and plexiform ganglia showed the cell changes diagnostic of rabies. They were given the Pasteur treatment at their home, the virus being mailed by special delivery each day by the Pasteur Institute of the Department of Health of New York City. On its arrival the virus was put on ice, and as soon after as practicable was injected with aseptic precautions into the subcutaneous tissue of the abdomen. The patient's bowels were kept open and alcoholic excesses were avoided. There was no constitutional disturbance, and no interruption of the daily work. On but two occasions did the treatment cause a local reaction, which, however, responded to antiseptic measures. Two weeks after the cessation of all treatment no symptoms of rabies had developed. The patients consequently were considered out of danger. Dr. Cohen concludes from such a case that a person when bitten by a rabid dog need not necessarily go to a Pasteur institute for treatment, but, if within a day's journey of one, may be supplied daily with the virus, which can then be injected by the family physician with apparent success.

Dr. Ernest Laplace referred to his privilege of working with Pasteur in 1885 and 1886 in his experiments upon that which has resulted in an absolutely preventive treatment of hydrophobia. Pasteur never made a diagnosis of hydrophobia unless a piece of the brain or spinal cord of the dog were injected into the rabbits and they died of hydrophobia. Dr. Laplace does not advocate the adoption of this method, but believes that for the scientific value of the treatment it is not well to be satisfied with this inoculation. Although the germ of hydrophobia has not been found, Dr. Laplace believes that the treatment is based upon a scientific foundation. That the poison exists is undeniable, for it can be produced and reproduced, attenuated, and made more and more virulent at will; and more can be done

with the poison than with any other, except that of anthrax. Pasteur's idea was to produce in a patient with dog hydrophobia, which requires three weeks for development, a tolerance with the rabbit hydrophobia, which is more virulent and takes only ten days to develop. The pains alluded to in Dr. Cohen's case he thought due to local causes. If treatment can be carried out at home he regards it as a step of great worth to medicine in general. The moral effect upon a patient leaving home in a desperate rush for treatment he considers very bad.

Dr. William M. Angeny referred to a patient bitten by a supposedly rabid dog, who was sent to New York for the first two days' treatment, and after which time the virus was sent to Dr. Angeny for use.

Dr. G. Morton Illman thought it strange that there should not be an admission of the diagnosis of hydrophobia, since the condition is proven by inoculation and is rapidly becoming associated with a definite pathology. In human beings there are distinct changes in the ganglion cells and the medulla. With such a complete Board of Health he thinks Philadelphia should have a laboratory in which this treatment could be carried out.

Dr. Cohen, in closing, said that in the question of whether or not a dog had rabies, if the head only were taken to the pathologist of the Live Stock Sanitary Board of Pennsylvania a report would be given on it.

Surgical Intervention in Cases of General Peritonitis.—Dr. Joseph Price said that the profession had been slow in accepting the overwhelming evidence of operating and clinical facts. A few of the early surgical obstructionists, however, are now the most aggressive and persistent advocates for early surgical intervention in abdominal traumatism and pathology. With the present precise knowledge of pathology and diagnosis he believes there is no excuse for delay in operation. Surgical intervention for peritonitis and perforated ulcers was suggested during the seventeenth, eighteenth and nineteenth centuries, but nothing of a positive nature was done until about 1878. Embolism of large and small mesenteric vessels, he believes, has not yet received deserved attention. Any variety of peritonitis or infection should be anticipated surgically. From a long experience he believes that about all the sufferers from perforations in and about all the viscera in the peritoneal cavity, typhoid perforations, suppurative, gall-bladder, gastric and duodenal perforations should be saved. It is the soiling of walled-off cavities Dr. Price believes dangerous and unreliable. The possibility of peritonitis remaining local or circumscribed by adhesions should not be considered if diagnosis of perforation has been made. Firm, pure silk he regards as the best suture material and the interrupted sutures as giving the best results with less risk of strangulation. If the margins of the ulcer are ragged they should be trimmed. A resection, he states, is unjustifiable. The irrigation should be a thorough cleansing with sterilized water of the entire surface. It is his impression that irrigation with hot normal salt solution is harmful, causing irritation. Curetting or wiping dirty points with gauze is followed by good results. The gauze pack, as so commonly and recklessly used, he regards as a dangerous procedure. Two typical cases were cited and the plea made for early diagnosis, early surgery and for more thorough toilets to arrest peritonitis and sepsis.

Dr. Ernest Laplace said that cases of peritonitis die because of their coming too late to the surgeon. This he thought was more often the fault of the physician than the patient. Two distinct problems in Dr. Price's paper, he said, were peritonitis as produced by perforating typhoid ulcer, and diffuse peritonitis from other causes. An important point of difference between the two is that when a typhoid fever ulcer perforates the contents of the intestines that flow into the peritoneal cavity it is largely harmless at the time, as it requires a little while for the germs to become pathogenic. If such a case gets well the poison was local. It is quite a different thing to treat a foul peritonitis resulting from a gangrenous appendix or from the rupture of an appendical abscess that has gradually leaked into the abdominal cavity. The abscess cavity in particular and the peritoneal cavity in general, he believes, are best cleaned out with sterile water. The much-vaunted saline solution, he thinks, is objectionable on account of its irritating effect. The cleansing of the abdominal cavity should be continued as long as it is possible without detriment to the patient, and to effect this he carries out a plan of repeated irrigation. Temperature and pulse records, while valuable with reference to shock, give no indication of the necessity for operation. Operation should depend upon the general appearance of the patient. In washing out the abdominal cavity he avoids the use of gauze, using rather the smooth surface of glove or bare hand. While idodoform gauze is a great power for good in some wounds, in some it causes increased inflammation. If used at all it should cover only the spot that was the seat of the abscess, and should be separated from the rest of the cavity by the plain gauze.

Dr. John H. Gibbon does not believe the diagnosis of typhoid perforation easy, and he regards it as a great mistake to wait for the typical symptoms of perforation before the surgeon is called in. The most valuable symptoms to the surgeon in his opinion are localized pain and rigidity coming on suddenly. He agrees with Dr. Price that resection is hazardous. Anchoring the bowel, surrounding it with cofferdams of gauze, he believes is the best method. The element of time he regards of the utmost importance in these operations. In localized peritonitis he believes that thorough drainage is better than thorough irrigation, but generalized peritonitis demands complete irrigation. Admitting that salt solution may give pain when applied to the peritoneum he yet believes that it does do good.

D. B. F. Baer's experience with salt solution does not agree with that of Dr. Laplace. He has used it for the last few years and believes it nourishes the patient by filling the blood-vessels. There are less apt to be adhesions and the skin is in a better condition on account of the effect of the salt solution upon the kidneys.

Dr. Laplace explained that he said he believed salt solution would irritate in general peritonitis where from the washing there could only be expected a cleansing effect, and where the amount of the solution was insufficient to prove an antiseptic.

Dr. Edmund W. Holmes thought surgeons should agree that the four symptoms of pain, localized tenderness, abdominal rigidity and some interference with respiratory action are indications for operative interference.

Dr. R. P. McReynolds thinks the diagnosis in typhoid perforation particularly difficult. In general peritonitis from gonorrheal infection he sees no reason for operating in the acute stage. The temperature comes down to normal if the patients are kept in bed, given hot douches and treated by the expectant method. After this the pus tubes may be removed and the abdomen closed without drainage.

Dr. Price, in closing, said that no progress in medicine

had pleased him more than that of the modern clinician in the question of diagnosis. It is his experience that often the rural practitioner will make a more refined and accurate diagnosis than he personally is willing to make. In the packing of gauze too often there results bowel pressure. It should be placed not too low down, and not packed upon viscera paralyzed by peritonitis and overdistention. The cases of peritonitis which he fears the most are those of enormous distention. With reference to waiting for recovery from collapse, or for reaction practised by early operators, Dr. Price believes surgery to be a very good treatment for shock.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Stated Meeting, held March 17, 1905.

Dysentery of Children.—Dr. J. H. M. Knox showed the pathological specimens of some children who had died with severe forms of this condition. So-called "summer-complaint" included, he said, three groups of cases; (1) intestinal indigestion, following a gross dietary indiscretion; (2) gastro-intestinal intoxications, in which nausea, vomiting and toxic features were prominent; (3) enteritis or ileocolitis, in which marked membranous ulcerative or other lesions were present. The first specimen was from a child who had an ordinary dyspeptic diarrhea with mucoid stools. After a time blood began to appear in the movements and nausea and vomiting became marked. There was also fresh blood in the vomitus, though the lungs were negative. The course was down hill and death occurred in asthenia. Widal had been negative. At autopsy discrete, punched-out ulcers were found throughout the intestine but ceasing entirely above the ileocecal valve. Cultures for typhoid and for dysentery bacilli were negative. The second patient was a baby of three months, who was admitted in collapse from some gastro-intestinal trouble. Some improvement followed treatment but death soon occurred in asthenia. Marked pyuria had been present and great numbers of colon bacilli were found in the urine. Autopsy showed caseous glands at the base of the lung and tubercles on the pleura. Three feet above the ileocecal valve was a pseudomembrane lining the entire gut, from which dysentery bacilli were obtained. The third patient had had mucoid stools for several weeks and at autopsy showed a membranous leitis from which dysentery bacilli were obtained. In the fifth case dysentery had been present for two weeks, the stools showed tubercle and dysentery bacilli and there were signs in the lungs. The bowel showed undoubted tuberculous ulcers besides others in the sigmoid and rectum thought to be probably dysenteric.

Hyperpyrexia in an Infant.—Dr. Mitchell reported this case. The child had been born healthy and was put at the breast, the mother, however, failing to lactate. On the third day the child's temperature was 100° F. on the morning of the fourth day 103° F., and that evening 106.6° F. In absence of the other signs a diagnosis of inanition fever was made and under milk feeding and baths the child made a good recovery. The moral of the case was that whenever a breast-fed child shows inexplicable fever inanition should be thought of.

Measles in an Infant.—This patient, reported by Dr. Mitchell, showed fever, coryza (lacrimation) and râles on the seventh day after birth, and a few days later a typical measles developed, without Koplik's spots. Infection probably developed on the day of birth and was pretty definitely traced to a shawl in which the child was wrapped and which had been used on a measles patient nine months previous.

Rheumatic Purpura.—Dr. Watson briefly reported three cases of this disease occurring in a single block. Dropsical symptoms were present in all.

BOOK REVIEWS.

THE DISEASES OF SOCIETY AND DEGENERACY. By G. FRANK LYDSTON, M.D. J. B. Lippincott Co., Philadelphia and London.

THE title which Dr. Lydston has given his book implies a wide range of subject, an implication abundantly fulfilled. In these days when the social idea is so prevalent, the qualifying phrase "of society" appended to a noun is rather expansive than limiting. Consequently we need feel no surprise to find a book with this inscription comprising studies in evolution, criminology, psychology and everythhing else that can be considered as bearing on the problems which menace society.

The author has collected a large quantity of data on his subject or rather subjects, both from observation and from literature, and has presented it with a literary style which is strikingly vivid, and, if the adjective be not out of place in so serious a subject, entertaining. No doubt it is inevitable that one who feels as strongly as Dr. Lydston evidently does on these matters and has at the same time the gift of swift epigram, rounded period and thrilling climax should use them lavishly; but although his handling certainly makes the book attractively readable, one is tempted to question whether its ultimate effectiveness might not have been furthered by a rather different tone. These matters need thinking of, certainly, doubtless also need talking of as a fruit of the thinking and an aid to further thinking, but both thinking and talking need a dispassionate and judicial attitude, and even while we feel ourselves swayed by brilliant rhetoric we distrust, perhaps unjustly, its deftly phrased and confident conclusions.

THE OPEN-AIR TREATMENT OF PULMONARY TUBERCULOSIS. By F. W. BURTON-FANNING, M.D. Cantab., Physician to the Norfolk and Norwich Hospital, Honorary Visiting Physician to the Kelling Open-Air Sanatorium. Cassell and Company, Ltd., London, Paris, New York and Melbourne. W. T. Keener & Co., Chicago.

THIS little volume has on its title page a quotation from Sir Thomas Brown, the distinguished author of the Religio Medici, which serves to show very well how long ago thinking men more than suspected that the open-air treatment of tuberculosis was the ideal. In a letter to a friend, Sir Thomas said:

"Some think there were few consumptives in the old world, when men lived much upon milk; and that the ancient inhabitants of this island were less troubled with coughs when they went naked and slept in caves and woods, than men now in chambers and feather beds." This quotation is an excellent index of the suggestive value of this volume. There is scarcely any phase of the subject of pulmonary tuberculosis threadbare, though it apparently has been worn by writers in recent years, which does not take on an air of newness under Dr. Burton-Fanning's hands. Even the most veteran advocate of modern phthisio-therapy is sure to find something of value in the reading.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 87. NEW YORK, SATURDAY, AUGUST 26, 1905. NO. 9.

ORIGINAL ARTICLES.

APPENDICOSTOMY AND CECOSTOMY IN THE TREATMENT OF CHRONIC COLITIS.[1]

BY WILLY MEYER, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND TO THE NEW YORK INFIRMARY.

IF in cases of chronic colitis and sigmoiditis internal medication and high medicinal irrigations have proved ineffectual, surgical means are indicated. Two methods are then at our disposal:

1. Temporary exclusion of the diseased part of the intestinal tract, by establishing an artificial cecal anus. This prevents absolutely all contents of the intestinal tract from coming into contact with the diseased mucous surface, and at the same time permits of the use of this artificial stoma to flush the colon.

2. Cecostomy or appendicostomy, *i.e.*, establishing a water-tight or at least but slightly leaking entrance into the very beginning of the large intestine for the sake of irrigation only, allowing the intestinal contents to run their usual course.

An artificial cecal anus invariably proves a great annoyance to the patient, principally on account of the intestinal contents being still liquid at this place; furthermore, a second operation is required for its closure. Hence, it stands to reason that neither surgeon nor patient will select this method until either of the simpler procedures, viz., cecostomy or appendicostomy has been tried. It is the latter two operations of which I shall briefly speak this evening.

Since October, 1902, I have made use of appendicostomy for obstinate chronic colitis, amebic as well as ulcerative, in four patients, and of cecostomy in one, a man in whom the appendix seemed of too small caliber to permit of thorough flushing.

Case I.—P. S., male; aged twenty-nine years; with multiple papilloma of the rectum, perhaps on basis of old specific disease. Entered hospital on May 2, 1902. Left inguinal colostomy according to Schede was done by one of my associates on July 10, 1902. On August 20, the rectum was resected with the help of the osteoplastic method of Rehn-Rydygier. When first seen by me in September, 1902, the wound was slowly closing; a posterior rectal fistula had become established at the site of the sutures. Further examination revealed a number of ulcerations and recurrent papillomata in the neighborhood of the internal opening of the fistula. The patient asked that the fistula be closed. Hence, on December 1 the osteoplastic flap was again turned back and a partially necrotic piece of the sacrum with coccyx removed. A large fistula, allowing the tip of my forefinger to pass, was found at the site of the suture. In order to reach the same it became necessary to make an additional resection of the sacrum, removing about one-half inch of it transversely. Then the fistula could be closed with a double row of chromicized catgut sutures, after freshening the edges. So far as the fistula was concerned, the patient did well; but retention of urine set in, due probably to some injury to the nerves of the bladder. The patient's general condition gradually improved, although he had to be catheterized at regular intervals daily. Eight months later he again passed his water voluntarily, having complete control, an occurrence well worth remembering. In course of time the inguinal colostomy wound became strictured, so that a second colostomy, somewhat further down, was performed by my colleague. After a time this new opening also began to functionate poorly. I personally have seen stricture of an artificial anus occur in syphilitic subjects only. This observation induced me to think also of specific disease in this case, although the previous history did not support such assumption and my colleague had found a papillomatous condition of the rectum at the time of the first operation.

When I resumed service at the hospital, in May, 1903, I found the patient much reduced, suffering from frequent diarrhea and hemorrhages. Appendicostomy was done on June 13; intermuscular incision, as usual. The appendix was long and thick, kinked in its middle by a band, and in a state of chronic inflammation throughout. After ligation and division of the mesoappendix in its distal half, the organ itself was fixed so that its base corresponded to the wound in the parietal peritoneum; continuous suture of the latter, running around the appendix, thus shutting off the peritoneal cavity. The abdominal wound having been closed in the usual way, the appendix projected about 1½ inch above the skin in the middle of the sutured wound; it was amputated and probably a little more retained than was necessary; it was found permeable. A bowknot was used to close the opening for twenty-four hours. The next day irrigation was commenced, solution of nitrate of silver 1-10,000, soon increasing in strength, and thymol 1-1,000 being used, alternating daily.

The patient's condition began to improve at once. The irrigations generally took from fifteen to twenty minutes, the entire amount of

[1] Read before the Section on Surgery of the New York Academy of Medicine, April 7, 1905.

solution being, as a rule, passed within that time, although, on some occasions, water was discharged through the strictured artificial anus a few hours later. The catheter was not left in place, but introduced for each flushing. After five months' treatment in combination with an antispecific regime, the patient had gained considerably in weight, his local trouble was much improved. Still, he was much annoyed and depressed in spirits by the presence of the artifi-

Fig. 1.

Case I.—Appendicostomy for amebic colitis. Appendix was large and thick, amputated about one quarter of an inch above surface of skin. Note the eversion of mucous membrane, a condition that can be avoided by dividing the organ close to the skin.

cial anus which, in spite of two plastic operations, had the tendency to contract. I therefore resolved to exclude the lower portion of the bowel beginning at the middle of the transverse colon. On January 4, 1904, after excision of the umbilicus, the abdomen was opened in the median line, the transverse colon brought into the wound, divided, its distal end closed by a double row of sutures, the proximal end fastened to the skin, thus excluding the lower half of the colon. The lumen of the gut here was very small and contracted, its walls were distinctly in a state of chronic inflammation; no papillomata were seen. The flushing of the ascending and half of the transverse colon through the appendicostomy wound was now much simplified. The new artificial anus in the median line performed its function nicely. Five weeks later, the patient was subjected to the ninth operation, excision of the lower half of the transverse and descending colon being done. In course of the operation an intra-abdominal, encapsulated abscess, apparently due to a suppurating gland within the mesocolon transversum, was encountered. In spite of immediate thorough disinfection, this seems to have been the cause of a septic peritonitis to which the patient succumbed on the sixth day after the operation.

On reviewing this case, I cannot but regret that I did not wait somewhat longer with the last operation. The patient had at last reached a point where he was fast improving, his intestinal tract down to the new artificial anus being in perfect order, and had he been given another year, his resisting power would unquestionably have been greater and he would have had altogether a better chance.

Case II.—F. R., male; aged twenty-three years. Amebic colitis. Lived in Egypt and Turkey for some time. Had been on the medical division of the German Hospital for obstinate diarrhea for five weeks in the early part of 1904. Intestinal disinfection, high medicinal irrigations in the knee-elbow posture, etc., produced an apparent cure. On November 28, 1904, patient reentered the hospital on account of a recurrence of the trouble. The number of stools varied from five to fifteen per day, being mixed with mucus and blood; patient complained of frequent abdominal cramps; much rectal tenesmus; had lost considerable flesh and strength. Examination of the feces established the amebic nature of the disease. In view of the obstinacy of the trouble I was requested by the attending physician, Dr. I. Adler, to perform appendicostomy.

Fig. 2.

Case II.—Appendicostomy for tuberculous colitis. Fistula is flush with skin; scar of latter appears broad toward Poupart's ligament on account of subcutaneous and subfascial suppuration, that had set in after retraction of stump of appendix below fascia of external oblique muscle, necessitating a short transverse incision downward. The organ must always be stitched to the skin by special sutures.

which was done on December 8. Intermuscular incision. Appendix well-formed, slightly thickened. Continuous suture of peritoneum, surrounding base of the organ. Ligation of distal part of meso-appendix down to the middle of the organ. Then typical layer sutures, appendix being made to emerge through the middle of the wound; finally a fine catgut suture on either side catches the appendicular wall and skin; bowknot ligation; division of the appendix with Paquelin's

cautery, about one-quarter inch above the surface of the abdominal wall. Removal of ligature after twenty-four hours; dressing of wound. Three days later a soft rubber catheter, No. 14 French, was easily introduced. Regular flushing of colon from this time on, nitrate of silver solution of increasing strength soon exchanged for a solution of sodium bicarbonate two per cent. and thymol, being used alternately, mornings and evenings. Improvement rapid; patient soon out of bed. Quite a large-sized tube can be easily pushed into the cecum. It is always removed after irrigation and a strip of gauze is introduced into the appendicular canal to prevent leakage. After five weeks of treatment irrigations are temporarily suspended, the patient feeling very well; examination revealed no ameba. A few weeks after this, in the latter part of February, the diarrhea suddenly returned and microscopical examination then showed the continued presence of the infecting agent. Flushing was resumed, twice a week, with thymol 1-1,000 and nitrate of silver

Fig. 3.

Case III.—Cecostomy (Kader-Gibson). Tube must be worn continuously in the fistulous tract, in order to avoid rapid contraction.

1-20,000. The amebæ again quickly disappear. To-day the stools are regular, once daily, well formed, ameba absent, general condition good. The fistula represents a large opening, projecting above the surface of the skin with some ectropion of the mucous membrane (see Fig. 1). This will always occur in patients having a large appendix, especially if it is amputated somewhat above the skin, as has been done in this case. The patient is ready to have the fistula closed. Cauterization of the everted mucous membrane and of the canal itself, will, I believe, suffice to accomplish this.

Case III.—M. S., aged twenty-one years. Tuberculous, ulcerative colitis. Father's brother died of pulmonary tuberculosis. The patient entered hospital for chronic diarrhea, on November 29, 1904. Six months ago, he had noticed blood in his stools. The number of stools gradually increased until he had three immediately after each meal, and also after every exertion of any severity. No pain during defecation, except some rectal tenesmus. Tubercle bacilli were not revealed by the microscope. Blood is bright red and fluid. He has lost some flesh and strength; is coughing slightly; has an incomplete fistula in ano. Internal treatment having been of no avail, the patient is transferred to the surgical division, where, also at the suggestion of Dr. Adler, I performed appendicostomy on December 24. Intermuscular incision. Appendix large, is stitched with its base to the peritoneum; it is again grasped with the suture closing the muscle wound; it is however, not attached to the skin; catgut bowknot about half inch above surface of latter; immediate division of appendix with Paquelin cautery. Slight rise of temperature on the night following operation. Two days later, first change of dressing in order to remove bowknot ligature. Stump has disappeared. It has slipped below the border of the skin, producing suppuration. Skin opened; loose tamponade. Two days later, under cocaine, the outer border of the skin is transversely divided to the extent of about three-quarters of an inch, in order to bring the line of the division of the appendix up to the surface of the skin. In trying to ascertain the cause of this mishap, it was found after opening the skin, that the line of division of the fascia of the external oblique muscle did not exactly correspond to that of the skin incision, the latter being about one-eighth inch further toward the umbilicus. This shows the importance of having the two incisions correspond exactly when doing appendicostomy. The accident further teaches the necessity of stitching the skin to the appendix itself.

The further observation of this case has given me a great deal of satisfaction and pleasure. At first we flushed the colon regularly with saline and a very mild solution of bichloride. However he did not do well under this treatment, had frequent pains and twice had a rather alarming intestinal hemorrhage. We then treated him on a strictly antituberculous basis, washing the bowel with saline solution first, then injecting pure balsam Peru, ½ oz. and iodoform emulsion, alternately. Internal administration of small amounts of tincture of laudanum to control the painful peristalsis; increasing doses of creosote internally; carefully selected diet; rest in bed. Under this treatment he has done wonderfully; the appetite has returned, the former profound anemia has improved; his diarrhea has ceased, stools occurring twice daily, being often formed; he has materially gained in weight; is out of bed. Entrance into appendix flush with skin, narrow, closed by a strip of gauze, no leakage (Fig. 2). At present, three months after the operation, rectoscope proves, however, the continued existence of the disease, at least in the lowest portion of the bowel, where the typical picture presents itself to the examining eye.

This case very nicely shows that even ulcerative colitis due to tuberculosis, this most rebellious and hopeless form of the disease, can be materially improved (if not perhaps even cured

in course of time), by flushing the colon. We shall certainly continue the treatment and keep the patient at the hospital as long as there is improvement.

Case III.—C. P., male, aged thirty-five years, admitted to hospital in November, 1904, on account of painful diarrhea. Has had diarrhea for the past three years; stools contain blood, pus and mucus. Has lost considerable flesh. This patient, too, has lived in southern countries for many years. No ameba are found. Rectoscopy shows a great number of disseminated ulcers throughout the entire rectum, presenting protruding granulations which are covered with muco-purulent deposits, a mucosa much inflamed. Usual treatment besides injections of mercury and internal administration of iodides bring relief; patient leaves hospital. Read-

Fig. 4.

Case IV.—Appendicostomy for specific colitis. Small fistulous appendicular opening in lower half of scar, persisting for two years and a half, without noticeable discharge or leakage. It is situated exactly within surface of skin, and admits No. 14 French scale after stretching.

mitted January 12, 1905, in great distress. Operation January 14: Intermuscular incision. Appendix adherent to cecum; very small; partially obliterated, therefore, could not be made use of. Amputation; inversion of stump. Cecostomy according to the Kader-Gibson method with a double row of silk sutures, well inverting the tube, which is fastened to the gut with a special catgut stitch. The second layer of inversion sutures are used to attach the visceral to the parietal peritoneum. Layer sutures of abdominal wall. Fascia nicked in its center, externally, to make way for the tube, which is stitched to the skin with silkworm gut. Careful irrigation from that time on with nitrate of silver and thymol solutions. The latter is not well borne, causing rectal burning and abdominal pain. The tube is worn continuously in order to avoid premature spontaneous closure of the cecal fistula; it fits watertight. (Fig. 3.) To-day the patient has much improved; he wishes to leave the hospital and return to work. He will be advised not to remove the tube, but to faithfully continue the irrigations at home, as rectoscopy, done a few days ago, still shows a few small scattered granulations, protruding above the otherwise normal mucous membrane.

Case IV.—C. N., female, aged fifty-three years. Patient had suffered from frequent diarrhea and pain for last two years; three months prior to her admission to the hospital in October, 1902, her symptoms had become aggravated. There were frequent, watery, extremely painful evacuations of exceedingly foul odor, accompanied by bloody discharge. She claimed to have lost 60 pounds in weight. Rectoscopy showed the lower bowel covered with numerous ulcers and, above these, a cock's comb-like granulating mass on the anterior wall. The disease was apparently of specific origin. The entire large intestine was tender on palpation, which fact, together with the patient's history and the great loss in weight and strength, made it seem probable that similar ulcers existed throughout the entire transverse and ascending colon. Appendicostomy was decided upon. On November 8, 1902, the abdomen was opened by means of an intermuscular incision. A comparatively small appendix was found. It was drawn upward, in an oblique direction, until it emerged in the lower angle of the wound, its tip projecting about one-half inch above the skin. The border of the meso-appendix, close to the appendix proper, was fastened to the subcutaneous tissue by a catgut stitch. It was not ligated, but wholly retained. The cecum was not sutured to the parietal peritoneum. The wound, including the skin was then closed by a continuous catgut suture layer by layer above the appendix. Two small strips of iodoform gauze are pushed alongside the appendix through the fascia wound. After proper protection, the tip of the appendix is cut off and a bougie introduced, which seems to have to overcome a few slight strictures. The tip is closed temporarily with a bowknot of catgut, so as to avoid soiling of the wound. Twenty-four hours later the two small strips of iodoform gauze together with the bowknot are removed. A small Nélaton catheter then passes with comparative ease and is at once used for irrigation, after which the tube is plugged and left in place. Regular daily flushing of the large intestine through this tube, beginning with a 1-10,000 silver nitrate solution followed by saline, the strength of the silver nitrate solution being gradually increased. Later the flushing was done every other day and the ulcerations in the rectum as well as ulcerating hemorrhoids were attended to locally. Protracted antisyphilitic treatment was given.

When patient was discharged from the hospital, on the first days of April, 1903, three months after the operation, the cut end of the appendix

was flush with the skin. She had gained 28 pounds in weight and her general health was much improved. For a time the treatment was continued at home, every other day; on the days on which the colon was not flushed, she had spontaneous stools without mucus, pus or blood. As the patient had encountered trouble in reintroducing the tube, I advised her wearing it continuously, which proved entirely satisfactory. The irrigations were carried out in the following manner: The patient placed herself upon a bedpan and, with a fountain syringe holding two quarts and raised about three feet, began flushing; three minutes later the rectum usually started to act and the entire two quarts were passed in about ten minutes. Rectoscopy at this time showed the mucous membrane to be perfectly normal. No leakage was observed on removal of the tube. The small appendicular opening acted exactly the same as the artificial openings made in the gastro-intestinal tract by the methods of Kader and Witzel.

The patient was presented before the New York Surgical Society on January 28, 1903, and her case has been fully described in a paper entitled "Appendicostomy (Weir) for the Treatment of Chronic Ulcerative Colitis." (Medical News, June 27, 1903).

In January, 1904, fourteen months after the operation, the tube was definitely removed and treatment stopped, the patient being, to all appearances, cured.

I did not see her again until six weeks ago. She stated that she had been in splendid condition until the early part of February of this year, when the old trouble, frequent thin evacuations mixed with blood and pus, set in again. Visual inspection of the rectum showed the lowest part free from ulcerations; but further up they could be seen forming a bleeding circle at the site of that cock's-comb-like granulation above described. Colonic flushing seemed again indicated and I thought of doing cecostomy now. However, on examining the abdominal scar, I discovered a slight irritation at the lower angle of the same and, on pressing upon the abdomen, a minute amount of moisture appeared. On closer investigation I found that the appendicular opening had not closed entirely, but still allowed a filiform bougie to pass. (Fig. 4.) After some stretching I succeeded in introducing a tube, No. 14 French scale.

The patient is now back at the hospital for further treatment, where irrigation is carried out every day. This experience shows that in an appendix thus used, and operated on, the opening may persist without causing annoyance to the patient, as a safety valve in the true sense of the word. Of course, had I at the time of definitely removing the tube, applied the pointed Paquelin cautery to the appendicular canal, the organ would have become closed beyond question, and there would have been no choice but to do now an additional cecostomy which might have proved rather difficult technically. As it was, I congratulated the patient on escaping this. This case certainly shows the tendency of the trouble in question to recur, and teaches the wisdom of not enforcing definite closure of the appendicular opening at too early a date.

With regard to the technic practised in this particular case, it is questionable whether it would be advisable to adopt the same generally, excellent though the functional results have proven in this instance, for, the proximal end of an appendix that is longer than the line in which it passes the abdominal wall, will necessarily remain within the abdominal cavity. In view of the possibility of a later attack of appendicitis, it might, therefore, seem wiser, from a surgical standpoint, always to pull up the base of the appendix to the wound in the parietal peritoneum. Then the proximal part of the organ will rest within the abdominal wall where it can do no serious harm, the distal end being cut off.

Referring to the technic of the operation in general, it might be advisable to stitch the place where the appendix enters the cecum, into the upper angle of the wound in the parietal peritoneum and to allow the appendix to pass the abdominal layers in an oblique direction so as to emerge at the lower angle of the skin wound. This would provide continuous drainage of the appendicular canal by gravity and allow the surgeon to preserve a longer portion of the organ, which means increasing the distance from the appendicular fistula to the cecum. Such procedure might perhaps afford a better chance of guarding against leakage, although the slight annoyance from this source is easily obviated by inserting a strip of gauze into the lumen after each irrigation, or by making the patient temporarily wear a gently pressing truss with a rubber pad filled with water or glycerin. Outside of this, closure of the abdominal wound by means of continuous layer sutures is simplified by having the appendix emerge at the lower angle of the skin wound instead of in the middle.

If the appendix is large, leakage may be still further reduced by reversing the above mentioned technic, in so far as to make the appendix emerge at the upper instead of the lower angle of the skin wound, thus giving it an upward course. But in cases of a small-sized appendix I consider it better to have the organ run in a direction obliquely downward; for the frequent introduction or continuous wearing of the tube might injure the mucous lining just distal to the junction of appendix and cecum, and produce a traumatic stricture in the course of the following rather protracted period of irrigation.

The tip of the appendix is best cut off at the close of the operation, with knife or scissors, after the proper dressings of the wound have been applied. If the canal should then be found constricted and refuse to yield to stretching, it is still time to reopen the wound, amputate and

invert the appendix and do an immediate cecostomy. If, however, the canal permits the passage of a flexible bougie, a catgut ligature with bowknot will close the lumen for the first twenty-four hours.

These five cases nicely demonstrate the great value of colon flushing in the various chronic affections of the large intestine, catarrhal, tuberculous, specific and amebic. Of course, in cases of chronic catarrh due to the presence of multiple papillomata, there is not much benefit to be derived from the treatment. They, further, show the excellence of Weir's idea of utilizing the appendix for this purpose, disproving the fear entertained by many, viz., that irrigation through a small tube would be unsatisfactory. If two quarts of fluid introduced through a tube, 14 mm. in circumference, can be made to pass the entire large intestine within ten minutes, this is, I think, all that can be expected.

In view of the obstinacy of ulcerative colitis in its various forms, and its tendency to recurrence, too much stress cannot be laid upon the advisability of keeping open the communication with the caput coli for a considerable length of time, and of insisting upon a properly selected diet in conjunction with rational internal medication. Both must assist the salubrious effect of colon flushing.

In closing I would say that I consider appendicostomy the operation of choice in all cases of obstinate, chronic colitis. It is simple, safe and effective, and the same is true of the after-treatment. I would, therefore, give it the preference over cecostomy in all cases in which the appendix is passable.

A CONTRIBUTION TO THE STUDY OF CHRONIC NICOTINE INTOXICATION OF THE NERVOUS SYSTEM.

BY F. ROBBINS, M.D.,
OF NEW YORK.

"The survival of the fittest" in the attempt at accommodation on the part of nerve centers and peripheral nerves to the insidious effects of the active principle of tobacco, is probably the explanation of the comparatively scant consideration the subject has received in our leading textbooks on nervous disease, in their discussion of the chronic intoxications.

Theoretically, tobacco tolerance might be produced in either of two ways: (1) By compensation, through the formation of antitoxins in the organism, or (2) by a destruction of the poison through oxidation. In view of the fact that aggravation of minor symptoms due to the habitual use of tobacco is so frequently co-incident with suboxidation caused by independent factors, the latter hypothesis would seem the more probable one.

The derivation of the word nicotine is perhaps more universally known in France than in this country. The etymologist traces it back to the name of Jean Nicot, Seigneur de Villemain, French Ambassador in Lisbon, who lived in the second half of the sixteenth century, and was one of the first importers of tobacco into France. A French monk, who had brought the weed with him from Brazil, about 1556, made the first but unsuccessful attempt at culture in his native province. A few years later the Ambassador presented the ground powder to the Grand Prior in Lisbon, and to Queen Catherine de Medici, in Paris, as a remedy for her migraine. The therapeutical effects history omits, but we know that the queen was well pleased with the gift, that she became an inveterate smoker, and that the plant was commonly called the Queen's herb. Another and more prevalent name for it was Nicotiane. The name under which it was destined to descend through the centuries is of much disputed and unproven origin. "Nicotine" has survived as the designation of the active principle of the tobacco leaf, an acrid, volatile, colorless liquid, of pungent taste and penetrating odor. Chemically, nicotine is an alkaloid, distinguished by its entire lack of oxygen ($C_{10}H_{14}N_2$). The essential oil of tobacco consists almost entirely of nicotine.

The remarkable variance of living authorities on the tobacco question involves perhaps a problem of atavism; for the early enthusiasts seem to have met with a no less energetic tribe of relentless foes, each side recruiting from the ranks of kings, popes and physicians. A very complete historical sketch introduces the subject of nicotine and tobacco poisoning in a monograph published by Dr. Fonssard in 1876.[1]

The greater susceptibility of the male, as roughly representing the smoking half of humanity, to certain diseases of the nervous system, such as tabes, general paralysis, muscular atrophy type Duchenne, cerebral congestion, encephalitis, hypochondriasis, etc., has been ascribed to the indiscriminate use of tobacco, by one of its radical opponents.[2]

The extinction of sexual desire and the destruction of reproductive force is claimed by Solly[3] as an inexorable result of tobacco used in excess.

It is significant that the minor and decidedly unpleasant concomitants of tobacco indulgence, such as dryness of the throat, dyspepsia, laryngitis and pharyngitis, last, not least, nervous irritability along the individual lines of least resistance, do not prove a more efficient bar to persons bent on penetrating into the precincts hallowed to the full-fledged connoisseur. There is little doubt but that the secret of its hold on the user—we all know that it is not easily relinquished—lies in its retardation of the metamorphosis of nitrogenous tissues. Like alcohol, tobacco retards tissue waste; and that is after all what humanity instinctively craves for.

3 Lancet, February, 57.

A certain degree of tolerance for the alkaloid, physiological in the adult, is easily raised, by continued use, in the average healthy individual. Were this due to the formation of antitoxins the old smoker would become practically nicotine-proof. Unfortunately, this is far from being the case. Time and again, patients will come under observation whose symptoms permit but of one interpretation: Failure of accommodation to the toxin of tobacco, dating from the gradual development of suboxidation, so common at the time, "when the fires begin to burn low." On the other hand, many a hale and hearty octogenarian, generally an old tar, whose ruddy cheeks and bright eyes shine from sunrise to sunset through a cloud of "fragrant" smoke, loudly proclaims the fact that the seed of nicotine poisoning will not thrive in a soil thoroughly oxygenated and redolent with nervous vitality constantly renewed, irrespective of calendar reckoning.

The following histories of two patients are given as an illustration of what is meant by failure of accommodation on the part of the nervous system to the habitual absorption of the tobacco alkaloid:

Case I.—Male, aged fifty-one years; merchant; Spaniard. Has always been a moderate smoker, beginning at about twelve years of age. Never felt harmful effects. He came to Cuba when thirty-six years old, and soon fell into the continuous smoking habit of the country, substituting at the same time a stronger brand of tobacco. Never smoked more than eight or ten cigars daily. About this time he was married. He gradually began to develop nervous symptoms, such as uncontrollable restlessness, a tendency to introspection, a nasal tic, and especially a tremor accompanied by discomfort in the thumb of his left hand. This was so marked that it prevented him from steadying the writing paper on his desk. Patient attributed the symptom to the fact that his attention had been called continually to his hand by the apprehensions of his wife. At the age of seven years, the patient had been successfuly operated upon for a supernumerary digit; and the wife feared an eventual transmission of the congenital deformity to her unborn child. In trying to soothe her his mind naturally dwelt on this particular region, thus perhaps determining the manifestation of the nicotine intoxication to this part. He also suffered from a chronic nasal catarrh, a gastric dyspepsia, and an irritation of the mucous lining of the upper intestinal tract; had several attacks of mucous colitis. The symptoms persisted for thirteen years, with marked remissions. During this time, five children were born, none of whom inherited the deformity. After the last birth, an exceptionally difficult one, it was decided to limit the family. Patient ascribed his rapidly increasing nervousness, dyspnea, sometimes with irregularity or increased frequency of the heart's action, a tendency to nightmares, and a now well-marked tremor of both hands, affecting especially the two middle fingers, to the practice of coitus interruptus. In this view he had been confirmed by two physicians, who had also told him, in explanation of his palpitation, that he had "irritable sexual heart." Patient had not had syphilis, and had always abstained from alcohol. He was a man of youthful appearance for his years (51), except his hair, which is quite grizzled. Of the tall, spare type, not a superfluous ounce of flesh, but looks fairly healthy and well nourished. Eyes clear and rather brilliant, complexion sallow, tongue very red, skin hot and dry. Intermittent tachycardia (86-134). No palpable arterio-sclerosis. No arcus senilis. Pupils dilated. Patellar reflexes exaggerated. Mental condition good, except for a tendency to hypochondria. No complaint of failing memory. Genito-urinary system normal. Family history negative.

Patient came for advice on account of failing energy and self reliance. Had met with business reverses, and was anxious to work in order to improve the prospects of his family. He felt that he was not old enough for resignation, but appreciated that he was rapidly going down hill.

My diagnosis might have been neurasthenia (which should be made reluctantly only) in the evident absence of organic, or other functional nervous disease. The nicotine intoxication I might have overlooked, or at least underrated, but for an incidental remark of the patient's, bearing on his eldest son, a boy fourteen years of age, who claimed to become temporarily blind as soon as he smoked more than half a cigar at a time. This tobacco amaurosis on the boy's part led me to seek the source of the man's nervous manifestations in his continued use of tobacco, to which he had become intolerant by a disturbance of his nervous adjustment to the alkaloid. The results of treatment—gradual but not total withdrawal of tobacco, combined with certain medicaments—justified the diagnosis. Good effects were obtained from the use of the bromides and also the pulvis camphoræ in pill form.

Opinions differ as to the antagonistic action of strychnine and nicotine. (As a matter of fact, death is produced by either poison through paralysis of the respiratory apparatus.) In this particular instance, strychnine was contraindicated on account of its aphrodisiac effect on an individual already above par sexually in both desire and power. This state of affairs in an old smoker does not agree with observations made by Dr. Depierris, and published in his work on Social Philosophy, under the title of Le Tabac, etc.[1] None of his experiments, however, were carried out for a length of time sufficient to allow for the establishment of tolerance. Moreover, they were made on very young animals, while a *sine qua non* for nicotine accommodation is a fully developed and perfectly matured nervous system, with its infinite capacity for adjustment to extraneous influences.

1 Paris, Flammarion, 1898.

Case II.—Female, aged forty-six years; of Belgian parentage; married to a native Cuban. Family history negative. Began smoking at about fourteen years of age, in the convent school where she was brought up. (The use of tobacco is practically universal in Belgium and Holland.) Had learned the profession of lace-maker, but did not keep this up in Cuba, her trade being ruined by the competition of cheaper Spanish lace. She married and attended to her household duties, remaining in fair health, with the exception of a chronic dyspepsia, with flatulency and also diarrhea. Insisted that all her symptoms were invariably relieved by a smoke. She accordingly smoked nearly all the time, using cigarettes and cigars indiscriminately, and taking all that was offered from the cigar cases of her friends. Suffered from dyspnea and palpitation, whenever obliged to move rapidly, or mount a flight of stairs. Notwithstanding these symptoms and her digestive difficulties, she had always considered herself fairly well. The trouble began when occasion arose for her to demonstrate a complicated lace pattern for business purposes. She then discovered that her fingers trembled too much for her to throw the bobinets around with the fine accuracy needed in preventing the delicate threads from becoming tangled. Prolonged effort only aggravated the condition, and a renewed attempt after a good rest again met with failure. She then realized that the tremor antedated its accidental discovery by a period of about one year. Fearing "paralysis," she sought professional advice and presented herself for treatment. Patient was a fairly well built and nourished woman, looking about fifty-six years old. Face flabby and sallow. Pupils contracted; sclera yellowish; tongue coated; no tachycardia. Pulse 98. Some evidence of arteriosclerosis in temporals and radials. Area of hepatic percussion dulness increased. Skin all over body looked and felt greasy. Hemorrhoids. No gynecological examination. Patient believed herself pregnant, ascribing to this her attacks of nausea and diarrhea. (She already had a record of eleven children.) Patellar reflexes normal. Mental condition sluggish, but not apathetic. The general condition of the patient did not appear to warrant the diagnosis of fatty infiltration of the liver, although she did present some of the minor symptoms. On the other hand, the coarse tremor of both hands, taken in conjunction with the gastro-intestinal catarrh, the palpitation, and the dyspnea, were at least suggestive of nicotine intolerance developing as an accompanying phenomenon of deficient oxidation. The approaching climacteric could well be interpreted as a predisposing factor. The patient absolutely refused to entertain the idea of tobacco being the source of her troubles, but she consented to give it up for one month, as an experiment. Meanwhile she was given internally the sulphate of strychnine in pill form, and also citrated caffeine. At the end of seventeen days she reported entire relief from the palpitation, and a marked improvement of the diarrhea. For the first time in six years she had ventured to eat some tropical fruit, without disastrous results. The dyspnea persisted and so did the tremor. Her strychnine pills were increased in strength, until she took the thirtieth part of a grain three times daily. At the end of the month the tremor had subsided to such an extent that her hands again obeyed her will in the construction of the very intricate lace pattern. A slight remaining tremulousness and slowness of movement, as patient was readily made to understand, were referable to the disuse of years, and her ambition to win a prize in the lacemakers' contest assisted the treatment to such an extent that at the end of six weeks she could be considered as cured, so far at least as the symptoms were concerned which had begun to trouble her, and which would in all probability have multiplied, if the daily dosing of an organism laboring under imperfect oxidation had been allowed to go on to the complete establishment of nicotine intolerance.

In the selection of the above two histories, care has been taken to limit the discussion of chronic nicotine poisoning to individuals who had used tobacco for periods extending over thirty-one and thirty-nine years, respectively. During the maintenance of fair general health the adjustment of the nervous system to the alkaloid seemed perfect, or nearly so, whereas the phenomena of failing nervous vitality due to the absorption of nicotine came to the front as soon as an additional nox from within or without turned the balance-beam, as it were, and interfered with accommodation.

A SUMMARY OF TWENTY-FIVE RADICAL OPERATIONS UPON THE RECTUM UNDER LOCAL (STERILE-WATER) ANESTHESIA.[1]

BY A. B. COOKE, A.M., M.D.,
OF NASHVILLE, TENN.;
PROFESSOR RECTAL AND GENITO-URINARY DISEASES, MEDICAL DEPARTMENT, UNIVERSITY OF NASHVILLE; SECRETARY, AMERICAN PROCTOLOGIC SOCIETY, ETC.

It is not the purpose of this brief paper to present the literature of sterile-water anesthesia, nor to discuss the technic of the method; but rather, by a terse recital of personal experience, again to direct attention to the subject, and to emphasize as forcibly as the limitations of my vocabulary will permit, its surpassing practical importance to us as co-workers in the field of proctology.

When Dr. Gant read his essay before this body at Atlantic City last June,[2] as the majority of you will recall, it was received with open incredulity, and the very free discussion following consisted of little else than criticism. The writer confesses to having been both doubter and critic. But a few days' observation of the practical workings of the method in the hands of its originator quickly

1 Read before the American Proctologic Society, Pittsburg, May 6, 1905.

2 "Sterile Water Anesthesia in the Operative Treatment of Anorectal Disease," Medical Record, October 29, 1904.

brought conviction. Dr. Gant was doing exactly what he claimed—from the standpoint of freedom from pain even more than he claimed—both in his office and clinic. The question now was, could I do in Nashville what he was doing in New York? The doubt was inspired chiefly by the simplicity of the method. It looked too easy. But it was what I wanted and needed, and I determined to at least give the method an honest trial. The result appears in the subjoined summary of cases. I should observe, however, that some care was exercised in the selection of cases, particularly in my earlier experience. When conditions or complications of unusual severity were encountered, I preferred to operate under general anesthesia. Increasing experience has caused a corresponding decrease in the frequency of such choice.

The operations performed under sterile-water anesthesia may be grouped as follows: Internal hemorrhoids, 15; prolapsus ani, 2; anal fissure, 2; external hemorrhoids, 6.

Of the fifteen cases of internal hemorrhoids, one was operated at my office, five (out of town patients) at the hospital, three at my clinic, and the remaining six at the several homes of the patients. Complaint of pain sufficient to attract attention was observed in only two cases. One of these occurred in an anemic, hysterical young woman, who, judging from her vociferations, suffered more than all the others of the series combined. The pathology in her case consisted of a single medium-sized tumor, easily reached and quickly removed. I was impressed at the time, and in the light of later experiences am convinced, that her suffering was largely psychic.

The other case attended by pain was met with in an old gentleman sixty-five years of age, of nervous temperament and unstable mentality, who also probably exaggerated the extent of his suffering. The pathology in this case, however, would have rendered it a severe test of the method in a more favorable subject. The tumors, four in number, were of long standing, unusual in size, and composed largely of fibrous tissue, rendering complete distention difficult and necessarily more or less painful. This patient had endured his condition for more than one-third of a century rather than submit to chloroform or ether. When he came into my hands general anesthesia was positively contraindicated by the constitutional conditions present.

The ligature operation was performed in all of the fifteen cases. The time required for each operation averaged about ten minutes. The number of tumors removed varied from one to five, average three. The average time of confinement to bed was less than two days. The average period of detention from business was approximately five days. After pain in all cases was practically eliminated with the exception of the few hours immediately following operation.

The fifteen patients comprising this group are numbered among the stanchest friends and adherents I have made in an active practice of almost as many years.

The two cases of prolapsus ani were the results in both instances of vicious cicatrization following fistula operations. The offending mucosa was ligated in segments and cut away. One patient was operated on at my office, the other at her home. The pain in both cases was trivial; results satisfactory.

It was only after closely observing the action of the sterile water method in a number of internal hemorrhoid cases that I could persuade myself to try it in lesions involving the more sensitive areas, *i.e.*, fissure and external hemorrhoids. Its action was equally as beneficent and satisfactory in each of the eight cases composing these two groups. Some little momentary pain marked the insertion of the needle and the distention of the tissues, but the further steps of the operations were entirely painless in every instance. Incision was the operative procedure resorted to in the fissure cases. Five of the six external hemorrhoid cases were of the thrombotic variety and were treated by incision, evacuation of the clot, and packing. The sixth case was a hypertrophied skin tag, treated by excision.

From the foregoing series of cases I feel warranted in drawing the following conclusions:

1. The method is simple, safe and effective.

2. Pain at the time of operation is so rarely encountered as to be exceptional.

3. Postoperative pain is inconsiderable—less by far than after the old methods.

4. Confinement to bed and detention from business are reduced more than 50 per cent.

5. Operations under this method are practically bloodless and secondary hemorrhage could scarcely occur except as the result of faulty technic.

6. It offers a reliable means of extending the benefits of surgery to a large class of cases which otherwise would be unsuitable for operation.

7. It robs these operations of their terror. Patients will consent readily and eagerly to a radical procedure, if only they can escape chloroform and ether, and even in the exceptional case where some pain is inflicted, will invariably express genuine gratitude at having been spared the customary dreaded ordeal.

In connection with the above several points, the crowning advantage of the sterile-water method should again be noted and emphasized, namely, that while doing away entirely with general anesthesia, with all its discomforts and dangers, it involves no abandonment of principle or sacrifice of thoroughness with reference to the operation performed. Even if the pain were uniformly considerable and the period of convalescence increased instead of diminished, this feature alone would mark the method as a distinct and noteworthy improvement, and should assure its welcome by surgeon as well as patient.

Summing up my personal experience with the sterile-water method, I would say that it has been

satisfactory beyond my fondest hopes. No accidents or complications of any kind have been encountered, and the results in every instance have been all that could be desired. If the promise of the past seven months' experience with the method is borne out in the future, I shall hope to extend its field of application until general anesthesia in rectal surgery in my hands becomes the rare exception instead of the general rule.

The truth is, Mr. President and fellows, that the great majority of the more common lesions of the rectum and anus properly belong to the domain of minor surgery. Among these lesions internal hemorrhoids is undoubtedly the one most frequently encountered. Speaking for myself, after an experience of more than three hundred operations for this malady under general anesthesia, I do not hesitate to say that, if the limitations of the sterile-water method were such as to restrict its employment to internal hemorrhoids alone, I should still regard it as one of the most signal advances which rectal surgery has ever made.

PRESIDENTIAL ADDRESS: THE INSANE IN CANADA.

BY T. J. W. BURGESS, M.D.,
OF MONTREAL, CANADA.

(Continued from Page 357.)

Instead, let me call your attention to another topic, briefly referred to by Dr. Blumer, in the line of prevention of the increase of insanity—the exclusion of defective immigrants. I do so for two reasons. Firstly, because during the past two years the influx of strangers into Canada has been so enormously increased; and secondly, because Canadian immigration laws, being much less stringent than those of the United States, our land is being flooded by a class of degenerates, many of whom, if not already insane, soon become so.

That a country so vast as ours should be much more densely peopled is a "consummation devoutly to be wished," but the question of number, desirable as it may be, is secondary to the character of the people who are being added to our population. The sturdy agriculturists and artisans of the British Isles, healthy alike in body and mind, always furnish a welcome addition to our ranks, but unhappily quite a large number of the immigrants brought to us are of a low standard of mentality, some of them even having been inmates of asylums before coming to this country. Such a condition, amid new environments and under new conditions of existence, is almost sure to lead to mental strain and insanity. The result is that these incompetents, many of them consisting of the scum and dregs of an overcrowded European population, are crowding our provincial hospitals, especially those of Ontario, Manitoba and British Columbia, to which provinces immigration has been largest, and those contiguous to large seaports, such as Montreal. Most of our institutions have a larger *percentage* of foreigners than is found among the native population, and while the greater number of the foreign-born inmates are legitimately there, having broken down mentally after they had earned a residence, there is in every asylum a proportion who should never have been brought to our shores. Some of these have come of their own accord, but it is evident from the statements of the patients themselves that in certain cases parochial boards, benevolent societies, municipalities, and even relatives, have sent out persons simply as the cheapest way of getting rid of them. The cost of a ticket is small compared to a lifetime's maintenance in an asylum, a poorhouse, or at home. The late Dr. R. M. Bucke, in giving his evidence before a Commission appointed to inquire into this subject, thus forcibly and truthfully expressed himself: "There are associations formed in England for bringing out to Canada what are called gutter children from the slums of England, Scotland and Ireland. Thousands are brought out by these organizations. This is scandalous and should not be allowed to go on. These people might as well collect smallpox and typhoid fever and send them out. It is just adding so much more to the number for which we have to provide, because so many of them are degenerates." But a few months ago it was proposed in London to form an organization for the emigration on a gigantic scale of British pauper babies and young children, and a meeting was convened at Mansion House under the auspices of the Lord Mayor, to discuss the subject. Canadians generally and naturally object to the establishment of British workhouse farms in Canada under the control of British poor law guardians for the reception of English foundlings, and, I am thankful to say, the Canadian Government withheld its approval of the scheme.

As typical of the class of persons sent out by their friends to get rid of them, let me read you a description of a batch of these defectives who had become hospital residents and were deported to Liverpool. It is from a report of the asylum in British Columbia, where this custom has been very common, I suppose, on the principle that the farther away a ne'er-do-weel is shipped the less likelihood of his return. "All these cases were illustrations of a practice too much in vogue in Great Britain, of shipping off to the colonies weak-minded young persons who are unmanageable at home, and unable to make a career for themselves, or earn a livelihood there. 'He has continued his wild and reckless conduct, and has now been shipped off to the colonies,' is a phrase made use of in the *Journal of Mental Science*, in a description of a case of the kind now in question. But if a patient of the sort here described is unable, with the assistance and supervision of his friends and relatives, to steer a straight course and make a position for himself in the Old Country, still less is he likely, when left to himself, to be able to cope with the strug-

gles and difficulties of Colonial life. Of the five cases above mentioned, in one the patient was of feeble intellect and the insanity strongly hereditary, in another the patient was obviously weak-minded originally, a third was a pronounced epileptic with consequent mania, and two others, a brother and a sister, suffered from strong family taint. The brother had been previously for three years in an English County Asylum, and the sister had suffered from an attack of insanity before coming out here. The brother had only been four days in the Province when he again became insane and was sent to the asylum. He was two years and one month in the Province, the whole of which time, except four days, he spent in the asylum at Government expense.

"It is hard upon the Colonies that the mother country should 'ship off' these waifs and strays, these victims of 'borderland insanity,' to become, as they almost inevitably must do, when thrown on their own resources out here, confirmed lunatics, who have to be maintained at the expense of the community."

That Canada is being made a "dumping ground" for the degenerates of Europe it needs only a glance at our general and asylum statistics to show. Few, however, realize the extent of the burden thus imposed upon our charities. Only those whose duty brings them in contact with the defective classes can fully grasp how urgent it is that greater restrictions should surround the admission of undesirable immigrants. Even conservative England, which has always prided itself on being held wide open as a refuge for the poor and oppressed of all nations, is becoming aroused to the necessity of raising a barrier against unrestricted immigration. The evils have become so palpably evident there, during the past few years, that the average Briton, once heartily in favor of admitting any and every one to his country, is now crying out against it, and the last Royal Commission on Alien Immigration, which was appointed in 1902 and presented its report last autumn, recommended the establishment of an immigration department, similar to that of the United States, for the purpose of debarring and repatriating "undesirables."

In proof that what I have said is no exaggeration of the ill-effects attendant upon immigration insufficiently safeguarded, let me call your attention to some figures bearing on the subject. By the census of 1901 the population of Canada was 5,371,315, the number of foreign born being 699,500; the total of the insane was 16,622, and of these 2,878 were foreigners. From these returns it will be seen that a little over thirteen per cent. of the general population—that is to say the imported element—furnished over seventeen per cent. of so-called Canadian lunacy. Stated in another form, if the native Canadians alone are considered, there is one insane person in every 339 of the population; while the proportion among the foreign element alone is one in every 243.

If further evidence were needed I would say that during the year 1903 there were admitted to Canadian asylums 2,213 insane persons. Of this number 1,726 were born in Canada. The remaining portion 487, representing 22 per cent. of the admissions, was foreign born. At Verdun, 2,048 patients have been received since the opening of the establishment, and of this number forty per cent. were of foreign birth. In the same institution there are at the present time no less than thirty persons, in a population of four hundred and sixty, who, if subjected to anything but the most cursory examination, would never have been allowed to set foot in the Dominion of Canada.

The cause of this load being foisted upon us is not hard to find. It lies in the laxness of our immigration acts which do not demand a certificate of good bodily and mental health from each person landing, and which limit the period during which such parties may be deported to one year.

No effort should be spared to relieve the Dominion of such an incubus, and the remedy is in our own hands. It consists in the passing of stringent laws providing for a full knowledge of the past history of every alien seeking our shores. The true place to prevent the coming of the dangerous immigrant is not at the port of entry but at that of departure. Each person preparing to emigrate to Canada should be rigidly examined by salaried medical officers, appointed by the Dominion Government, as to his mental fitness at the time of examination, and should also show proof that he has never been insane or epileptic, and that his parents have never been affected with insanity. If found to fulfil all the legal requirements, a sworn certificate, containing his full personal description and vouching for his mental and physical health, should be given him. Without such a certificate he should not be allowed to land, and the vessel bringing him should be obliged to take him back on its return trip at the expense of the owners. The health officers at our ports should, in addition, be clothed with authority to reject any immigrant on arrival if circumstances, developed during his passage, should demand it, and instead of one year, the period of probation during which an immigrant might be returned to his own country if afflicted with insanity, unless surely due to causes arising after his arrival, should be extended to two or even three years.

Doubtless such legislation would be bitterly opposed by steamship companies as tending to lessen the number of their steerage passengers, and by irresponsible emigration agents who send out every soul they can for the sake of the commission received on ocean and railway tickets. But the interests of the State should be paramount to such selfishness, and the Government should insist that Canada, while a hospitable refuge for the deserving poor, be not made an asylum for the diseased and defective.

Canadian requirements, speaking generally, are many. The most pressing, to my mind, are separate accommodations for idiots, epileptics, inebriates and the criminal insane; proper means for the segregation of the tuberculous; some provision for the temporary relief of friendless convalescents; and the abolition of political patronage in asylum affairs.

In the matter of proper and sufficient accommodation for idiots and imbeciles, Canada is wofully behindhand, there being in the whole Dominion, not a single institution for these classes conducted on the lines that modern science and experience have found most satisfactory and successful. In all the provinces, with the exception of Ontario, the feeble-minded, which is a generic term now used to include all degrees of idiocy and imbecility, if provided for at all, are housed in poorhouses and other establishments which provide for sane persons as well, or are mixed up with the insane population of the lunatic asylums. Ontario alone has attempted any adequate provision, and even she, from a spirit of false economy, has allowed a once promising institution to drift backward.

The care, training and education of the mentally defective is an accepted public duty, and should be undertaken by the State at public cost, at least to the extent of providing the necessary institutions and schools for their care and teaching.

Mere custodial care, even if provided in separate establishments, does not meet the requirements of the case, it being admitted by all who have made the interests of this class a life study, that any effort made in the direction of bettering their condition is useless unless a training school is combined with the custodial asylum. Surely it is just as essential to educate the imbecile as it is to educate the deaf-mute or the blind. To allow him to grow up without education or "habit-training," is simply to allow him to degenerate into a repulsive, helpless creature, often so brutal in his propensities that, for the protection of the public, he has to be placed in custody. Of the milder types, many of the boys commit crime and find their way to reformatories: the girls fall from the paths of virtue, become mothers, and bring forth children more feeble-minded than the parent. The education, however, as well as the method of imparting it, must be made to suit the incomplete mental organization with which we have to deal. Even the least weak-minded are generally unable to profit, to any extent, by the instruction of ordinary schools, and often they suffer unmerited hardship at the hands of teachers, who, ignorant of the mental defect, attribute backwardness to laziness or perversity. So well is this fact recognized that the public schools of New York, Philadelphia, Boston and Baltimore are organizing special classes for backward and feeble-minded children. Cognizant of the same thing, the Royal Commission on the Care and Control of the Feeble-minded, recently sitting in London, England, expressed the opinion that the provisions of the Defective Children's Act of 1899, by which the school authorities are permitted to compel the parents of feeble-minded children to send them to special certified schools for suitable instruction, should be made compulsory.

The ultimate aim and object in the teaching of the feeble-minded being to fit them, as far as possible, to become useful men and women, it necessarily follows that school teaching should be followed by manual training. Imbecile children, when they have acquired such elementary education as their limited abilities will permit them to assimilate, should be set to learn some useful trade, by the practice of which they may become at least partially self-sustaining. It is in the industrial departments of the large establishments for the training of imbeciles that one sees what the better class of these unfortunates is capable of learning, and what really good workmen many of them become under the supervision of patient and intelligent instructors.

It was the lack of manual training that constituted the great barrier to further progression in the Ontario institution, to which I have alluded as the only one of the kind in the Dominion. As early as 1872, Mr. J. W. Langmuir, then Inspector of Asylums, urged the creation of an asylum for idiots which should consist of two distinct departments, one a training school for young idiots, the other a custodial department for the safe-keeping of adult idiots who were unsafe to be at large. By the adoption of the second portion of Mr. Langmuir's scheme the Ontario Government established the first custodial asylum for idiots on the continent. Later, a teaching department was added, and for several years Dr. Beaton, the Superintendent, was enthusiastic in his praise of the good results attained. Ere long, however, he discovered that it would be impossible to secure any permanent benefit if manual training was not made to go hand in hand with mental and physical culture. Time and again he appealed to the Government for the provision of industrial instructors, but all in vain. In addition, his staff of teachers was reduced to such an extent that, in 1902, the training school had to be discontinued. In concluding his report for that year, Dr. Beaton says, "It is to be hoped that they (the schools) will soon be reopened with a capable staff of teachers and instructors, and that the institution and schools will not only be placed on the popular footing of years ago, but far in advance." I am sorry to say that this hope has not yet been realized.

With the reports that many imbeciles, after training, are independently capable of earning their own livelihood, I am not prepared to agree. Without continuous supervision little can be expected from them no matter how highly trained and educated they may be; their whole disposition and temperament, away from control, in the vast majority of instances completely negatives the

supposition. A few improvable cases may be rendered capable of earning a modest competence, but a few, and only a very few, are successful. In nine cases out of ten when such cases are said to earn their own living, it will be found that they have some advantages in the line of continued supervision. There can be no doubt, therefore, that it is the duty of the State to provide some means of permanent guardianship for these cases if friendless, and the need could be admirably met by the creation, in all institutions for the feeble-minded, of a separate department for improvable cases, who, after having undergone their period of training, could be drafted into workshops of various kinds, or do farm and garden work under the supervision of an inspector. In this way they could be made in a large measure self-supporting,—perhaps even a source of revenue to the State. The model institution outlined by Dr. W. W. Ireland, than whom we have no higher authority, would consist of three separate departments; a custodial department for the extreme and non-educable class; an educational department for those capable of being taught and trained; and a semi-custodial department for those whose education and training has been completed; these three departments to be distinct buildings at a moderate distance apart, but all under the same superintendence.

As respects special accommodation for epileptics, Canada is even worse off than she is in that for the feeble-minded, because, up to this date, no separate provision whatever has been made for them. Like the idiot they have either been kept at home, confined in poorhouses, or scattered through the various wards of insane asylums. Every principle of justice and humanity is opposed to the indiscriminate mingling of epileptics, lunatics and paupers, and Ontario, to her credit be it said, has already taken steps to right this wrong by founding an epileptic asylum at Woodstock. This, it is expected, will be ready for occupation during the present year, certainly not before it is urgently required, since, by statistics compiled by Dr. Russell, of the Hamilton Asylum, in 1893, there were at that date no less than 292 epileptics among 4,251 asylum residents, with probably more than double that number scattered through the country, a burden to their friends and a menace to the public.

The peculiarities and requirements of epileptics are such as to characterize them as a distinct class, for whose well-being separate accommodation is necessary. Only under such circumstances can they receive that special care in the way of occupation, diet and moral treatment that their condition demands; only in that way can we spare our insane patients the annoyance arising from the paroxysms of their disease, their irritability and the violent outbursts of maniacal excitement to which many of them are subject. That the insane epileptic is properly a State charge every person agrees, but the same cannot be said of those who are sane. Personally, however, I am of the opinion that all epileptics ought to be under proper care and treatment, and to a certain degree under control, and if these requirements cannot be supplied by the friends, then, both for the patient's sake and for that of the community in which he resides, provision should be made for him by the State. The boundary line between sanity and insanity in the case of most epileptics is a very narrow one, and our Provincial Governments would do well to follow the example of the United States, Germany and other countries where timely care of the epileptic often prevents his passing into the category of the insane.

According to the best modern authorities employment is a *sine qua non* in the treatment of epilepsy. Those in touch with epileptics all maintain that the fits tend to disappear during working hours. Dr. Spratling, of Craig Colony, is strongly of this opinion and states: "On holidays and on rainy days, when patients were compelled to stay indoors and could not engage in any occupation, the number of seizures was doubled." In this point of view the colony system undoubtedly offers the best mode of care for the victims of the "sacred disease." In colonies a variety of trades can be carried on to advantage, and, if a sufficiency of land be secured, floriculture, fruit-growing, and market-gardening, all of which are among the best forms of occupation for epileptics, both male and female, can be made sources of profit. In this way the colonists are enabled to contribute in some degree toward their own maintenance. Probably the most promising plan to meet all requirements, at least expense, is that advised by the Manchester and Chorlton Joint Asylums Committee, whereby one portion of a large estate is set apart for the accommodation of sane epileptics, another portion for those who are imbecile or insane.

The equity and wisdom of separating the criminal insane from those innocent of wrong-doing cannot be disputed. In Canada, however, we have no provision for such segregation, and the asylum authorities are obliged to receive not only all criminal lunatics but all insane criminals on the expiration of their penal sentences. The former evil, bad as it is, is dwarfed by the latter, because patients of this type, as a rule, retain all their criminal instincts and are among the most vicious and depraved of the human race. The presence of such patients in the wards of an ordinary asylum is a standing menace to the peace and discipline of the whole institution. In their sane moments, they never had the most distant ideas of the rights of property, and seldom placed any value on human life when it stood in the way of the prosecution of their criminal designs; when insane, these traits are intensified, because what little power of self-control they had is generally lost and the fear of punishment for their misdeeds is banished. The more an or-

dinary lunatic improves, the more easily he is managed, whereas the more rational an insane criminal becomes the more dangerous he is. If taunted by their fellow-patients, as is apt to be the case, such lunatics are prone to violence; in addition they are constantly making efforts to escape, and safeguards have to be provided against their accomplishing their purpose. In this way the innocent are made to suffer for the guilty, because we cannot fully carry out the modern idea which discourages the use of bars and locks, in fact everything that partakes of the nature of a prison. Many of the insane retain all their self-respect and object to associate with this class of patients, while their friends, quite rightly, feel it a grievous wrong to have their unfortunate relatives housed with men and women who have been deliberately guilty of crime, and who, while undergoing punishment for such crime, have been overtaken by insanity. Rockwood Hospital suffers most from this cause owing to its contiguity to the penitentiary, and its Superintendent, Dr. C. K. Clarke, who has long and strenuously protested against it, forcibly concludes his report for 1903, in these words: "People outside of institutions do not care to associate with instinctive criminals—there is no reason why the non-vicious insane should be forced to accept a companionship that would be repulsive in everyday life."

The following motion presented by Dr. Pliny Earle, and adopted by this Association in 1873, applies forcibly to Canada at the present day: "Resolved, That when the number of this class in any State (or in any two or more adjoining States that will unite in this project) is sufficient to justify such a course, these cases should be placed in a hospital specially provided for the insane, and that until this can be done, they should be treated in a hospital connected with some prison, and not in the wards or in separate buildings upon any part of the grounds of an ordinary hospital for the insane."

The former is undeniably the better plan, and, if Ontario be taken as an index to the existing state of affairs in the Dominion, there is certainly a large enough proportion of the criminal classes of the insane to warrant the creation of a special asylum for them. In 1899 there were in the asylums of that province no less than 77 criminal lunatics guilty of offenses but acquitted by the courts on the ground of insanity: the number of lunatic criminals would probably at least equal this; and there must be a large number of like cases in the other provinces. For the Federal Government to erect an institution for the reception of these cases, taxing the various provinces in proportion to the patients they send, would seem to me the best and most economical way to meet the requirements. Failing this, all such patients should be kept in the penitentiary asylums, which should be open not only to insane criminals, whether their sentences have expired or not, but to the criminal insane as well. Criminality alone should be the criterion for the separation of these people from the ordinary insane.[1]

For some years a conviction has been steadily growing in the minds of physicians and the general public that Canada is behindhand in the lack of any provision for the care and control of inebriates belonging to the lower ranks of society. In 1875 the Province of Ontario took steps toward providing for these unfortunates but the good intention was abandoned. To my mind there is no doubt that the custodial care and treatment of inebriates is a question of the gravest importance, and that the establishment and maintenance of a hospital for this purpose fall within the true sphere of the Government. The great barrier to the creation of such an institution has been the threadbare cry, the "liberty of the subject," but the rights of the individual should be subordinate to the rights of society. We are told that the inebriate by his drunkenness violates no law, and this may be so. But, are we, therefore, justified in allowing him to continue his debauchery until he commits a crime, as so many of them do, while many more are only by the merest accident kept from so doing? If a lunatic threatens suicide or the life of a fellow-citizen, we put the law in force and confine him, without, as a rule, waiting until he has made an attempt on his own life or committed a homicide. It should be the same with an inebriate.

The distinction between drunkenness and insanity has frequently been the subject of forensic investigation, but it is daily becoming more and more evident to the profession, and to some extent to the laity, that inebriety and dipsomania are diseases of the brain, resembling, if not in some cases constituting, true insanity. That an individual should in all other matters appear to be of sound mind, but that at certain times he should be subject to a morbid desire to reduce himself below the level of the beast by means of drink, is hard to grasp, but none the less true. Equally true is it, as shown by recent German studies, that the continuous use of alcohol to excess produces certain molecular changes in the brain cortex, which are apt to be permanent. The result is a lowering of the moral tone, a dulling of the mental powers, and a weakening of the will, which constitute an organized, progressive degeneration. Nor is the ill-effect of the excessive use of alcohol confined to the individual himself. There is strong evidence to show that the children of intemperate parents

[1] The following paragraph, published in one of the daily newspapers in January last, furnishes a striking example of the need of special provision for insane criminals: "Samuel Jarvis, who shot a Windsor policeman last week, escaped last summer from Rockwood Asylum, where he had been placed after his release from the Penitentiary, on the completion of a third term. The greater part of the past seventeen years has been spent by him behind prison walls. Until recently Jarvis was in the penitentiary insane ward. When the time of such prisoners has expired the law requires that they be placed in an asylum. This was done in the case of Jarvis, who was transferred from the penal institution on one hill of Portsmouth to the institution for the insane on the other. He had not been there more than a month before he decided to escape, and this he succeeded in doing. All attempts to locate him were futile."

inherit a marked tendency to intemperance, insanity, idiocy, epilepsy, or some other form of mental disorder. Such eminent authorities as Prof. Kräpelin, of Heidelberg, and Prof. Berkley, of Johns Hopkins University, agree in considering alcohol as a powerful factor in the production of insanity, the latter going so far as to say, in his work on mental diseases, "Of all the varied inciting causes of mental infirmities, heredity and alcohol are most important." Personally I would go still further and say that, in the majority of cases at least, inebriety itself is a mental disease,—a true psychological condition. If, as has been done, we define an insane person to be, "one who owing to perverted or deficient mental powers, the result of functional or organic disease of the brain, cannot adapt himself to his natural environment, and whose conduct is not in a sufficient degree guided and restrained by the ordinary safeguards of society," we include a large section of those at present known as habitual drunkards. But whether prepared to go thus far or not, I think there are few who will not agree that alcohol does much more harm in the way of producing mental degradation in the many who are never placed under care, than in the few who now find their way into asylums. Everyone is acquainted with men and women whose mental powers are so shattered by long-continued indulgence in drink that they have reached the borderland between sanity and insanity, even if they have not overstepped it.

To try to reform this class by any other means than personal restraint is "wasting our sweetness on the desert air." They must be placed in custody in an institution, the superintendent of which is clothed with authority to detain his patients for an indefinite length of time. In other words, the same policy in respect to their personal liberty should prevail, as now prevails in respect to lunatics. It matters not what the form of commitment be, provided it is statutory and means a definite and prolonged term of oversight and treatment. This treatment should be conducted in a special establishment where work of various kinds,—one of the best of remedies,—can be enforced after the necessary medical regimen has paved the way for it. In this manner the cost of maintenance would be greatly lessened.

As early as 1833, Dr. Woodward, soon after taking charge of the Worcester Insane Asylum, in Massachusetts, urged that inebriates be regarded as insane and sent to the asylum for special treatment, but this is manifestly wrong. To associate the ordinary lunatic with the inebriates, even if we consider the latter to be truly insane, is an injustice to both. In the words of Dr. Joseph Workman, "Inebriates are soon dissatisfied, and strongly disposed to magnify the causes of dissatisfaction which the discipline of an insane hospital unavoidably presents,—this dissatisfaction becomes contagious. One inebriate can upset the quiet and comfort of a whole ward."

In view of the declaration of modern science that tuberculosis is a communicable, preventable, and curable disease, the non-provision of proper means for separating the phthisical from the non-phthisical insane might almost be called criminal, and yet in only one of our Canadian institutions, Rockwood, is there any special arrangement for such segregation. In all the other hospitals the medical officers have to combat the plague as best they can by attending to cleanliness, disinfection, and the isolation of the affected as far as possible. So much, however, has been written on the subject of tuberculosis during the past few years that I shall not detain you with any detailed account of my own views on any of the points connected therewith, but content myself by saying that I doubt whether, owing to the rigor of our climate, the "tent treatment," so successfully practised by Dr. A. E. Macdonald, at the Manhatten State Hospital, East, would be practicable with us during the winter months. Instead, I would favor the erection of a separate, isolated building, to be used for tuberculous cases only, one portion of the structure being set apart for suspected cases, another for those in whom the presence of the malady in an active state has been positively established. Such a building should be frame, and constructed as inexpensively as possible, so that, if its destruction on account of infection seemed advisable, the loss would be slight.

An important problem confronts the superintendents of Canadian hospitals, as it does those of the United States, in the case of the discharge of friendless patients. This is the securing of homes and employment for them. Who of us but can call to mind cases where the discharge of patients, though fully warranted by their mental condition, has been delayed for weeks, even for months, because they had no friends who could or would take charge of them on their return to the world, no homes to go to, no employment awaiting them by which they could earn their bread? The average citizen seems to have a morbid dread of the poor unfortunate who has been insane, and utterly refuses to even think of hiring him, while his wife is equally resolute against engaging as a domestic any woman who has been an asylum inmate. To turn such persons adrift without means or help is virtually offering a premium for their return to the hospital, whereas, if given some slight assistance they might earn a fair living and not again become a charge on the public.

"'Tis not enough to help the fallen up,
But to support him after."

Criminals discharged from prisons and reformatories are helped and encouraged by Prisoners' Aid Societies, often, indeed, assisted by the State with gifts of clothing and money. Fallen women are taken in hand by societies with a view to their reformation. Orphans are housed, educated and clothed by the charitable. Only for the poor creatures who have emerged from the gloom of

dethroned reason is there no helping hand, no assistance of any kind. The best remedy for this pitiful state of affairs is to be found in the organization of "After-Care Associations for the Insane," such as exist in France (which country was the pioneer in this branch of philanthropy), Switzerland, Italy, Germany and Great Britain. These associations would have to be the outcome of private enterprise, because the Governments of the several Provinces have already as much as they can do to provide for those actually insane. Doubtless, however, if once started by private benevolence and brought to a successful issue, State aid would not be wanting to help the good work along.

Last but certainly not least of the wants to which I would call attention is the abolition of political patronage in the matter of hospital appointments and the administration of hospital affairs. The "spoils doctrine" which decrees that "office is a reward for political service," has done much to keep down the record of scientific work in Canadian hospitals for the insane. Merit has had little weight, especially in Ontario, as against "political pull," and the consequence is that almost two-thirds of our existing asylums are directed by superintendents destitute of special training prior to their appointment. That men taken from the ranks of the general profession do sometimes prove themselves admirable asylum officials, I do not dispute. But what I do maintain is that the principle is wrong. To subject the care of the insane to political purposes is a flagrant injustice to the patients, who should be afforded the best possible chance for recovery; to the tax-payer, who should receive the best value for the money he pays for their support; and to deserving juniors who are thereby debarred from all chance of promotion. Superintendents are made, not born, and it requires years of conscientious study to acquire a knowledge of how to deal satisfactorily with the manifold problems of psychiatry. Moreover, assistants generally take their cue from the superintendent, and if the superintendent be not specially trained for his work and take no active interest in it, his subordinates will almost inevitably lapse into routine. Nor can we blame them much that such should be the case. With no example set them, no prospect of advancement to cheer and encourage them to put forth their best efforts, what else could we expect?

Were the "spoils system" confined to the appointment of the heads of asylums the resulting ills would be lessened. Unfortunately it is not. Every medical office connected with our asylums, from the highest to the lowest, is regarded as "political pap" to be administered where it will do most good for the dominant party. Governments are unable or unwilling to grasp the fact that the scientific study of psychiatry consists primarily in the study of mental phenomena, and that this can only be done to advantage by men specially trained for such study. As a result, well-developed seniors, who have been failures in life, are often given the junior places that should be awarded only to young men who have shown interest in, and capacity for, original research. This is manifestly unfair both to the inmates of our asylums and the superintendents thereof. "Responsibility and authority must go hand in hand," is a time-honored axiom, but the system of governmental appointment of assistants furnishes the anomaly of superintendents, held responsible for the successful management of their hospitals, and yet deprived of the authority to appoint the officers upon whom such success in great measure depends. Surely a superintendent should be best capable of judging of the fitness and competency of his assistants, and it comports with common sense that he will, if only through self-interest, endeavor to procure the best he can find.

A vigorous editorial, "Insanity and Politics," recently published in the *Montreal Medical Journal*, deals so searchingly with the ills of political patronage in our asylum service that I may be pardoned if I quote a portion of it: "Most persons will admit unless they are incapacitated by congenital perversion, or political prejudice, that a hospital for the insane exists—pun or no pun—for the purpose of extending hospitality to the insane, and not to the protégés of a political party. In short, it is mental not political degeneracy which entitles an entrance to the enjoyment of such hospitality as it can offer. In Canada, there are to-day eighteen hospitals for the insane, and all but six exist for the combined care of the insane and the politicians. In twelve the present superintendents owe their appointment to influences other than their attainments in psychiatry.

"The answer which the politicians make to all protests is that the men who occupy the posts of assistants are not sufficiently qualified to become superintendents. This is partly true, and because it is partly true the case is the worse; because, if there are incompetent men among the assistants, it was the politicians who put them there. But the answer is inadequate, because, in spite of the politicians there are enough good men in the service to fill every vacancy which may occur during this generation. The wonder is that there are any remaining, when they have seen themselves passed over time and again by men whose attainments were unproven. The rewards of the specialty of psychiatry are small enough, and should not be filched away. The injustice is not chiefly to the men who have spent a lifetime in acquiring a knowledge of the insane, of their diseases and of their treatment; it is to the wretched insane themselves, who are deprived of that experience which might aid in their recovery.

"We yield to none in our admiration of the general practitioner. We are aware of his energy, his resource and his fidelity, but not even the general practitioner will lay claim to a capa-

city for treating off-hand and to the best advantage grave lesions of the eye and ear, or of the more secret parts of the body. He should adopt the same attitude toward the brain. In time it will come to be a shameful thing for a general practitioner to accept a position for which he is not qualified, since thereby he is committing a wrong toward his colleagues and toward his patients.

"The ideal service is that which prevails in New York. The superintendent is appointed by the Board of Management, and he must be selected from men who have served at least five years in an institution for the insane, and have proved their capacity and instinct for such work. The assistants in turn are appointed by the superintendents and they obtain advancement according to their merits, no step in advance being made unless the candidate has had previous experience in the specialty, and proved his fitness by passing an examination before promotion."

Nor is it solely in the way of appointments and promotion that our Provincial Governments have shown themselves remiss. The good men in the asylum service, and good men there be, are, in most instances, hampered by the want of proper equipment and the paucity of the medical staff employed. It is the duty of the State to aid in every way the attempts of its physicians to do scientific work. Only so can they be stimulated to keep pace with the trend of modern research in other countries,—only so can we guarantee that our patients will be under the care of ever-widening experience. Hitherto the governmental policy has been to provide little or no equipment for study, and so to limit the number of physicians that the greater part of their time is taken up with clerical duties. The numbing effect of such routine work is great, and might well make the average assistant adopt the words of Mr. Mantalini and pronounce life "one demd horrid grind."

Before we can properly enter on the study of psychiatry, as we ought to do, our governments must learn that to make a hospital a center of scientific research its physicians should be appointed from the best class of men; should be paid sufficiently well to free them from anxiety as to their future livelihood; should be certain of promotion if they prove themselves fitted therefor; should be assured of a retiring allowance, graduated on length of service, as is the case in England and other transatlantic countries; should be freed from an overburden of routine work; and should be provided with books, apparatus and assistance to properly pursue their researches.

Much more might be said on this and other subjects relating to the care of the insane in Canada, for example, the necessity of separate hospitals for acute cases and of pavilions connected with general hospitals, of nurses' homes, and of retiring allowances for medical and other officers, but I fear you will already have applied to me the old Spanish saying anent a tedious writer,—"He leaves no ink in his inkpot." I shall, therefore, no longer trespass on your forbearance, but content myself by saying in conclusion, that while with respect to custodial care and ordinary treatment, moral and medical, Canada, generally speaking, is well up to the times, she is doing little toward the solution of the many problems connected with the scientific aspects of insanity. In this respect she presents but a sorry picture when compared with the good work being done in many hospitals elsewhere. To stand still is to fall behind. The universal motto should be,—

"'Press on—' for in the grave there is no work
And no device.'—Press on while yet ye may."

THE NATURAL AND ARTIFICIAL PROTECTION OF MAN AGAINST TUBERCULOSIS.*†

BY F. FIGARI, M.D.,
OF GENOA, ITALY.

The faculty which the bacillus of Koch has of producing an infectious disease depends on many and various factors, which are represented on one hand by the property the said bacillus possesses, of multiplying and diffusing itself throughout the organism which shelters it, and of producing toxin, which has local effect at the point of development and generally throughout the entire organism; on the other, by the degree of resistance, congenital or acquired, which the organic cells present to the bacterium.

Very numerous are the ways by which this widely spread bacillus daily menaces the public health, and we must not have too much faith in the protection which the integrity of our teguments opposes to it; the skin and the mucous membranes show continually small cracks which may become ways of entrance. The tonsils by their anatomical structure are receptacles for the bacilli, which, in contact with the lymphatic elements, have easy access to the interior.

In the lungs, notwithstanding that the "Epitelie Vibratili" (ciliated epithelium) with its movements is the same tissue, it opposes a certain resistance to the invasion of the bacillus. Also these germs introduced by respiration into the alveoli are easily absorbed by the lymphatic glands, and that without any previous grave lesions of the alveoli.

The normal secretion of the stomach has no appreciable influence on the attenuation of the bacillus of tuberculosis, which, entering the stomach with the food, can pass unaltered into the intestines, where, whether by the great number of lymphatic glands, or by the wealth of fluid lymphatic elements, it finds more than anywhere else the most favorable conditions for the development of the disease.

The organism with its teguments does not

* From the Institute for the Study and Cure of Tuberculosis and other Infectious Diseases, Genoa.

† Read at First Annual meeting of the National Association for the Study and Prevention of Tuberculosis, Washington, D. C., May 19, 1905.

offer sufficient protection against tuberculous infection, and we have seen that there are many easy ways of entrance at the disposition of this terrible germ, which, widely diffused throughout nature, comes in daily contact with our skin. We absorb it into our lungs with the air we breathe; we introduce it into our stomach with our food; yet, notwithstanding the many and easy ways of infection, not every person becomes tuberculous, which proves that the body, in spite of the insufficient means of resistance of the teguments, possesses in its intimate nature specific defensive energies which prevent the bacillus from penetrating into the interior and from multiplying, and which neutralize the action of its secretions—substances antibacterial and substances antitoxic; substances which, acting together, constitute that phenomenon called immunity.

If, however, an organism endowed with these specific substances is exempt from a tuberculous infection of medium violence, it will not be so from an ultra-violent infection, and also it might, at certain moments, if the harmonious functions of its tissues be interrupted, find itself an easy prey to these bacilli, hence the great value of prophylactic rules, and of the hygiene of living and of alimentation, to protect it from tuberculosis.

If we think, however, of the immense number of tuberculous people who continually sow abroad the infectious virus by means of expectoration, and of the difficulties of the financial conditions with which the greater number of people are confronted, we find ourselves before an insurmountable barrier in our attempt to put these individuals in good conditions of life and alimentation.

Hygiene, food and air, potent and useful means of defense against tuberculous infection, are not, because of the actual conditions of society, rigorously applicable, and so we cannot depend absolutely on them in the struggle against tuberculosis. With time certainly, with the diffusion among the masses of hygienic rules, and with the financial amelioration of certain social classes, these defensive means will acquire greater utility. For the present we must depend on the organism.

The antitoxins, the antibodies, elaborated in the cells of our tissues, are the best means of protection against tuberculous infection, and their presence in a great number of individuals is perhaps the only reason why, with such a diffusion of virus, a great many people do not become a prey to the bacillus of Koch. To engraft these means of protection into the organism is, at the present, the surest means of fighting against tuberculosis, and the easiest method which is now at our disposal.

The bacillus of Koch penetrates into the organism, fixes itself upon an organ, where it develops and produces its special toxin, which has a local action, and also an action on the distant organs, disturbing and preventing the normal functions of the tissues, depriving them of their vitality and so predisposing them to excessive infection of the same, or even of a different nature. Not only the toxins, but also the dead bodies of the bacilli exercise a like deleterious action on the tissues.

It is to the neutralization of the action of this toxin that Maragliano first turned his attention by the introduction in therapeutics of a serum possessed of a high antitoxic value, obtaining as a secondary result also a bactericidal action, since the cellular elements having become insensible to the deleterious action of the bacterial toxins by means of these antitoxins, artificially introduced, can exercise their normal bactericidal energy, which is in all the tissues.

It is with this means that Maragliano in 1894 succeeded in rendering animals immune against experimental tuberculosis and combating vigorously human tuberculosis, if in a curable condition.

Maragliano afterward thought that besides these substances capable of neutralizing the bacterial toxins, one could inoculate with substances directly "bactericidal." One would have in the result of these means of defense that force of resistance which is called immunity.

Following his advice, and under his guidance, I, with Marzagalli, sought to obtain sera strongly bactericidal, injecting into animals the living tubercle bacilli; and we have observed that by making subcutaneous injections of this pulp of bacilli into rabbits, goats and cows, these animals produce in their serum large quantities of substances which combat the bacillus of tuberculosis. These sera are capable, *in vitro*, of preventing the development of the bacillus of tuberculosis.

In vivo, if one injects into experimental animals, rabbits, guinea-pigs, the bacillus of tuberculosis, supplemented by this serum, the animals do not contract the disease; while equal doses of the same bacillus, supplemented with physiological serum, give, in the same kind of animals, acute, mortal tuberculosis.[1]

The sera so prepared have a high protective and "immunizing" power.

Animals of different species, treated prophylactically with these sera become refractory to an excessive infection of tuberculosis by endovenous injection certainly fatal to animals not so treated.[2]

Hypodermic injections of this serum have a high specific therapeutic value in the tuberculosis of man and animals. Monkeys, which have become tuberculous normally, or by direct infection, are completely cured by it.[3]

Doctor Ricci has had most favorable results in patients affected with lymphatic tuberculosis, and with pulmonary tuberculosis.[4]

Doctor Ghedini has experimented on the action of these sera on experimental tuberculosis of the joints and has found that local in-

jections are capable of making the disease, already in a very advanced state, regress, even to a complete cure.[5]

Not only in the serum but in the corpuscles of the blood,[6] and in the milk drawn from these animals,[7] one finds these specific substances, which, administered by the mouth, become absorbed in the digestive tract and are capable of favorably influencing a tuberculous infection in man, even to complete cure.[8]

In animals, young or old, in healthy children or adults, administered by the mouth, they become absorbed in the digestive tube and excite in the serum of these individuals the formation of specific defensive means in such quantities that all the animals experimented upon when infected in the veins by doses of tubercle bacilli capable of killing in a very short time animals not so treated, victoriously overcome the infection.

As the result of these experiments, confirmed by other observers, whom for brevity I omit to quote, is shown the possibility we now possess of exciting in individuals who are poor, or absolutely without means, the formation of a natural protection against tuberculosis; a natural protection which we can produce by subcutaneous injections of serum obtained from animals treated with pulp of bacilli and with bacillary toxins; or by administering by the mouth milk or blood obtained from the same animals. Whichever be the means adopted, the results are about equal. By subcutaneous administration, the effects are more rapid, although in administration by the mouth these defensive energies very soon begin to show themselves in the serum.

In order to administer these specific substances to human beings by the mouth, the already mentioned experimenters and myself have used a preparation of the Institute for the Study and Cure of Tuberculosis much appreciated by physicians. This preparation, called "Emoantitossina Sofos," is only a solution of antitoxic and bactericidal substances which can be preserved indefinitely, and which by the addition of aromatic substances excites the gastric functions, and becomes very agreeable to the palate.

Having thus accepted the possibility of creating an immunity against tuberculosis, by administering specific defensive substances, I wanted to see if it would be possible to produce an active immunity in laboratory animals by injecting directly into the animals which I wished to render immune attenuated bacilli or bacillary extracts.

This second method of "immunization" is called by almost all the authors "active immunization," while the method first used is called "passive immunization. For convenience of diction one may use these expressions, though, biologically speaking, this distinction does not exist, because, even in the so-called passive immunity it is the organism which actively participates in the formation of defensive substances under the exciting and stimulating action of the antitoxins and of the bactericidal substances, which we introduce.

As animals for experiment I used six monkeys. In four of these monkeys I injected into the veins, in emulsions of physiological serum, a minimum quantity of very slightly virulent tubercle bacilli.

These monkeys did not show any local reactions whatever, nor general derangement. They had no fever nor did they lose weight. Three months after these injections, in order to ascertain whether these endovenous injections of bacilli, which had proved innocuous, had had a preventive and vaccinating action, I injected into the veins of these four monkeys, and also into the other two, an emulsion of the most virulent tubercle bacilli. All the monkeys contracted an acute tuberculous infection which brought them rapidly to death. The monkeys treated with the preventive injections died first, and then the others. At the autopsy all of them presented the characteristic lesions of acute tuberculosis.

Also rabbits, which I attempted to render immune with subcutaneous injections of attenuated bacilli, which were incapable of producing infection, and which did not provoke any reaction, local or general, showed no resistance whatever to experimental infection. Rabbits treated preventively, as well as others not so treated, contracted a diffused tuberculosis which killed them.

These experiments did not certainly authorize us to reject completely this method of rendering immune. It may be that new methods and great experience will show some utility in it. I, for the moment, must say that I have obtained no immunizing effect on monkeys or on rabbits. On the contrary, according to the results of my experience, these injections had an effect predisposing to infection.

In conclusion, I can now affirm that if we have not succeeded in immunizing animals against tuberculosis with living cultures, it is experimentally ascertained that we can produce this immunity by injecting subcutaneously, or administering by the mouth, specific substances taken from animals treated for that purpose. As serum, blood and milk have this property, certainly the flesh of these animals will possess it. These for the present are the sole means on which we can count for the cure of tuberculosis, by rendering immune the children of tuberculous people and individuals who are predisposed to it. It is only by widely practised preventive immunizing that we can hope to stop the spread of tuberculosis.

DERMOID CYSTS OF THE MEDIASTINUM.

BY ROGER S. MORRIS, A.B., M.D.,
OF ANN ARBOR, MICH.;
INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF MICHIGAN. *

Sarcomata and carcinomata of the mediastinal structures are of comparatively infrequent occurrence; much rarer, however, are dermoid cysts in this region, and particularly in this country, where only five cases have been reported, does this assertion seem to hold good. Within the last few years a number of cases of mediastinal dermoid have been recorded in foreign journals, notably German, and four in our own. Because of the paucity of cases, in addition to the extreme importance of correct diagnosis from a therapeutic standpoint, it is incumbent upon those in a position to observe patients suffering with this malady, to render the fullest possible account of their findings, in order that a more accurate and widespread knowledge of the affection may be obtained. To assist in accomplishing this end, it has seemed that it might be advantageous to give, together with my own case,† abstracts of those which I have been able to find in the literature, with an analysis of the same.

C. R., male, aged twenty-three years, American, unmarried, a railroad man by occupation, entered the out-patient department of the University Hospital July 19, 1904, complaining of cough, expectoration of large quantities of foul-smelling sputum, and hemorrhages from the lungs. From certain points in the history and objective examination which will appear presently, I diagnosed the conditon as probable dermoid cyst of the thorax, hesitating to make the diagnosis unqualifiedly, as I was not aware of similar cases. The patient was advised to enter the hospital as an in-patient; this was impossible at the time, but on July 27, 1904, he returned and was admitted to the medical ward. The folowing notes were made:

Family History.—Father is living and well. Mother has had "stomach trouble" nearly all her life but is in good health at present. The patient has two brothers and three sisters alive and well. One aunt on the father's side died of "hemorrhages from the lungs and dropsy"; nothing more definite is known of her case. Otherwise the family history is negative.

Personal History.—As a child the patient was very well. He had "measles," "chicken-pox," and a mild attack of "diphtheria" or "tonsilitis"; in all instances recovery was uneventful At the age of twelve the patient had a diarrhea which persisted about a year. Since then the patient has been in good health until the onset of the present trouble. His habits are good.

History of the present disease.—About nine years ago (eight years according to out-patient history), the patient had a severe attack of "pneumonia" on the left side, followed by a feeling of tightness across the chest and pain on breathing; the latter was localized to an area about the size of the hand in the praecordial region. Prior to the pneumonia, the patient was *struck over the heart* by a drunken man and ascribes the penumonia which soon followed to the blow which he received. Between the time when he was struck and the development of the pneumonia, he had *neuralgic pains in the region of the heart and in the left shoulder.* A year later the patient had another attack of "pneumonia" which lasted about eight weeks. During a coughing fit a large quantity of "pus" was brought up at one time ("over a quart"). The "abscess" or "empyema" discharged three times within three or four days. The patient describes the so-called pus as a "yellow, semi-fluid material." After raising this he became much better but has coughed and expectorated a good deal ever since. Four years ago the patient had a very severe hemorrhage from the lungs and has had a few since then. He says they are brought on by severe paroxysms of coughing or straining. They occur about every six months. At times the hemorrhages amount to about one pint. During the last three years the patient has noticed a "rotten" odor to the sputum. In March, 1904, he went to Colorado for his health. He was examined and told that he had empyema; operation was advised. This the patient did not submit to. No tubercle bacilli were found in his sputum at this time. For some time the patient *has coughed up hairs* in his sputum; these are from one to six inches long. Since last March (1904) there has been some soreness over the right side of the chest. Expectoration is much more profuse when the patient is lying down. He has not lost weight.

Status præsens.—July 29, 1904. Temperature has been normal since admission. At 8 A.M. respirations 20, pulse 72, regular, of fair size and tension; no sclerosis of the arteries. Patient looks very well nourished. Active dorsal position, mind clear, expression natural. Strong frame, rather short and stocky build. Panniculus moderate in amount, muscles large and rather soft. The skin is of good color, smooth, dry, and elastic; no edema at the ankles. There are no stiff joints. Lymph glands above left clavicle and behind the left sterno-cleido-mastoid are slightly enlarged; otherwise negative. The pupils are equal; react well. Sclerotics are clear, slightly bluish. Conjunctivæ and lips are of good color. The teeth are in good repair; the tongue is large, clean, and moist. Neck is negative.

The thorax is well formed, the left side being, if anything, slightly fuller than the right.

Fig. 11*b*. Dangschat, von Eiselberg (51). Shading represents dulness and weakened vesicular.

The epigastric angle is about a right angle. Expansion is rather small, slightly less on the left side, especially on deep breathing. This change is more noticeable in the lower part of the thorax. The clavicles are equally prominent. On percussion the apices are of equal height, about 1⅛ inches above the clavicles. Above the second rib the percussion note is the same on the two sides. Below this level the note is somewhat hyperresonant on the right with relative dullness (see Figure 1) throughout the left front, *the upper border sloping downward into the left axilla. Traube's space is clear.* There is no absolute liver dulness. The lung-liver border is on the sixth rib in the right nipple line and extends straight around. On deep inspiration the lung descends to the seventh rib. Auscultation above the right clavicle gives rather harsh vesicular breathing with fairly high-pitched sibilant râles on inspiration; below the clavicle, throughout the right side there is moderately strong vesicular breathing with no adventitious sounds. Above the left clavicle the vesicular is obscured by sonorous rhonchi which are heard both on inspiration and expiration. Below the left clavicle there is harsh vesicular breathing accompanied by dry râles of medium pitch, the vibrations of which can be felt on palpation. Below a line drawn from the left nipple to the anterior axillary fold, the vesicular is very weak and toward the end of inspiration a few crepitant râles are heard. Auscultation of spoken voice: slightly weakened between second and fourth ribs on left; vocal fremitus absent here.

Back.—Apices of lungs are of equal height on percussion. Below the level of the spine of the eighth dorsal vertebra there is relative dulness on the left side; this is continuous with that previously described in the axilla. In other respects percussion is negative. The upper border of relative dulness is not altered by change in the position of the patient. Auscultation reveals fair vesicular throughout the right back and on the left side down to the dull area where it is weakened. Pectoral fremitus is slightly weaker on the left side below. Ausculation of spoken voice is negative behind.

Heart.—Apex is best felt in the fourth intercostal space in the nipple line. A slight pulsation, which was forcible enough to be palpated, was seen in the second and third interspaces at the beginning of the examination. Absolute heart dulness begins on the fourth rib and extends outward to the apex; on the right it extends to the left edge of the sternum. To the left of, and above, the absolute heart dulness is the relative dulness obtained over the lung; this is inseparable from relative heart dulness. On auscultation the heart sounds are moderately strong and clear. The second pulmonic is reduplicated and accentuated.

Abdomen is on a level with the ribs. It looks natural. The walls are quite resistant, making palpation difficult. Spleen and liver are not felt. Percussion is negative. Leucocyte count 9,256 on July 27, 1904. Urine examination is negative.

Sputum was examined July 31. The color was whitish-gray; it had a foul odor, like that of "bad" eggs. It separated into three layers. No tubercle bacilli were found; no elastic tissue. Later a hair was found; compared to a hair from the patient's head, this was distinctly lighter in color and seemed somewhat finer.

Fluoroscopic examination of thorax. There is a light shadow throughout the left side above. Below the level of about the eighth dorsal spine to the eleventh dorsal on the left there is a dark shadow extending straight across. A skiagraph was taken; unfortunately the negative was poor.

The patient failed to react to the maximum diagnostic dose (10 mg.) of tuberculin (Koch), a fact which was omitted from my first report through an oversight.

The diagnosis in this case rested largely on the history of expectorating hairs, together with the evidence of an abnormal condition in the left side of the thorax, all the objective signs of which might readily be explained by a mediastinal tumor occupying chiefly the left side and separated from the thoracic wall by a moderately thin layer of lung tissue.

After a short stay in the medical ward, the patient was referred to the surgical clinic where operative treatment was advised. Certain reasons made this impossible at the time, but the patient signified his intention of returning later for surgical intervention. Very recently (January, 1905), I have learned that the patient, while on a visit to Chicago, sought the advice of Dr. Nicholas Senn, in whose care he placed himself. Additional information will doubtless be given by the report which it is to be hoped and expected the operator will make.

The following cases are given, as nearly as possible, in chronological order and are in large part selected quotations taken from the sources indicated. They are given in some detail, but this has seemed unavoidable both for the purpose of analysis and because dermoid cysts of the mediastinum, like other diseases, do not follow a definite course and produce certain fixed symptoms, so that one description will suffice for all cases.

1. *Gordon.* A Case of Tumor in the Anterior Mediastinum Containing Bone and Teeth. Medico-Chirurgical Transactions, Vol. XIII, p. 12, 1825.

M. C., female, aged twenty-one years, strongly built, was admitted to the Islington Dispensary June 17, 1822 with the usual symptoms of pneumonia. An irritating cough remained; pulse 120. Pain in the side occasionally recurred; cough was convulsive and suffocating and was attended with an expectoration which was at first mucous and afterwards purulent. Previous health had been good. No emaciation. About two months after admission a small round tumor was found below sternal end of left clavicle.

about the size of a nut and pulsating regularly and strongly. The tumor rapidly increased in the course of three weeks and rose above the clavicle, and then somewhat receded. Patient was always dyspneic. The attempt to lie down always excited cough. The tumor now remained stationary for some time and there was some improvement in her health. In the spring of 1823 the tumor gradually extended over the trachea, occasioning great irritation and threatening suffocation. On June 25, 1823, it pointed and burst, serous fluid escaping. Examination with probe proved this to be a small superficial sac. After August first no discharge took place and by September twelfth there was no trace of the tumor. The patient left the hospital and went to work. On October twelfth she was readmitted with symptoms of general fever and oppressed breathing but without any local complaint. Death on October twentieth.

Autopsy.—Tumor in anterior mediastinum, closely attached to upper two-thirds of sternum and sternal end of right clavicle. Fluid in left pleura where not adherent. Right innominate enveloped by thickened cellular tissue, which connected the tumor with the surrounding parts. Contents of the tumor were: serous fluid, sebaceous matter mixed with hair, and an apparently fatty mass at the bottom, which, being cut open, proved bony. On more careful examination, a bone was detected very nearly resembling the upper maxillary, a portion of alveolar process which might seem to belong to the upper or lower maxillary, and seven teeth.

2. *Münz.* (1839). Alber's Pathologische Anatomie, Erläuterungen, Abtheilung III, p. 342. Bonn, 1833-1846.

M. V., female, aged twenty-eight years, had been somewhat delicate during youth. Body is, however, well developed. During her earlier years she often suffered with catarrhal affections, and in her fifteenth and sixteenth years she noticed that she frequently expectorated hairs with mucus after severe coughing. From her twentieth year the catarrhal affections which increased, especially in the winters, in severity and duration, became phthisical. In 1838 she entered the hospital; on continued coughing she raised a foul-smelling puriform mucus, which frequently contained hairs singly or matted together. After several weeks foul, purulent sputum, dropsical phenomena and hectic fever increased, the expectoration of hairs decreased. Colliquative diarrhea set in and the patient, exhausted and dyspneic, died March 13, 1839.

Autopsy.—Lower lobe of right lung in some parts was solidified, in others there were softened tuberculous masses. Left lung about the cavity (see below), had a tuberculous appearance, but there was no vomica. In the left lung there was found on its inner surface a mass consisting of two communicating cysts; the upper one being the smaller and communicating with the left bronchus. The cyst wall resembled both skin and mucous membrane. On the inner surface hairs were found attached. These were of light brownish to reddish color, and somewhat lighter than the hairs of the head. Cyst was filled with a fatty, puriform fluid containing many hairs (Ekehorn).

3. *Büchner.* Ein seltener Sectionsbefund. *Deutsche Klinik,* Bd. V, p. 311, 1853.

C. Z., female, aged thirty-six years, entered the clinic (Tübingen) on June 3, 1853. According to the statement of a relative, she had complained of pain in the chest, cough, and dyspnea for nine months; she had an attack of pneumonia in February, 1853, which left her with increased cough and whitish expectoration. Five weeks before admission a pneumorrhagia set in suddenly, when about three-quarters of a pint of dark blood was raised; since this time the patient has continually coughed up blood.

Status præsens.—About six to eight ounces of bloody sputum are raised in twenty-four hours. Frequent vomiting of material mixed with blood; frequent chills; pulse soft, 120. Examination of the chest gave the following: The right side of the thorax from the second to the fourth rib bulges slightly and the entire right side expands less than the left. There is a very weak elevation and sinking of the prominence on the right, synchronous with the heart impulse; this is more evident on palpation. Percussion (see Figure 2) gives complete dulness on the right side of the thorax anteriorly, beginning at the lower border of the second rib and extending down to the diaphragm. Toward the left the dulness has a sharp border along the middle line of the sternum; to the right, on the contrary, it passes over into the resonant note behind only gradually. Right back and entire left lung give good resonance. Between the first and second ribs on the right the note is full and has a tympanitic quality. Auscultation gives bronchial breathing and resonant râles over the entire right side of the thorax anteriorly. In several places, as in the region of the right nipple, a blowing, systolic murmur can be made out. Right back and entire left lung give increased vesicular. Heart is free. Eight days after admission the patient died. Two or three days before death bronchial breathing and dulness were found over the right lower lobe, with simultaneous increase of fever and cessation of bloody sputum.

Autopsy.—Left lung negative. Right lung, on removal of sternum, not visible; in its place is a whitish-yellow mass which reaches from the second rib downwards to the diaphragm, on the left beyond the median line. Pericardium adherent to the mass on the right. The tumor, the size of a child's head, is cystic and adherent to the anterior chest wall. In it are found bone, cartilage, hair, etc. The cyst is roughly divided into two parts; the wall of the larger is covered with blood clots and communicates directly with the ascending portion of the aorta just above the semilunar valves, while the

lower sac has perforated into the lower lobe of the lung, the opening being about the size of the little finger. Pneumorrhagia resulted from the communication between lung and cyst. No cholesterin crystals could be found.

4. *Lebert.* Beobachtungen und klinische Bemerkungen über Dermoidcysten. *Viertel-jahrschrift für die praktische Heilkunde,* Bd. LX, p. 25, 1858.

H. R. v. T., male, aged sixty years, hat-maker, was admitted to the Zürich Hospital December 17, 1853. The patient had been dyspneic upon exertion or climbing since his sixteenth year. Coughed from time to time. In the last few years he has had constant dyspnea and frequent cough, especially in winter. No assignable cause. Early in the autumn, dyspnea became worse; in December he caught a severe cold, after which he had chills, fever, frequent cough, expectoration, and considerable dyspnea. Several days after each exacerbation copious, blood-tinged expectoration. On admission the patient was not emaciated; the lips and cheeks are cyanotic. Thorax is broad, intercostal spaces are full, also the supraclavicular fossæ, particularly the left. Percussion of anterior thorax gives hyperresonance; no heart dulness. Breathing in front and behind weak. In front at various points piping râles; behind, at both sides below, mucous râles. Cough is frequent and painful. The sputa are in part tenacious, in part globular, without blood. Neck veins swollen. Lower extremities slightly swollen. Orthopneic at night. On January 5, 1854, the dyspnea suddenly became very urgent, the patient collapsed and died in the evening.

Autopsy.—Both lungs markedly emphysematous. Between the two lungs and above the heart a large nodular tumor was found, which was loosely adherent to the pericardium; the mass was 7 cm. long and broad and 4.5 cm. thick. On opening the tumor a pale yellow pulp escaped. The tumor consisted of a large cavity with smaller communicating cysts. On the inner surface of the cyst there were polypoid excrescences which consisted of cartilage. In some places the surface was covered with pavement epithelium, in others with cylindrical epithelium. Hairs were not present. The liver was pressed downward; it was not enlarged.

5. *Cordes.* Dermocystoid im Mediastinum anticum. *Virchow's Archiv,* Bd. XVI, p. 290, 1850.

J. J., aged twenty-eight years, fusilier, was in the maneuvers in the summer of 1858. He had always been well, except for asthma at times. On August 25, 1859, he was taken ill suddenly with severe headache, fever, intense pain in the region of the stomach, great collapse with a small, intermittent pulse, and dyspnea. Examination revealed the following: Nutrition moderately good. The patient complains of dyspnea, and pain in the stomach region and under the sternum. Temperature normal; pulse frequent, unequal. Respirations 48, shallow. Frequent and copious vomiting. Heart dulness three square inches, rather quadrangular, extends under the sternum and begins on the third rib. Apex beat not felt. Heart sounds weak and clear. Condition was diagnosed acute catarrh of the stomach and pericarditis with effusion. In a few days the symptoms became less severe.

On September 5, patient complained of cough; raised small masses of glairy, tenacious, clear sputum. Percussion and auscultation of lungs negative. Pericardial effusion increased gradually in next few days with dyspnea and increasing edema of feet. Until death, on October 16, the symptoms mentioned gradually increased. Cough became more severe, while the respirations became fewer (to 19). The sputum was deeply stained with fresh blood, very tenacious, slightly foamy, in amount about two ounces in twenty-four hours.

Autopsy.—Pericardium greatly distended with compression of lungs. It contained a sea-green, moderately clear fluid, on which a considerable quantity of yellow flakes floated; the latter were fatty and were shown to be identical with the contents of the tumor described below. In the anterior mediastinum a tumor the size of a man's fist was found, lying upon the aorta ascendens, arch of aorta, and part of the aorta descendens, and upon the bifurcation of the trachea. Below it reached to the base of the pericardium, on the left to the middle of the left lung, on the right to the pericardium. It was surrounded by a sac which was generally adherent to the pericardium and the cellular tissue surrounding the great vessels and the trachea. The sac contained a sulphur-yellow, fatty material, which consisted of hairs and, on microscopic examination, of dark gray, strongly refractile masses, pavement epithelium, and round cartilage cells. Small hairs were found attached to the inner wall of the cyst. From the upper left side of the sac there extended a projection about 2½ inches long and three-fourths inch broad, having contents similar to the main cyst; this communicated with the pericardium. No pericardial fluid was found in the tumor. The cyst measured 10 cm. long and 5 cm. broad. Sebaceous glands, hair follicles, and bone were found in the wall.

6. *Cloëtta.* Ueber das Vorkommen einer Dermoidcyste in der Lunge. *Virchow's Archiv,* Bd. XX, p. 42, 1861.

The patient was a woman, aged twenty years, who had the usual symptoms of chronic tuberculosis on the left side during the latter part of her life. The chief point, which was noticed by the patient, was the expectoration of a large amount of sputum which frequently contained hairs in large quantity. This was looked upon by the attending physician as a deception.

Autopsy.—On cutting through the lower lobe of the left lung, a sac was found filled with hair, epithelial cells, and fatty material. To this sac there were two communicating compartments.

The smaller cavity comprised the real dermoid tumor; the larger one was a lung vomica. The dermoid cyst was situated on the inner surface of the lower lobe of the left lung, was as large as a small sized apple; its walls, which were very thick, consisted of a hard tissue in which cartilage and pieces of bone were embedded, but no teeth. The inner surface was uneven, with projections; on it there were many long and short hairs. The cyst extended for about one-third of the way through the lung. On the posterior wall of this cavity a large bronchus opened.

Servant girl, aged twenty-four years, entered the hospital December 7, 1861. She had been well as a child. In 1851 she had scarlet fever, and since then she has complained of cough with pain in the chest and back. In 1860 the patient had measles, followed by inflammation of the lungs. Cough has become worse, and for the last two weeks the patient has had severe pains in the chest. On admission the patient had some fever, and the attacks of coughing were frequent and severe, lasting often several minutes and exciting sharp pains in the chest, especially in the right side. Sputum not foul smelling. Dull note on percussion of upper part of right lung; vesicular here weak, with prolonged expiration accompanied by dry râles. Amphoric breathing, increased voice and coughing sounds, and numerous moist, somewhat ringing râles below the inner end of the right clavicle and behind in the supraspinatous fossa. Examination otherwise negative. The disease progressed rapidly, the patient emaciated, expectoration increased, speech was difficult, and on January 4 she complained of more severe pains in the chest, spit up about one-half pint of dark fluid blood (not foamy), and died about half an hour later.

Autopsy.—Right lung adherent throughout. From right apex thick pus escaped. Right lung was crepitant only in lower part; no bronchiectasis found. In a small bronchus extending toward the hilus of the lung there was a communication with a cyst about the size of a pigeon's egg which adhered to the pericardium and pleura. The inner surface of the latter resembled skin and was filled with a thick pulp of a brownish red color with yellow spots or points and with small brownish hairs. In the apex a tuberculous cavity of about the same size was found. The entire appearance of the lung resembled that of infiltrated and softened tubercle. Microscopical examination showed the inner surface of the cyst to consist of pavement epithelium with sebaceous glands and hair follicles. Cartilage was found in the wall.

8. *Collenberg.* Zur Entwickelung der Dermoidkystome. Inaug.-Dissert., Breslau, 1869. Also reported by *Waldeyer.* Dermoidystom des vorderen Mediastinalraumes. *Archiv für klinische Chirurgie,* Bd. XII, p. 843, 1871.

A. M., male, aged fifty years (44-Waldeyer), entered the hospital December 28, 1867, with the signs of pleuropneumonia of the right lower lobe. Patient was very cyanotic and extremely dyspneic. Temperature was high, pulse small, weak, irregular, and intermittent. Weakness was marked. Patient died ten hours after admission with signs of edema of the lungs, making it impossible to obtain the history.

Autopsy.—(Waldeyer).—Large, muscular cadaver. On removing the sternum a fluctuating tumor somewhat larger than a child's head presents in the lower right half of the thorax; its walls feel calcified in places and are loosely adherent to the anterior thoracic wall. The tumor extends downward from the sixth rib, pressing on the diaphragm. The heart apex in sixth interspace almost in the anterior axillary line. Right lung is pushed backward by the tumor. The tumor is surrounded by the pleura and is connected with the right lobe of the thyroid gland by a narrow band. The mass is cystic. Contents of cyst are partly solid, partly fluid; the latter is a simple fat emulsion containing solid particles formed of pavement epithelial cells and cell fragments. Single reddish hairs are also found. Microscopically the wall contains connective tissue and stratified pavement epithelium with sebaceous glands.

9. *Nobiling.* Kurze Mittheilungen aus den pathologisch-anatomischen Demonstrationen des Prof. Dr. Buhl. *Aerztliches Intelligenz-Blatt,* Bd., XVI, p. 3, 1869.

A preparation of a dermoid cyst in the lung was demonstrated. The condition was diagnosed during life because of the fact that the patient, a man, had coughed up hairs.

10. *Villard.* 1869. (Cited by Dardignac). The patient was a woman, aged fifty-five years. She entered the St. Antoine Hospital October 9, 1869, and a few days later died.

Autopsy revealed a tumor the size of a large walnut between the layers of the pleura on the right. It rested on the diaphragm, and was adherent to the thoracic wall and the base of the right lung. The tumor proved to be a cyst. The wall was calcified, no trace of glands in it. Its inner surface was covered with layers of cornified epithelium. In the cyst was a substance soft and friable, formed of fat and cholesterine crystals, numerous fat droplets, some red blood cells, and a substance resembling altered pavement epithelium. No hairs were found.

11. *Pöhn.* Dermoidcyste des Mediastinum anticum. Inaug.-Dissert., Berlin, 1871.

B., male, aged thirty-four years; was always healthy till the summer of 1866, when he suffered from severe cutting pains in the right shoulder and upper arm. They gradually decreased in intensity, but returned in the summer of 1867 with renewed force, together with pa-

retic symptoms in the affected parts. Patient was well during the next two years, when the pains reappeared and there was sensitiveness to pressure over the right sterno-clavicular articulation. Soon a pulsating tumor developed at this point. In the following years it grew very slowly but constantly, and the pains in the right arm continued without signs of paralysis. The general condition of the patient was good and no change in his daily life was necessitated. In 1870 pain was noted in the region of the left sterno-clavicular articulation, with weakness and impaired sensation in the left arm. A pulsating tumor developed here also. The tumor on the left side began to grow rapidly, especially downwards, in March, 1871. Severe neuralgic pains and paretic symptoms then appeared in the left arm. There were no signs of compression. The patient remained in this condition till the middle of July, when he was admitted to von Langenbeck's clinic in Berlin. Examination July 14, 1871. Strong frame; healthy looking man. There are two tumors in the neck (as above); their surface is smooth and the skin is freely movable over the right; somewhat thin, reddened, and adherent on the left. Thorax is symmetrical; expansion equal on the two sides. Heart apex is in the sixth interspace just outside the nipple line. In both tumors there is a pulsation synchronous with the radical pulse. Fluctuation waves pass from one tumor to the other. Heart dulness is found between the left parasternal and nipple lines; sounds normal. Percussion and auscultation of the lungs are normal. Auscultation over tumors negative. The tumors were diagnosed as cystic. July 14 a trocar was inserted and a few drops of pus escaped; the tumor was then freely incised, and there was evacuated first pus, then a tenacious, yellow, fatty mass containing many long and short curly hairs. Under the microscope the contents were seen to consist of fat, both amorphous and in droplets, a few chloresterin crystals, and bits of epidermis (after treating with alkali). The ultimate result of the treatment is not given.

(To be Continued.)

MEDICAL PROGRESS.

MEDICINE.

Immunity.—The seventeenth chapter of the special article on Immunity (*Journal A. M. A.*, June 17) commences with a statement of the nutritional aspects of Ehrlich's side-chain theory as developed by him in his earlier work on the oxygen requirements of the body and before its application to the explanation of the phenomenon of immunity. It assumes that all substances that enter into the structure of protoplasm (food substances) are bound in the cells and the union must be considered a chemical one. Such a chemical union demands the presence of two binding groups of maximal chemical affinity which are suited to each other. He called these binding groups residing in the cells side-chains or receptors, those in the food molecules, haptophrorous groups. He also assumed that protoplasm is endowed with a large number of such side-chains, chemically adapted to the various foodstuffs, thus providing for nutrition. To adapt this theory, however, to the explanation of immunity it is necessary that it be elaborated in order to account for the formation of antibodies. Why these are not formed for nutritive substances is explained by assuming it to be probable that, in the normal condition, a physiologic equilibrium exists between the food substances on the one hand and the cellular activities on the other, so that the union of food and protoplasm forms no abnormal stimulus to those of the cell. When, however, union with a toxin occurs, the result is described as a cell defect, consisting in the functional elimination of the receptor. To repair the defect, the vital center of the cell (*Leistungskern*) sends out new receptors, and not only enough, but, in harmony with Weigert's hypothesis, a great excess, so that many are thrown out into the circulation. The proofs of the three tenets that form the framwork of Ehrlich's theory are next taken up in detail. The first of these, that antitoxins counteract toxins by entering into chemical union with them, is deemed to be well supported by experiments *in vitro*, such as those made with ricin and antiricin, the neutralization experiments with diphtheria and tetanus toxins and their respective antitoxins, etc. Admitting that these neutralizations are of a chemical nature, the first essential step in the establishment of the chemical or side-chain theory is assured. It is not so easy to demonstrate this as regards the union of agglutinin and amboceptors with the cells, but here also the proof is considered strong. The second tenet: that toxins in injuring cells combine chemically with a definite constituent of the protoplasm, the cell receptor, is held to be strongly supported by Wassermann's famous experiment of neutralizing tetanus toxin by grinding it up with the central nervous system of guinea-pigs. The chapter concludes with a reference to the analogous results obtained by von Dungern with precipitins, showing that albuminous substances, other than toxins, are taken up chemically by the cells.

Pernicious Effects of Alternating Current of High Voltage.—F H. Millener (*Buffalo Med. Jour.*, June, 1905) presents a paper on one phase of the great subject of electricity and its relation to mankind, having reference specially to its pathological effect upon the health and lives of men engaged directly in the manufacture, transforming or transmission of this mysterious fluid. From an observation of eighteen cases of men who were affected by the electricity, the author concludes that continuous employment in the immediate presence of electrical generators or transformers, where one is continuously in an atmosphere heavily charged with electricity, or ozone, or some light or ray as yet undiscovered, results in such disturbed conditions of the digestive fluids or of the secretions of the stomach and its cognate glands and organs, as to greatly impair the digestive function; and that persons so employed lose their appetite, and become of an almost chalky complexion, and experience pain and distress after partaking food, and often have to obtain short periods of vacation in order to recover their ability to eat and digest their foods in a normal manner.

Vicarious Action of the Bowels for the Kidneys in Tuberculosis.—Lawrence F. Flick and Joseph Walsh (*Am. Med.*, July 22, 1905) call attention to the fact that it has long been recognized that in certain cases of tuberculosis there is a looseness of the bowels not due to ulceration. This looseness has been termed irritative diarrhea and has been ascribed to errors in diet. A careful study of the number of cases which have been

under observation a long time clinically and which have come to autopsy lead us to believe that in these cases the looseness of the bowels is due to the vicarious action of the bowels for the kidneys and that nature is really trying to protect the system by this vicarious action. Eleven cases are reported. In all of them there was severe diarrhea usually over a protracted time. In all the intestines were practically normal and the kidneys showed acute alterations. The cases were studied clinically from four weeks to three years; diarrhea lasted from four weeks to eight months. In three cases out of the eleven the autopsy showed the ileum slightly congested; in all the remaining cases the intestinal tract, with the exception of the appendix, was normal. Several forms of nephritis were found, toxic nephritis, parenchymatous nephritis, diffuse nephritis and intestitial nephritis. In seven cases out of the eleven there were scattered tubercles in the kidneys. The diarrhea was considered to be a vicarious action for the kidneys because no other definite cause was found. The rest of the paper deals with nephritis in tuberculosis, its frequency, its etiology, its symptomatology and its treatment. It is caused by the growth of tubercle bacilli in the tissue of the kidneys and by the toxins secreted through the kidneys from other lesions elsewhere. It also may be caused, perhaps, by the dead tubercle bacilli in the process of elimination. The treatment is magnesium sulphate and nitroglycerin.

OBSTETRICS AND GYNECOLOGY.

Sarcoma of the Uterus.—This type of cancerous growth of the uterus is rare. It may occur in the cervical portion, in the mucous membrane, and in the parenchyma of the organ. A fourth extremely malignant type may occur, the deciduoma malignum, which is always associated with pregnancy. Sarcomata of the cervix usually takes on a mulberry appearance, the sarcoma botryoides. They occur, as a rule, in young women, but may appear after the menopause. This type develops from the most superficial layer of the mucous membrane, and is extremely malignant. In sarcoma of the mucous membrane of the uterus, polypoid growths may form, only to be differentiated from the benign mucous membrane hypertrophy by the microscope. The so-called fibrosarcomata, springing from the parenchyma, usually grow slowly, and often attain large dimensions before giving rise to serious symptoms. H. Grad (*Am. Jour. Obstet.*, May, 1905), questions whether these tumors are sarcomatous from the inception of their growth, and suggests that they may be secondary metamorphosed fibromyomata. The researches of Backer, Graves and Beyea are cited to lend evidence in support of the assertion that sarcomatous degeneration of uterine myomata is not extremely uncommon. A case is reported by the writer, of extensive sarcomatous involvement of the uterus and upper vagina, which was changed from a hopelessly inoperable to an operable condition by six weeks' treatment with X-rays. For ten months after operation the patient was free from all adverse symptoms. Subsequently a recurrence appeared in the rectum, the patient became discouraged over the slow therapy of the ray treatment, and obtained the services of a Christian Science "healer." This last treatment was continued several months, a physician being called in time to sign the death certificate.

Cæsarean Section for Placenta Prævia.—R. W. Holmes (*Journal A. M. A.*, May 20), as the result of an extensive statistical study of the comparative mortality of Cæsarean section and of placenta prævia treated obstetrically, decides that Cæsarean section for placenta prævia lowers the fetal mortality 30 per cent., but increases the maternal death-rate nearly threefold. Approximately, the mother is sacrificed for the uncertain chance of life of the child. He questions the statistics somewhat, holding that some maternal mortality is unrepresented. A rigid os is one of the rarest complications of placenta prævia; most cases so diagnosed are, he holds, wrongly so considered. A true cicatrical cervix or rigid cervices of old primiparæ may afford an indication for Cæsarean section in placenta prævia. Pelvic contractions are indications for Cæsarean section in the presence of prævial hemorrhage, the deformity, not the prævia, being the determining indication. The earlier the interruption of gestation, other things being equal, the more may the pelvic deformity be disregarded. Usually the condition is not recognized until hemorrhages appear. Cæsarean section for placenta prævia will never have so low a maternal mortality as when done for a pelvic indication. Repeated examinations for diagnostic purposes must be made, and the temporary use of a vaginal tampon may be required until the patient can be transported to a hospital or due preparations be made for operation. The acute anemia and the anatomic conditions postpartum add special danger to the operation. Suitable cases for Cæsarean section usually call for operation independent of the fetal condition, as the primary object is to save the life of the mother. It should only be a last resort, and if an abdominal operation is forced on the obstetrician he should remove the uterus as a prophylatic against hemorrhage and infection. The profession should await the adjudication of the field for Cæsarean section in placenta prævia by obstetric authorities before resorting to it.

The Pathology and Treatment of Puerperal Eclampsia in the Light of Recent Work.—A. W. Sikes (*Practitioner*, May, 1905) considers that, apart from the well-known pathological findings in this condition, it is produced by the non-elimination of the normal metabolic products of the fetus, this non-elimination being accounted for by renal inadequacy due to extra strain on the kidneys hampered by pressure on the ureters, and by the alteration in the pressure in the renal blood system. When once these metabolic products cannot leave the system, the liver is soon deranged, and deficient oxidation here makes the condition worse. The mother's own metabolic changes are interfered with, and insufficiently oxidized proteid substances, circulating in the blood, act on all the tissues, blood vessels, etc., causing an increase of fibrim in the blood and thromboses in the vessels of both mother and child. All the work on eclampsia shows that the difficulty of elimination is the paramount cause, and anything which interferes with elimination—old disease of heart or kidneys, narrow pelvis or protracted teeth—all favor the onset of the disease. The author, in considering the prognosis in this class of cases, thinks that from the clinical aspect, the smaller the amount of albumin the more normal the pulse in rhythm and tension, the nearer the onset of the fits to the end of pregnancy, the shorter time the fit lasts, and the greater the time between the fits so much better will the prognosis be. The prophylatic treatment consists in rest, purgation by saline aperients, milk diet and very small quantities of meat. The patient should drink as much fluid as possible. Exposure to draughts, cold and damp should be carefully avoided. When the fits have started the author recommends

saline aperients, narcotics, chloroform, and carefully considers the use of diapharesis enteroclysis, hypodermoclysis and bleeding, and is in favor of the active line of treatment.

Tuberculosis of the Fallopian Tube.—The source of tuberculous infection of the tube cannot always be demonstrated. The infection may be carried through the blood or lymph stream or spread directly from the peritoneum. A. W. W. Lea (*Jour. Obstet. and Gyn. of Brit. Emp.*, April, 1905, states that the disease usually commences by the appearance of miliary tubercles in the mucous membrane of the tube. The process in most cases extends as a diffuse miliary tuberculosis, in which the mucous membrane is greatly thickened, area of caseation appear, the abdominal ostium is occluded and perisalpingitic adhesions are formed. As a result of closure of the ostium a tuberculous pyosalpinx may form. The process may take the form of a diffuse fibroid tuberculosis, characterized by a formation of considerable fibrous tissue in the walls of the tube. In some cases the tube may show merely catarrhal changes, and the tuberculous character only demonstrated by inoculation into guinea pigs. The ovary escapes infection in the majority of cases. Contrary to the findings of most observers the writer did not find the uterus involved in a series of eight cases. An absolute diagnosis is not always possible, the previous history of the patient, menstrual changes, pain and leucorrhea are important. No rise of temperature is to be expected when the disease is limited to the tube. Bimanuel examination is not especially suggestive unless tuberculous peritonitis is associated with tubo-ovarian swellings. The prognosis is reasonably good if the tubes are removed before general tuberculous infection has occurred. Without operation the disease steadily progresses to a fatal termination.

THERAPEUTICS.

The Therapeutic Value of Ergot in Labor.—J. C. Applegate (*Am. Med.*, June 24, 1905) does not regard ergot as an appropriate or safe remedy at any period during labor until the presentation or expulsion of the placenta, notwithstanding the statement in many text-books that it is valuable for uterine inertia. Its physiologic effects on the uterus are unlike the rhythmic labor contractions, in that they are less intermitting, more continuous and predispose to constriction, particularly of the lower segment. Paralysis of the fetal heart from compression, retention of the placenta and membranes and rupture of the uterus are the attending dangers. Complications of the third stage of labor or postpartum hemorrhage rarely follow the expression of the placenta after the Credé method. He regards ergot as a safeguard and valuable at the end of the third stage of delayed labor or when uterine inertia has been a factor, also after placenta prævia and reposition of an inverted uterus. With a uterus normally contracted, the author considers it valueless and rather detrimental when used for the prevention of septic infection, since its tendency is to disturb the venous thrombi and lock too completely within the uterus excreta that would otherwise be liberated. Ergot may be administered by the mouth as a safeguard, but for the control of hemorrhage better results are obtained by hypodermic administration.

Poisoning by Wood Alcohol.—C. Koller (*Med. Rec.*, July 1, 1905) describes the case of a man of forty-two who presented himself at the clinic for nervous diseases of the Mount Sinai Dispensary, suffering from acute, total blindness. Investigation of the history showed that the loss of sight had come on during the second night after taking about two ounces of whisky, a quantity which subsequent analysis showed contained about 20 c.c. of wood alcohol. The visual disturbance rapidly progressed, until about thirty-six hours later he was completely blind. Other symptoms which had accompanied the development of the eye condition were nausea, vomiting, weakness, chilly feelings and cold extremities. On ophthalmoscopic examination the optic nerves presented the picture of a neuroretinitis of moderate intensity and in the macular regions were disposed numerous yellowish, bright, shining spots similar to the picture described as choroiditis guttata. Potassium iodide, hot baths and good nourishment were prescribed, and six months later the right eye showed complete recovery of function, except a moderate diminution of visual acuity, and the left eye presented marked though moderate concentric contraction of the field, considerable diminution of central vision and absence of perception for green. The author reviews the subject of wood alcohol poisoning in general, and its ocular manifestations, among which complete bilateral blindness, dilated pupils with lost reaction, and, ultimately, atrophy of the optic nerve and retina are prominent. Sweating by hot bath or pilocarpine, potassium iodide internally, and sufficient diuresis, perhaps by milk diet, are rational and sometimes successful measures of treatment. The matter of prophylaxis is of the greatest importance, and the public must be enlightened as to the poisonous nature of the substance.

Potassium Chlorate Poisoning.—Lester W. Day (*Journal A. M. A.*, July 22, 1905) reports an interesting case of poisoning from potassium chlorate. The patient, a man aged thirty years, purchased at a drug store a bottle containing fifty 5-grain tablets of potassium chlorate. Though the printed directions were to dissolve one tablet in the mouth, every hour or so, the patient used the entire fifty between March 10 and April 1. On April 2 the patient complained of itching, and on April 6 the thighs, legs, ankles, trunk, forearms and wrists were seen covered with innumerable reddish macules: there were also numerous petechiæ. There was no nausea, diarrhea or headache. The patient made a slow but unventful recovery.

PRESCRIPTION HINTS.

Alimentary Urticaria.—The following prescriptions are recommended by Dauchez (*Gaz. des Hopitaux*, August 3, 1905) in the treatment of urticaria of alimentary origin in a child of four years. For two or three days give

℞ Magnesia (English)
Sulphur (sublime and washed)
Cream of Tartar
White honey } aa 5 gr.

M. et S. One or two teaspoonfuls daily.

(2) Keep child on a mild diet. On increasing the diet, prohibit fish and fruits. (3) Give prolonged warm, mucilaginous baths. (4) Use following liniment:

℞ Chloroform pur. .2 to 4 gr.
Tinct. Aconiti .6 gr.
Ilei Amyg. Dulcis .90 gr.

M. et S. For external use.

(5) If there is much irritation at night, one may use warm lotions of a decoction of tobacco, to be followed by the application of the following powder:

℞ Tale (pulv.)
Zinci oxidi
Starch flour, chem. proc. } aa ʒss

M. et S. For external use.

SATURDAY, AUGUST 26, 1905.

YELLOW FEVER AND THE MARINE HOSPITAL SERVICE.

The accent on the yellow fever situation, which has long been grave, has now become acute, and two things are painfully apparent to even the casual observer of the condition of affairs at New Orleans. Of these the first, and perhaps the most important, is that the epidemic is not under the control that the laity expected or the medical profession hoped for, when it was placed under the care and supervision of the Marine Hospital Service. And, second, that there is little likelihood of the fever being "stamped out," or "eradicated" until the coming of the frost, when it will die a natural death.

Unfortunately, however, this period is somewhat remote, and it strikes us that it has now come to a point in the affairs of the Marine Hospital Service when they should not only do—as they have already done—all that modern science and special skill can accomplish, but that they should give the *highest* evidence in their power to the people of the country at large that they were so doing.

As to who is responsible for the introduction and spread of the disease it is too late to argue, but in justice to the medical officers in charge of the earlier cases it is only right and fair to call attention to the fact that they were hampered from the start by the perhaps natural desire of the friends and relatives of the victims to conceal the presence of fever in their homes. Also that the mercenary and commercial unwillingness of the city authorities to interfere with their business prosperity by the installment of a strict quarantine, gave the time necessary to permit the epidemic to become general and so firmly rooted that it has proved impossible to drive it out.

For if the first group of cases had been taken in time, had been isolated in mosquito netting and properly treated, the patients, it is true, might have died, but the disease itself would not have spread or have become so general as it now undoubtedly has, for it requires about a period of thirteen days for the fever-bearing mosquito to become inoculated, and during that time much could have been done to have checked the invasion of a general epidemic and to have kept it within the affected territory. But this was neglected, and when the sanitary control of the city was passed over to the government of the United States, and by it to the Marine Hospital Service, the disease had become so widely spread, so impossible of control, that the officers in charge not only recognized the fact, but, to their great credit and wisdom, were frank enough to state it openly and without reserve.

No one who has watched the rise of this service, from its small beginning to its present deserved standing in the medical world, can fail to appreciate what its services have been to this country, or refuse to recognize the scientific attainments of the members of its staff. To it the country owes much of its medical advancement in sanitation, and its work alone on the mosquito problem would place it in the front rank of similar organizations in other countries. So that having achieved so much that has been brilliantly successful, it is a pity that it should lose either prestige or honor on account of a situation that was thrust on it and for which it is in no way responsible.

That Dr. J. H. White, who is in charge at New Orleans, is doing all that can be done; that he is using every modern application and new method that has been devised, we do not question. That the presence of any one else could aid him, either with assistance or advice, we doubt. He has had great previous experience and he is by nature a man who is fitted to be at the head of affairs in such a crisis as the

present one, but he has not the rank of the head of the Bureau, and for the *morale* of the country, and particularly for the sake of the Marine Hospital Service itself, it seems to us that the time has come when the presence of the commanding officer is imperatively needed at the seat of activity.

When a nation is on the eve of a decisive battle the commanding general should be at the head of his men himself. He may be able to direct the strategy of his army as well from his headquarters as he could in the field, but what is needed is the personal presence of the commander, the individual influence that will strengthen and encourage the men. All this, too, is more necessary when the odds are against success and the situation, as in the present case, is desperate. Then in case of failure the country at large would recognize that no stone had been left unturned; and that the strength and power of the government had been expended without stint and without reserve.

That the President of the United States has not ordered Surgeon General Wyman to Louisiana, in accordance with his own desires, is due perhaps to the pressure of other public matters at this time. There is certainly a precedent for such action, for Surgeon General Hamilton, if we remember rightly, was sent to Florida during the noted epidemic there by the President then in power, and as Dr. Wyman himself has built up the Service to its present efficiency, as he has led it to its great advancement and been the author of its prosperity, he most certainly, in its time of need, should be permitted not only to direct and control its affairs, but should be allowed in person to see that the instructions for which he will unquestionably be held responsible, are carried out with promptness and despatch. The laborer is worthy of his hire, and surely the Surgeon General of the Marine Hospital Service is entitled to this modicum of executive courtesy.

PNEUMONIA ONCE MORE.

A very striking set of statistics with regard to pneumonia is to be found in an article on Croupous Pneumonia in the June number of the *American Journal of the Medical Sciences*, which shows a general mortality in the Philadelphia hospitals for a period of about six years, embracing nearly one thousand cases, of over 50 per cent. Five hundred and thirty-three deaths took place in nine hundred and ninety-one cases. The writers confess that this is, of course, an extraordinary high death-rate, and can only be accounted for by the class of patients from which the statistics are derived. Most of the patients were in extremely unfavorable conditions. Considerably over three hundred were more than fifty years of age, and nearly one hundred were above seventy years of age, eleven of them being over eighty. The younger patients were most of them sufferers from complications of various kinds, or were run down in general health as the result of various abuses and especially alcoholic excesses.

It is from such statistics that the insistent declaration in recent years, with regard to the increase in the death-rate from pneumonia during the last decade, finds its justification. As explained by the authors, however, there is no true justification for such conclusions in these special statistics. Pneumonia in young and healthy adults is by no means a fatal disease. It has been pointed out that the German army statistics show a mortality of not much above three and one-half per cent. in over forty thousand cases of pneumonia occurring in recent years. A Russian observer, who had the opportunity of treating pneumonia as it occurred among young Russian soldiers, had a mortality of only two per cent. when he employed large doses of digitalis. As a matter of fact, however, even two per cent. in the selected young lives that were under his care is more than might be expected under ordinary circumstances, and the digitalis had little, if anything, to do with lowering the death-rate. In spite of this consideration, however, for a time large doses of digitalis were used very generally by medical clinicians in various parts of Europe, and even by a certain number in this country. It is very likely that the remedy did more harm than good, since the overstimulation of the heart during the advancing stage of the pneumonia was an unfavorable preparation for the period of stress which it had to undergo at the acme of the disease.

Of course, the old die of pneumonia. It is rather a fortunate thing that they do, since this forms one of the easiest modes of death for old persons. Dr. Osler said, not long since: "It is the old man's friend, it helps him to escape those cold gradations of decay. It is a painless release from the troubles of life." Owing to the lack of oxidation, there is a lowering of consciousness from the very beginning of the affection, and as

a consequence the pain and discomfort that are present are at most but vague and indefinite. Old persons never have the acute symptoms which characterize the beginning of pneumonia in young, strong adults. A death from pneumonia is at least as merciful, as a rule, for the patient, and it has none of the appalling suddenness for the friends as of death from cerebral hemorrhage.

It used to be said that pneumonia attacked the strong and healthy even more frequently than it did the aged and the weak. This tradition, however, has been completely disproved in recent years, when more careful observations are being made, and when it is recognized more and more that the terminal stage of many affections in old age is really a fatal pneumonia. The fact that this tradition existed, however, is of itself a demonstration that the statistics of pneumonia have changed in recent years. Formerly, only the pulmonary affection which takes off the young and apparently strong was given the name pneumonia. Now it is recognized more frequently, notwithstanding the presence of other complications that used to seem serious enough to account for the patient's condition.

As a matter of fact, it remains true that it is not the pneumonia itself that is a fatal disease, but the complication which it so frequently exacerbates to a serious extent. The old maxim, that it does not make so much difference what sort of a disease the patient has as what sort of a patient has the disease, has its highest application with regard to pneumonia. A distinguished French physician used to say, the prognosis depends not on the pneumonia nor on its extent, but on what the patient takes with him into the pneumonia. It is very generally recognized now that patients suffering from heart disease, and especially an affection of the mitral valves, which is known to be so common, are almost sure not to recover from pneumonia. No matter how young and apparently strong a patient may be, if he goes into pneumonia with nephritis, the outcome will almost inevitably be fatal. On the other hand, the more careful study of tuberculosis in recent years had led to the determination of the prognostic rule, that if patients have previously suffered from active pulmonary tuberculosis, even though their present affection may be apparently a pure croupous pneumonia, the affection will not end by crisis, as in ordinary cases, but will almost surely end by lysis. These are the cases in which there is a subsequent development of tuberculosis, and in which, apparently, the tuberculosis had its beginning in the pneumonia. Another important set of previous symptoms concerns the blood. If patients suffered from anemic or chlorotic conditions in youth, then the pneumonia frequently does not end by frank crisis, but drags on for some time, and may eventually prove fatal, in a sort of typhoid condition.

It seems that in future, if the statistics of the mortality from pneumonia are to have definite value, all of these factors of the previous history of the patient, so far as they can possibly be obtained, must be made to enter into the mortality tables. Needless to say then, the death-rate from uncomplicated pneumonia will not be so great as to produce the unfortunate feeling of hopelessness that now so often prevails in patient's minds when they are told that they have pneumonia and when they remember all the sensational reports which they have recently heard with regard to the excessive mortality from the disease in recent years.

This is an important consideration for the therapeutics of the disease now sadly hampered by the despair of recovery that only too often follows the suspicion in a patient's mind that he has pneumonia.

ECHOES AND NEWS.

NEW YORK.

Warning to East Side Poor.—An East Side physician writes to the New York *Times*, saying that the poor people of the east side should not go for treatment to certain east side dispensaries. "For among the vast army of physicians on the east side there is a certain restless, ever-scheming element which cares little for professional ethics and less for the welfare of the community. These are what we may call commercial doctors. Their scheme is to increase their practice by advertising themselves as professors, specialists, visiting physicians, or surgeons to certain hospitals. As they cannot connect themselves with existing institutions on account of their limited and deficient knowledge of medical science, they create hospitals and dispensaries of their own. Seven or eight such doctors make equal investments of about $50, obtain a charter through some political influence, hire a house, put up two or three big signs with blazing golden letters announcing the professors' hours, and the dispensary is in full blast. Dr. Boaster becomes specialist of stomach diseases; Dr. Upstart takes the nervous specialty; Dr. Skinem, surgery. The understanding between these so-called specialists is to write two or three prescriptions for each patient, in order to extort an additional 20 or 30 cents from the poor sufferer, and Mr. Waterful, the druggist, dispenses the same colored aqua and calomel tablets to each and every patient."

Growing More Nervous.—The yellow headlines have it so for, according to Health Commissioner Darlington, nervous diseases are on the increase in this city. A table has been prepared by the Health Department officials in Chicago and another by those in this city, showing that certain nervous diseases appear to be decreasing.

The following is the table supplied for Manhattan and the Bronx:

Year.	Population.	Death from nervous diseases.	Death rate per 10,000.
1870	943,300	3,275	34.72
1880	1,209,196	2,788	23.06
1890	1,612,550	3,210	19.91
1900	2,181,611	3,091	14.17
1904	2,235,060	4,442	19.88

Ailments classified in the New York Department of Health as "Diseases of the Nervous System and Organs of Sense" are encephalitis, simple meningitis, locomotor ataxia, other diseases of the spinal cord, apoplexy, congestion of the brain, softening of the brain, paralysis, general paresis, other forms of insanity, epilepsy, convulsions, tetanus, chorea, and nervous diseases of the eye and ear. Regarding the results set forth in the table, Dr. Darlington is reported to have said: "As set forth, nervousness is on the increase among the people of this city. Certain diseases may not be so prevalent, and again they may have been wrongly diagnosed years ago. Insanity is certainly on the increase. While the people may be consuming less whisky, which is bad for the brain and heart, they are consuming more malt liquors, which are bad for the liver and kidneys." He is satisfied that nervous diseases certainly are not on the decrease. It should be borne in mind that these are more in the way of impressions than detailed statistical analyses.

Typhoid in New York.—While typhoid continues to increase in Brooklyn, and particularly in the Thirtieth Ward, official reports indicate an abnormal prevalence of the disease in Manhattan borough also. At the same time a growing number of cases was reported from the Bronx. Figures for the second week of August show 92 cases in Manhattan against 38 for the same week last year. There were 41 cases the first week of August this year. Dr. Darlington and his subordinates in the Health Department are preparing to give the same attention to the disease in this Borough as they have given to it in Brooklyn. The first task is to ascertain the source of infection. There has been much talk of the milk supply, but so far nothing definite has been obtained along that line. One thing Dr. Darlington is bent on, and that is to keep the public aware of the actual conditions and to insist on full reports on all cases. Only in that way can the public be aroused to the danger which threatens it, he says, and only in that way can it be possible to fight against the further spread of the disease with any chance of success. In accordance with this policy he caused yesterday the publication of the following figures showing the state of affairs this year as compared with the conditions prevailing last year, when the number of cases here was normal:

1904.	July, 3 wk.	July, 4 wk.	Aug., 1 wk.	Aug., 2 wk.
Manhattan	33	44	29	38
Bronx	2	11	5	13
Brooklyn	27	15	26	32
Queens	2	7	5	2
Richmond	1	2	2	1

1905.	July, 3 wk.	July, 4 wk.	Aug., 1 wk.	Aug., 2 wk.
Manhattan	4	67	41	92
Bronx	7	11	10	7
Brooklyn	75	59	67	149
Queens	2	1	1	4
Richmond	..	3	3	2

School Children Inspection.—The health authorities, under the direction of Dr. Hermann M. Biggs, have just completed a very important investigation into the health of some of the school children of this city, which has shown a prevalence of disease exceeding their expectations. As a result they are compiling now a report to be made to the Board of Estimate which will describe the conditions found and which will ask that the city make a special appropriation for school inspectors sufficient to permit of regular monthly examinations of school children much wider in scope than any ever undertaken before. The figures compiled by the medical inspectors and now in Dr. Biggs' possession show that out of almost 14,000 children examined, more than 6,000, or almost half, had something the matter with them. That this proportion should exist, according to the doctors, shows the necessity of adopting some system by which every child showing disease of any form can be followed up by regular monthly examinations. To do that it will require a large increase in the present appropriation. While the health authorities have been gradually extending their work of looking after the health of school children, they have never gone so far as to make the general physical condition of a child part of the work of the Health Department. Until recent years all that the medical inspectors in the schools did was to examine all cases reported by the teacher as being possibly infectious. This work in itself requires a lot of inspectors. Later, skin diseases and pediculosis, which was especially prevalent, were included. For a year or more past monthly examinations have been made for the purpose of discovering such cases. The Health authorities have also been employing fifty trained nurses, known as school nurses. In Manhattan and the Bronx these nurses subject the children sometimes to daily examinations, besides visiting their homes and advising their parents. Last spring, when a sociological student raised the cry of breakfastless school children, Dr. Biggs had an examination made of this phase. It had hardly been completed before it was decided to have a general physical examination made of a certain number of children, which should include all kinds of diseases, bad nutrition, nervousness, mentality, enlarged glands, condition of the breathing organs, vision and hearing and all deformities of the spine or chest. No such examination had ever been undertaken before. The work was done by 100 inspectors. Four schools of the primary grade were taken. All of them were in the poorer quarters, but the worst quarters for disease were avoided in order that the results might be taken as general. About 2,000 children a week were examined, one doctor doing about six a day. The work was completed just before the end of the school year and the figures have just been put together.

The exact number of children examined, as announced yesterday by Dr. Biggs, was 13,941. Of this number, those described as "requiring medical attention" was 6,294. The number of ill-fed children found was 1,092. This is the complete result:

Total number examined, 13,941.	
Bad nutrition	1,092
Swelling in anterior glands	2,604
Swelling in posterior glands	706
Chorea (nervousness)	136
Cardiac disease	232
Pulmonary disease	204
Skin disease	227
Deformity of spine	118
Deformity of chest	162
Deformity of extremities	210
Defective vision	3,219
Defective hearing	460
Nasal breathing	1,623
Bad teeth	3,314
Deformity of the palate	196
Bad mentality	823
Requiring medical attention	6,294

In the case of many of the children put down as dull by their teachers it was found that this was due either to defective vision or defective hearing, for which absolutely nothing had ever been done by their parents. With the 13,941 children examined as a beginning, the health authorities have begun to keep a card index, which they hope to extend throughout the entire school system. On a card is put the name of the child and the date of the examination and just what he or she is suffering from. Printed notices have been prepared and sent to the parents, stating that the examination had shown the child to have an apparently abnormal condition, and suggesting that a doctor be consulted at once. It is the plan to examine all diseased children at the end of each month. If it is found that the parents have not consulted a doctor, one of the health inspectors or nurses will visit the child's home and find out why. "That every other child out of those examined should be found to require medical attention," said Dr. Biggs yesterday, "is something to which too much attention cannot be given. The influence these children have on the community's health is very large. The result was a surprise to us, particularly in the number found to have defective vision and swollen glands. The proportion is so high that the city should do something at once to reduce it. It can only be done by increasing vastly the number of inspectors and nurses in order to hold monthly examinations of the general physical condition of children and following up the parents of every child whom we see is not getting any attention. As yet we have been able to do only a few schools in Manhattan, but it is our purpose to take in the entire city."—*New York Sun.*

CHICAGO.

Apprehensive as to Yellow Fever.—According to a recent interview, Dr. James A. Egan, Secretary of the State Board of Health, expressed himself as being apprehensive of conditions in the South, and feared that yellow fever might gain a foothold in Southern Illinois unless extraordinary precautions were taken.

Rigid Inspection.—The restrictions imposed by the State Board of Health will be continued until frost comes, and every effort will be made to keep refugees from the infected districts out of Southern Illinois. Every passenger and freight train and boat coming from the South is carefully inspected at Cairo, Thebes, and Brookport. Day and night watchmen are stationed on the Illinois Central bridge at Cairo, and the entire water front is patrolled day and night.

Asks for Reforms in Cells.—According to Health Commissioner Dr. Charles J. Whalen, no basement in Chicago is a fit place for the housing of human beings. Commissioner Whalen recommends that the practice of confining prisoners in basement quarters be discontinued by the city as rapidly as possible. Mayor Dunne has received the Commissioner's report, and has agreed that radical changes should be made in the housing of prisoners in the police stations of the city.

Scopolamine-Morphine Anesthesia.—Dr. Emil Ries, of this city, has used scopolamine-morphine in a wide range of operations. He has used it so far on 72 patients in 92 operations. The following is a list of the operations performed. The number of operations is greater than that of the patients, because in a number of cases several operations were performed at the same time—for instance, appendectomy and femoral hernia, cholecystostomy and nephropexy, plastic operation on the vagina, curettement and ovariotomy, etc.: Amputation of breast, 1; amputation of thigh, 1; appendectomy, 12; appendiceal abscess, 2; cholecystostomy, 1; colostomy, 1; curettement, 8; cystoscopy, 3; extirpation of carcinoma recti, 1; extirpation of carcinoma uteri, 1; extirpation of goiter, 3; extirpation of testicle, 1; extirpation of tuberculous glands, 2; extirpation of tumor of chest wall, 1; extirpation of urethral caruncle, 1; operation for stenosis of cervix, 1; hemorrhoids, 6; abdominal hysterectomy, 5; vaginal hysterectomy, 3; laparotomy for pus tubes, 2; nephropexy, 1; nephrotomy, 1; plastic operations on vagina, 14; prostatectomy, 1; radical operation for femoral hernia, 2; for inguinal hernia, 10; for femoral hernia, 1; vaginal celiotomy, 3; vaginal ovariotomy, 1; varicose veins of leg, 1; ventrofixation, 1; total, 92. Of these seventy-two cases, three have died. A carcinoma of the uterus died from hemorrhage due to laceration of the iliac vein in dissecting off adherent enlarged lymphatic glands. The case of carcinoma of the rectum, in which the affected portion of the rectum was torn into during the operation, died of peritonitis five days after the operation. The case of prostatectomy, a very bad case of an old man in a septic condition, who was very anemic in consequence of repeated severe vesical hemorrhages, and who had the largest prostrate he had ever seen, much larger than his fist, died some six hours after the operation. In none of these cases could he accuse the scopolamine-morphine.

GENERAL.

A Correction.—In our report of the Section on Obstetrics of the American Medical Association we referred to Dr. Gould, of Wisconsin; it should have been Dr. W. E. Ground, of Superior, Wisconsin.

Dr. Simpson Retires.—Professor A. R. Simpson has retired from the chair of midwifery at the University of Edinburgh after a service of thirty-five years. Professor Simpson was the nephew and successor in the chair of Sir James Young Simpson, the discoverer of chloroform as an anesthetic.

Birthday of Dr. Benedikt.—Professor Moriz Benedikt, of the University of Vienna, known for his work on diseases of the nervous system, has celebrated his seventieth birthday. A dinner was given in his honor by the Neurological Society of Vienna and congratulations were presented from various societies of which he is a member.

Appointment of Dr. Manwaring.—Dr. Wilfred H. Manwaring, S.B. (Michigan, '95), M. D. (Hopkins, '04), at present fellow of the Rockefeller Institute for Medical Research and assistant in pathology in

the University of Chicago, has been appointed head of the new department of pathology and bacteriology in Indiana University, with the rank of associate professor.

Suits to Purify Water.—Attorney-General McCarter, representing the State Board of Health of New Jersey, began six suits in the Court of Chancery to-day for injunctions to restrain the pollution of tributaries of the Hackensack and Pequannock rivers, from which the cities of Newark, Hoboken and Hackensack derive their water supply. The pollution consists of the discharge of sewage and stable refuse into the streams.

Indiana Methods and the New York Medical Association.—In a decision recently by Circuit Judge Buckingham in the case of the State Board of Medical Registration against Dr. John M. Rhodes, he took occasion to score the board for the methods employed to secure alleged evidence against the physician. It was admitted in the argument for an injunction that the board employed a woman named Boykin to visit physicians and endeavor to get them to perform an illegal operation, and after such employment she would file charges against them before the board. She was accompanied by a man named McClelland, and both of them, after filing a number of affidavits against reputable physicians, left the State. It was upon this evidence that the board was proceeding against Dr. Rhodes, when he filed suit for an injunction, which Judge Buckingham granted to-day, thus preventing the board from proceeding on the woman's *en debem*. In his decision Judge Buckingham says that "if the State Board is so much interested in this matter that its decision would be biased and it has conspired to secure evidence on which to revoke the licenses of physicians by employing immoral persons to make advances, then the whole proceeding should be investigated by some competent board. The board in presenting its argument has not denied that these parties were in its employ." It is understood that the case will be appealed to the Supreme Court. We commend these statements to the attention of the present legal luminaries engaged in collecting fines for the New York State Medical Association in New York City.

A Plan for the Handling of Drunkenness.—A discriminating plan which Massachusetts has adopted for dealing with intoxicated persons is discussed in some of its aspects by *Charities*, writes the *Evening Post*. The new law which has recently gone into effect and has furnished the theme for much disrespectful humor is not, as is here pointed out, any novelty in principle. In fact, ever since 1891 the law has made a sharp distinction between habitual and occasional inebriates. At first the police were given the power of releasing the offender when sober, if he belonged to the second class. After two years this power of release was simply transferred to the courts. Instead of being asked to plead to the charge of being drunk, the question put to the man arrested was simply "whether he had been drunk before." If not, he could go his way. As a matter of fact, 16,000 men a year actually were so released. The new law again transfers this power, bestowing it this time on the probation officer, a functionary who did not exist when the principle of discriminating in such cases was first adopted. An important consequence of this change is that the arrested man will not have to appear in court at all, if the probation officer is satisfied that he will respond to a summons if wanted, and if the records show that he has not been arrested twice before within a year. If the general principle of leniency to first offenders is to be granted, as most of us believe, it is common sense that public appearance in court, with the disgrace that follows it, is almost as trying an ordeal as an actual sentence. It will at least be interesting to note how the change affects the proportion of first offenders who later reappear on the court records.

Medical Education in the United States.—The annual Education Number of the *Journal A. M. A.*, August 19, gives details about the location, course, faculty, equipment, students, etc., of every medical college in the country. During the year ended June 30, 1905, 26,147 persons (including 1,073 women) studied medicine at 157 colleges in 36 States and Territories, and 5,006 of these graduated. The students numbered 1,995 less than the number in 1904; graduates 141 less. The attendance at regular schools, 24,119, was an increase of 457 over 1904, but a decrease of 801 below 1903, and 759 below 1902. Attendance at homeopathic schools has been decreasing steadily since 1900, when it was 1,909; this year it was 1,104. At eclectic schools attendance increased yearly from 1900, when it was 552, to 1904, when it was 1,014, but this year it dropped to 578—a falling off of nearly one-half. All graduates number 141 less than last year; 92 less than 1903. Homeopathic graduates in 1903 were 420; 1904, 371; 1905, 276; but eclectic graduates (153) numbered more in 1905 than in any year since 1900. Three of the 157 colleges are exclusively for women, 63 for men, and 91 co-educational. In 1904 56.8 per cent. of the colleges had terms of less than eight months; now only 39 per cent. are in this class. Six months' schools have decreased from 27 (16.3 per cent.) to 15 (9.4 per cent.). Nine months' schools were 19 (11.6 per cent.) in 1904; now they are 38 (24 per cent.). Many other interesting facts may be derived from this painstaking collaboration of facts and from the critical editorial survey. *The Journal* says that the standards of preparation of study and of graduation have been raised considerably, showing that there is a disposition on the part of all concerned to elevate the standard of the profession by bringing into it men and women who are better prepared to practice medicine, and who will be a credit to the profession in every way. There has been a distinct gain in the entrance requirements during the past two or three years. This change for the better is due, in part, to a few individual colleges, but largely it is the result of concerted action on the part of several organizations which have it in their power to promulgate and to enforce rules and regulations for the government of colleges. The State examining boards, in particular, have exercised a most wholesome influence by raising the requirements and by taking an active part in the regulation of preliminary or preparatory education. It is evident that the length of the term does not sway the student in his selection of a college, because over 61 per cent. of students attended long-term colleges. Students are more and more taking into consideration the standing of the college and what it has to offer. Fees, entrance requirements and length of term are secondary considerations with the better class of students.

Birth Rate's Decline Since 1860.—That "there has been a persistent decline of the birth rate in the United States since 1860," is the conclusion reached in a bulletin issued a week ago by the Census Bureau. The bulletin was prepared by Prof. Walter F. Willcox, of Cornell University, and it is explained that "although the analysis made offers many suggestions as to probable tendencies in the birth rate of the United States, it is, primarily, not a study in birth rates, but a study

in the proportion of children to the total population or to the number of women of child-bearing age. The result of the study shows that at the beginning of the nineteenth century the children under ten years of age constituted one-third, and at the end less than one-fourth of the total population. The decrease in this proportion began as early as the decade 1810 to 1820, and continued uninterruptedly, though at varying rates, in each successive decade.

Between 1850 and 1860 the proportion of children to women between fifteen and forty-nine years, the child-bearing age, increased, but since 1860 it constantly has decreased. It is stated that the decrease has been very unequal from decade to decade, but that if the computation is made upon the basis of twenty-year periods, it has been regular. In 1860 the number of children under five years of age to 1,000 women, fifteen to forty-nine years of age, was 634; in 1900 it was only 474. The proportion of children to potential mothers in 1900 was only three-fourths as large as in 1860. No attempt is made by the author of the bulletin to determine the probable causes of this decline. An extended argument by Gen. Francis A. Walker is given suggesting that it is largely due to the influx of foreigners, and the resultant shock to the population instinct of the natives. Prof. Willcox does not express a definite opinion, claiming that the vital statistics of the United States are not sufficiently developed to afford a sound basis of judgment. He notes, however, that there has been a similar marked decline in the birth rate of Australia, where there has been no such torrent of immigration. Considered sectionally it is found that in the North and West there has been a more or less regular decline, while in the South the change has been less regular and the decline less marked. In 1900, for the United States as a whole, the proportion of children was only two-thirds as great in cities as in the country districts. In the North Atlantic division, however, it was almost as great in the cities as in the country. In the Southern division it is hardly more than half as large in the cities as in the country, while in the Far West the difference is intermediate in amount. A comparison is made between the proportion of children born of native mothers to 1,000 native women of child-bearing age and the proportion of children born to foreign-born mothers to 1,000 foreign-born women of child-bearing age. In 1900 the former proportion was 462, the latter 710, the difference indicating the greater fecundity of foreign-born women. The proportion of negro children to negro women fifteen to forty-nine years of age was largest in 1880, and smallest in 1900. There has been uniformly a larger proportion of negro children than of white children. That difference more than doubled between 1860 and 1880, but in 1900 it was less than half what it was in 1880, and less than at any other census except 1860. Though negroes have a larger proportion of children than the whites, it has been noticed that the whites of the South have a larger proportion than the whites in other sections of the country.

OBITUARY.

Dr. Edward W. Doty, formerly of Paterson, N. J., who died at the home of his father-in-law, Captain D. F. Allen, at Dover, N. J., last week, had a varied career, having been a railroad man, telegraph operator, newspaper correspondent, gold miner and physician. He was born in Newark in 1856. He learned telegraphy and worked at this vocation in a little Ohio town, at the same time acting as correspondent for several papers. Later he took to railroading and later studied medicine. Subsequently he became interested in a gold mine and organized a company to work it, but the enterprise was unsuccessful. After graduating at the Long Island College Hospital in 1886 he went to Paterson and established a large practice.

Word has been received of the death at Uremea, Persia, of Dr. Joseph Plumb Cochran, a missionary of the Presbyterian Church, who has been in that field for twenty-seven years. His father and mother labored in the same field before him and are buried there. Dr. Cochran was educated in Buffalo, and in Yale, and took his degree in the College of Physicians and Surgeons in New York. He was very successful in his field of endeavor, establishing the first hospital in all Persia, and gained tremendous influence. In 1880 he interferred so successfully in an invasion of Kurds into northwestern Persia that Uremea, threatened by the tribes, was saved, and the Shah conferred on him the Order of the Lion and the Sun, which at that time had been conferred only twice on non-Mohammedans. More than a year ago, Dr. Cochran's life was threatened by a fanatical native in resentment over his effort to protect a mountain tribe from Kurdish oppression, and in the hostilities that followed the Rev. Benjamin Labbaree was murdered. Dr. Cochran went to Persia in 1878, and has been home only twice on furlough.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirtieth Annual Meeting, held at Niagara Falls, May 25, 26 and 27, 1905.

(Continued from Page 381.)

Appendicitis in Its Relation to Pregnancy.—Dr. A. Lapthorn Smith, of Montreal, said that no machine was stronger than its weakest part, and in the human mechanism the weakest part was the one which was the least used. Owing to present methods of living the vermiform appendix was one of the least used organs, and consequently the weakest. In all cases of pelvic disease, and in most cases of pregnancy in cities, the whole organism was weakened and labored under difficulties. There was, therefore, in such cases a special reason why an organ, which even in man was unable to withstand the attacks of bacteria, should be unusually liable to infection, ulceration and gangrene. In many cases of supposed pelvic disease, and fever after delivery, the appendix was responsible for most of the trouble, although it might not always present gross lesions. Therefore, no woman should be allowed to begin or continue a pregnancy with an appendix which was known to be chronically inflamed, and all operations for the removal of the uterine appendages should begin by the removal of the vermiform appendix.

Dr. Seth C. Gordon said it was his invariable rule, whenever he opened the abdomen for any other purpose, to remove the appendix, whether good, bad or indifferent.

Dr. Frederick W. Sears stated that one should not be fearful about operating upon pregnant women for appendicitis, as his experience had been that they bore the operation better than the non-pregnant. His experience in operating on pregnant women for appendicitis had been limited to three cases.

Dr Andrew F. Currier did not believe that it was good surgery to remove any organ of the body which he was not convinced was diseased. In certain cases in which there was a strong probability of malignant disease, an exception could be made; but the function of the surgeon was to build up rather than to remove.

Dr. Clement Cleveland looked upon the appendix as a useless organ, and when operating for other intra-abdominal conditions he would not hesitate to remove the appendix. In cases where the appendix had not been found diseased, but had been removed, there was no history to show that any harm had come to those patients. The effect had been *nil*. The arguments of Dr. Currier did not appeal to him.

Dr. Fernand Henrotin said that so far as clinical observation was concerned, the appendix was not only responsible for inflammatory attacks, but for a good deal of indigestion, colic, dyspeptic symptoms, and trouble in the abdomen which was never accurately diagnosed. After an operation for its removal patients were less affected. He would remove the appendix in every instance when operating for some other purpose, unless there were contraindications to its removal.

Dr. Herman J. Boldt said that quite recently a woman, pregnant about the fourth month, had a number of attacks of acute pain in the abdomen. Upon bimanual examination under ether it was impossible to determine anything definite, but because of the extreme pain he opened the abdomen and found an appendix about six inches long, curled upon itself, in a state of acute inflammation. Since its removal the woman had been well. He narrated other similar instances.

Dr. James F. Baldwin, of Columbus, Ohio, had for the last eight years made it a routine practice to examine the appendix in all cases when operating for other intraabdominal pathological conditions, and had removed the appendix in a large number of cases. Out of 3,000 abdominal sections, he had removed the appendix 1,800 times.

Dr. E. P. Davis said there were special reasons why appendicitis should appear in pregnant women, and why the appendix should be removed during pregnancy. As a general proposition, the *Bacillus coli communis* was present in abundance in the intestine of every pregnant woman, and any condition of the intestinal tract during pregnancy which in the slightest degree lessened peristalsis of the normal intestine predisposed to infection by that organism—infection of the adnexa, the uterus, or the appendix. On the other hand, a pregnant woman, whose metabolism was well maintained, was in good condition for a surgical procedure, because she had a physiological blood plethora. She bore anethesia well. The removal of the appendix was applicable to pregnant women and need not be delayed until after delivery, as it was much safer to do the operation during pregnancy than to let the woman run risk.

Dr. Arthur W. Johnstone said that his experience had been limited to four operations performed on pregnant women for appendicitis between two and a half and four months. All recovered. There were no miscarriages.

Dr. Malcolm McLean had not arrived at the point where he would remove an organ simply because it might in the future give trouble. He advanced reasons for taking this stand.

Dr. Ely Van de Warker saw no reason why, if one saw a perfectly healthy appendix, and the abdomen was opened for some other purpose, it should be removed for fear that something was going to happen to it in the future. Such a proposition seemed to him too absurd to discuss. Appendicitis was comparatively rare, in his opinion. In going through the community, and he had spent his life in doing gynecological work, and having opened the abdomen thousands of times, he had examined the appendix and had never removed one, yet he had seen no harm ensue from leaving it. If one were to follow such reasoning, he might as well remove the gall-bladder and other organs for fear they would cause trouble in the future.

Dr. J. Riddle Goffe did not believe in removing a healthy organ, such as the appendix, when we did not know what its function was. It might have some function. There was a time when physicians did not know the function of the spleen, but it was not removed because the abdominal cavity was opened. There was a time when we did not know the function of the thyroid gland, but surgeons did not take it out. He thought we might wake up to the fact some day that the appendix had a function.

Dr. Philander A. Harris raised his voice very strongly against removing perfectly healthy appendices unless there was abundant time to do it, or unless the patients desired it.

Dr. H. J. Lipes, of Albany, said the appendix had a decided function. It was composed largely of mucous glands, situated in the lower part of the cecum, and there was no more stagnant portion of the intestinal tract than it, and no portion that needed lubrication more in getting rid of the fecal material. He thought this mucous secretion helped along the digestion.

The Radical Abdominal Operation Versus the Vaginal Operation for Carcinoma of the Uterus.—Dr. C. C. Frederick, of Buffalo, N. Y., read a paper on this subject, in which he drew the following conclusions: "(1) The radical operation for carcinoma of the uterus should be done only when the gross lesions can quite certainly be diagnosed as confined to the uterine tissue. (2) The deeper tissues of the cervix were generally invaded first, and also the deeper layers of the vagina in the immediate vicinity of the cervix were infected before the disease appeared upon the mucous surface. (3) The bladder wall was very early infected, especially when the anterior lip of the cervix was the starting-point of the growth. (4) When pain became a prominent symptom, the growth had passed beyond the uterine tissue. Such an involvement was a positive contraindication to a radical operation. (5) Carcinoma of the body presented an entirely different condition. In these the liability of extrauterine lymphatic infection was less for the same period of growth. (6) When the radical operation was done, it was necessary to remove as much of the vaginal walls and pericervical tissues and broad ligaments as possible. (7) It was a well attested fact, that in most recurrences after hysterectomy, the growth was found in the cicatrix and the adjacent vaginal tissues. (8) In view of the point at which recurrence began, removal of the pelvic lymphatics and glands did not insure against recurrence. (9) If the vagina was ordinarily capacious, and if the uterus could be drawn down, it would seem that the vaginal route was naturally the one by which the operation could be most readily and thoroughly done. (10) It was possible, yes probable, that some cases of recurrence were due to the infection of the freshly incised tissues at the time of operation by contact of the carcinomatous mass or its fluids. By the vaginal operation this might to a degree be prevented by the removal of the cancerous mass or by thoroughly cauterizing it before beginning the operation proper. (11) The operation could be more quickly done than by the abdominal route. (12) Convalescence, after vaginal operations, was much more rapid; there was much less pain, and there was much less shock to the nervous system. (13) For the cervical carcinoma, in most instances the combined clamp and cautery operation seemed to be the preferable one. (14) Undoubtedly, infected areas were reached and rendered harmless by the free use of the cautery in this operation. (15) The vaginal walls and all

tissues should be seared by it, except those at the utero-vesical junction." The writer would therefore limit the abdominal operation to those patients in whom the condition of the vagina or immobility of the uterus made the vaginal operation practically impossible.

Paravaginal or Abdominal Operation in Carcinoma of the Uterus.—Dr. George Gellhorn, of St. Louis, Mo, in a paper with this title, presented the following conclusions: (1) The object of the symposium was to discuss how we might prove our operative technic in order to better the results in uterine cancer. (2) The following conclusions applied only to cancer of the cervix uteri. (3) The radical abdominal operation, so far as the routine ablation of the lymphatic organs of the pelvis was concerned, had thus far failed to yield the desired results. (4) On the other hand, the eradication of the parametria had been found to reduce greatly the percentage of cures. (5) The simple abdominal and vaginal operations which did not include this procedure should be discarded. (6) For the extirpation of the parametria, Wertheim's method was the best of the abdominal operations. It had, however, he believed, certain disadvantages as compared with the paravaginal method of Schuchardt. (8) Considering the encouraging results of igni-extirpation, a combination of thermo-cautery with paravaginal extirpation gave promise of further improvement in operative results.

A Suggestion for the Surgical Treatment of Incontinence of Urine in Women.—This was the title of the President's Address, delivered by Dr. E. C. Dudley, of Chicago. After referring to the expansion of gynecology, he suggested an operation which was based on the same principle as that proposed by Albarran, namely, advancement of the meatus urinarius to the clitoris, but this was done without dissecting the urethra free and, therefore, it obviated the danger of sloughing of the urethra; it was performed as follows, in two steps:

"*First Step.*—A horseshoe-shaped surface is rather deeply denuded between the meatus urinarius and the clitoris, and to either side of the urethra throughout the entire length of it.

"*Second Step.*—The meatus is drawn up to a point near the clitoris, and is secured there by means of two sutures. The lateral portions of the denuded surface are now closed. The effect of the operation is to replace and to retain in its functional relations the sagging displaced urethra. The two purse sutures necessarily stretch the urethra upward to the region of the clitoris, and that the lateral sutures must tend to hold it in its new position. By this means, it is proposed to straighten out the urethrocele by longitudinal traction, and by lateral traction to collapse and hold together the dilated walls of the urethra, and thus to overcome the sacculation at the neck of the bladder, where residual urine is apt to accumulate and give rise to trigonitis, cystitis, and possible incontinence. In many cases, it will be necessary to combine with the operation some appropriate surgical treatment for an associated cystocele and in nearly all cases to perform perineorrhaphy to relieve also relaxation of the posterior vaginal outlet."

In one case he saw fit to narrow the pouching urethra in order to overcome the urethral dilation. He had performed this operation five times since January 1, 1905. In the first four cases, relief from incontinence was immediate, and had been continuous. The last operation was too recent to be taken into account. In one case there was so much relaxation of the skin and other soft parts in the region of the clitoris that he feared the sutured urethra might pull these structures down to the old malposition instead of being held up by them, but so far it remained well in place. In such a case, again, or in the event of recurrence from such a cause, he should be disposed to make a deep oval denudation over the pubes on the nons veneris, just above the clitoris, the longer axis of the oval being directed transversely, and to unite the margins of this wound by a transverse line of union, so as to make the clitoris a fixed point on a sufficiently high plane to hold the urethra taut. For obvious reasons, this procedure would be preferable to the removal of the clitoris, and the union of the meatus to the parts thereby exposed.

The Mortality in Operations for Fibroid Tumors of the Uterus.—Dr. J. Montgomery Baldy, of Philadelphia, contributed a paper on this subject. Degeneration of fibroid uterus, except malignant and necrotic, were of more scientific interest than practical value. The greatest dangers of fibroids lay in the large death-rate following operations due to heart degeneration, arterial changes, lung thrombosis, etc. He pointed out the conditions inherent in all fibroid tumors of the uterus, and said the tumor should be removed at a period early enough to anticipate the changes.

Migratory Uterine Fibroids.—Dr. Reuben Peterson, of Ann Arbor, Mich., reported cases showing the different stages of the separation of uterine growths from the uterus, and their attachments to other abdominal organs. The causes and results of such migration were studied in the light of the literature on the subject, and the personal experience of the author. Case I was an irregularly shaped subperitoneal fibroid, the size of a fist, attached to the uterus by a very slender pedicle. The latter was very friable and broke away from the uterus during the removal of the latter. The omentum was attached to the posterior surface of the fibroid and partially nourished it. Case II was one of the subperitoneal uterine fibroid, the size and shape of a normal kidney, connected with the uterus by a narrow pedicle, twisted once on itself. The tumor was situated on the right uterine horn, although the pedicle came from the other horn. The tumor was also attached to the bladder, pelvic peritoneum, omentum, and appendix. Case III was a hard, smooth tumor, the size of an orange, unattached to the uterus, having all the characteristics of a subperitoneal fibroid, surrounded on all sides by the omentum and nourished entirely by the omental blood vessels.

Surgical Treatment of Ulcer of the Stomach.—Dr. William H. Wathen, of Louisville, Ky., after discussing the various pathological conditions indicating the necessity for stomach drainage, and the operations that had been performed, drew the following conclusions: "(1) Some cases of acute and subacute gastric and duodenal ulcer, and many cases of chronic and duodenal ulcer, should be treated by efficient stomach drainage into the duodenum or jejunum. (2) Drainage by pyloric divulsion and by pyloroplasty with its modifications has not been sucessful, and these methods are now practically obsolete. (3) Gastroduodenostomy, as modified by Kocher and Finney, may give efficient drainage in many cases, but it should be limited to such cases as cannot be operated upon a posterior retrocolic gastroenterostomy with the anastomosis near the duodenojejunal flexure. (4) Anterior anticolic gastroenterostomy should not be an operation of election, but an operation of expediency or necessity, to give temporary relief, or to meet special abnormal conditions that may contraindicate the posterior attachment. (5) The ideal operation of election must be the posterior retrocolic attachment near the beginning of the jejunum, and at the bottom of the stomach in the pyloric end, thus eliminating the

loop. (6) This gives the most efficient drainage, prevents the vicious circle and regurgitant vomiting, stomach and intestine in nearly normal relation, and is followed by better immediate and ultimate results. (7) The intestinal incision should be made longitudinally, and not less than two inches long, and the stomach incision of corresponding length, preferably in the oblique direction. An elliptical strip of mucosa should be incised from both stomach and intestinal incision. (8) The anastomosis is best made with a continuous suture (Pagenstecher or silk), using a full curved round-pointed needle. The suture should be applied in double layers, the inner to include all the visceral layers, and unite the cut edges of the opening; the outer, one-fifth inch away, to include the serous and subserous layers. (9) Enteroenterostomy, or closure or resection of the proximal jejunum or the pylorus, is unnecessary. It commits a traumatism and leaves a deformity that may cause immediate and subsequent bad results."

SYMPOSIUM ON THE TOXEMIAS OF PREGNANCY.

Clinical Types of Pregnancy Toxemia.—Dr. J. Clifton Edgar, of New York, contributed a paper with this title, in which he considered the benign type, subacute type, acute type, fulminant type, toxemic coma without convulsions, acid toxemia simulating hepatic pregnancy toxemia, persistent hyperemesis without clinical symptoms of toxemia, etc. Cases illustrating each type of toxemia were reported.

Renal Insufficiency.—Dr. Henry C. Coe, of New York, contributed a paper on this subject as a part of the symposium. This referred not only to diminished amount of urine, but to deficient excretion of urea, with or without accompanying albumin and casts. The importance of this subject could not be overestimated, on account of its direct bearing on the prevention of eclampsia. He mentioned the erroneous views formely held that eclampsia always came suddenly, without warning. Now it was known that danger signals were seldom absent long before the attack, if careful watch was kept over the urine. Diminished urea, not the presence of albumin, was the important point. There were two channels for the excretion of toxins, the kidneys and intestines. Both must be made use of. The kidneys and bowels should be flushed, and the diet regulated all through pregnancy. One should know the daily amount of urine at frequent intervals, and the amount of urea. He should not wait for general evidences of toxemia, gastric disturbances, puritus, headache, etc., but anticipate them. Preventive medicine had nowhere more important application than in the case of a pregnant female. Everyone had had occasion to reproach himself for carelessness in this particular. Illustrative cases are cited.

Pernicious Vomiting of Pregnancy.—Dr. J. Whitridge Williams, of Baltimore, after pointing out the distinction between vomiting of and vomiting in pregnancy, divided the former into three groups, and discussed their nature, etiology and treatment, namely, reflex, neurotic, and toxemic. The reflex vomiting of pregnancy might be due to the presence of abnormalities of the generative tract or ovum, which existed prior to the onset of pregnancy, or were coincident with it. Among such conditions might be mentioned retrodisplacements of the uterus, ovarian tumors, certain forms of endometris, and abnormalities of the ovum, such as hydatidiform mole, hydramnios, and certain cases of twin pregnancy. The observations of the author and others showed that typical lesions might be found at autopsy in certain cases, and these consisted in the necrosis of the central portions of the liver lobules, and fatty degeneration and necrosis of the secretory cells of the kidney. Such changes could be produced only by the circulation in the blood of some toxic substance, which acted destructively upon the cells in question. The occasional occurrence of jaundice in some cases added confirmation to the existence of an hepatic lesion; while the not infrequent association of peripheral neutritis with the vomiting accentuated the probability of its toxemic origin. The liver lesions were identical with those observed in acute yellow atrophy of the liver, and icterus gravis, though in most of the cases of vomiting no marked diminution in the size of the liver had been noted. As the former affections occurred usually in the second half of pregnancy, and the vomiting in the first half, it seemed probable that the effect of the toxemia varied somewhat with the duration of the pregnancy. At present the profession is unacquainted with the exact nature of the toxic substances, though they were supposed to be metabolic in origin, but whether derived from the mother or fetus, or both, was not known. All that was definitely settled at present was that one had to deal with a toxemia, which gave rise to serious lesions in the liver, and later in the kidneys. That the latter were secondary in character was indicated by the fact that the urine did not contain albumin or casts until shortly before death. Associated with these lesions was a striking change in metabolism, manifested by a marked increase in the percentage of the total nitrogen of the urine put out as ammonia, which, instead of being two to five per cent., as normal, might rise to 16, 32, or even 46 per cent. Whether the increased ammonia output was due to the fact that the liver lesions interfered with the normal oxidation of nitrogenous material, so that large amounts escaped conversion into urea, and were therefore excreted in a less highly oxidized form, as ammonia, or whether it represented an attempt to neutralize an acid intoxication, was as yet undetermined. The practical point established was that a marked increase in the percentage of the urinary nitrogen excreted as ammonia indicated the existence of a serious toxemia, which, if allowed to continue, would bring about lesions in the liver and other organs inconsistent with life, and accordingly abortion should be induced as the only hope of saving the patient. It was probable that an ammonia output of 10 per cent. represented the danger signal, and as soon as it was reached immediate interference was demanded. In the reflex and neurotic forms of vomiting, the ammonia output remained normal, and accordingly in such cases the treatment should consist of correcting genital lesions, if present, and the employment of mental suggestion and rest cure. There were at least two forms of toxemia of pregnancy, one giving rise to pernicious vomiting and acute yellow atrophy, and the other to eclampsia. These conclusions as to the nature of the vomiting of pregnancy were based upon a number of imperfectly observed cases in previous years, and seven carefully studied cases occurring during the past two years.

Eclampsia and Its Treatment.—Dr. Cyrus A. Kirkley, of Toledo, Ohio, said that other toxins than urea might produce eclampsia. Mixed infection was most probable. Renal insufficiency rather than albuminuria was an etiological factor. Although the source of the toxins was unknown, recent research rather pointed to functional disease

of the liver. Prophylactic treatment, as a rule, was successful, and this consisted of means to promote elimination through the great emunctories. Venesection in suitable cases, both as a prophylactic and curative measure, stood first in the list of remedies.

The Treatment of Eclampsia.—Dr. Frank S. Newell, of Boston, Mass., before considering the curative treatment of eclampsia, discussed the prophylactic treatment, because there was little question but that eclampsia was a preventable disease in the great majority of cases, even of those who developed the signs of a toxemia. Prophylaxis should be directed to the prevention of any accumulation of waste products at any period of pregnancy, combined with the ordinary hygienic measures to maintain and improve the patient's general condition. The treatment, to be efficient, should have four distinct objects in view: (1) The prevention of further absorption of toxins by the removal of the cause; (2) limitation of damage by the toxins already in system; (3) elimination of the toxins, and (4) treatment of the patient. These objects were discussed in consecutive order, and at considerable length. As to after-cure of the patient, for some days after the acute process had subsided the patient should be kept on a liquid diet. Absolute quiet and freedom from care were imperative, and free excretion should be maintained. Sedatives and stimulants should be used as indicated.

Vaginal Cæsarean Section, Its Indications, Advantages and Technic.—Dr. Henry D. Fry, of Washington, D. C., said that the chief indications for the employment of vaginal Cæsarean section, and that which had mainly led to its adoption, were the prompt and easy emptying of the uterus in cases of grave eclampsia. Other indications claimed were cancer of the uterus, rigidity of the os, threatened rupture of the uterus, prolapse of the funis, placenta prævia, heart disease in the pregnant woman, and hemorrhage from the normally implanted placenta. The writer entertained grave doubts regarding the application of this operation or any other method of rapid dilatation to the treatment of placenta prævia. The reduced maternal mortality from this serious complication was largely due to recognizing the value of slow dilation. One might be tempted to employ it in a case of placenta prævia complicated by long undilated cervix, but this condition presented the limited field assigned to abdominal Cæsarean section. He summed up the various indications for this new operation. The advantages of vaginal Cæsarean section were the rapidity with which the uterus could be emptied. From six to ten minutes was all the time that operators had reported necessary, and as they became more familiar with the technic, it might be further reduced. Few operators had done more than one or two operations. Twenty to thirty minutes should complete the sewing up of the wound. There was little traumatism, and a clean surgical cut to sew up instead of leaving the lacerated surface. In eclampsia the blood resulting from the operation was beneficial, and the patient was returned to bed in the best condition to overcome toxemia.

The Mortality of Operations, Other Than Strumectomy, in Cases of Exophthalmic Goiter, with Special Reference to Gynecological Operations.—Dr. Barton C. Hirst, of Philadelphia, said that to learn the collective experience of American surgeons with Graves' disease complicating operations, 336 letters were despatched to the members of the national societies of surgery and gynecology. Forty-three surgeons reported 60 cases. This number added to the 6 collected and reported by Sanderson, made a total of 75. Of this number, 13 died. In 11 of these fatal cases the cause of death was expressly stated to be acute thyroidism, with tachycardia to an extreme degree, and eventual heart failure. In one case of appendiceal abscess the patient died of the combined effects of sepsis and thyroidism. In another case of pelvic abscess, the patient died under chloroform before the operation was begun. Excluding these two cases, the mortality from thyroidism was 14.6 per cent., or, including them, 17.3 per cent. The character of the operation semed to have made little difference in the results. The mortality of the minor operations was 16 per cent.; that of the hysterectomies and myomectomies, 13.3 per cent. It appeared, therefore, that the existence of exophthalmic goiter added about 15 per cent. to the mortality of any operation performed upon the patient. In the first of the author's patients, there had been a distinct goiter and exophthalmos for years, but the tachycardia was moderate. The symptoms in this case were never very alarming, and soon yielded to treatment. It was not known that the second patient had Graves' disease until two days after the operation, when the pulse rose to 180; the eyes protruded, and the throat swelled. He then learned that since girlhood the woman had been subject to such attacks, but lately had been free from them. Although some improvement was shown after hypodermoclysis, purgation and heart stimulants, on the first day that symptoms appeared, a rapid and complete recovery was secured in the next three or four days, apparently in consequence of the administration of suprarenal extract in three grain doses every four hours.

Sudden Death During or Immediately After the Termination of Pregnancy or Operation on the Pelvic Organs in Women.—Dr. Edward P. Davis, of Philadelphia, reported three instructive and interesting cases, and presented a table of 25 typical cases, selected from 193 papers on the subject consulted, and drew the following conclusions: (1) That sudden death might occur after abortion, labor or operation, from undemonstrable causes. (2) Death might follow abortion, labor or operation from the rapid formation of a pulmonary embolus. Examination of cases showed that this happened after so many different procedures that it was impossible to designate any one operation or manipulation which produced it. Pulmonary embolism might develop before the placenta had been delivered, or when delivered by Credé's method; although it was impossible to select any one manipulation which produced this accident. It was not frequent after Cæsarean operation, nor after the more complicated obstetric operations. Predisposing and probably exciting causes were bronchial infection and abnormal conditions of the blood. In 18,800 women in childbirth or having operation, 30 cases of immediate pulmonary embolism occurred, with a mortality of 73 1-3 per cent. Diagnosis, respiratory spasm, with continued heart action. Treatment, hypodermatic stimulation and electric current. Intravenous saline transfusion had not been proven efficient. (3) Primary thrombosis and secondary embolism might cause death after the termination of pregnancy or operation. Causes: Preexisting infection, mechanical violence, altered conditions of blood serum, and lesions in the walls of the vessels. Most important symptom, Mehler's sign, rapid pulse.

Temperature curve in these patients fell on the third or fourth day, while the pulse curve rose. Death usually occurred from secondary formation of pulmonary embolus. Treatment consisted in absolute rest, bandaging of extremities, and in some cases abdominal section with ligation and excision of the veins of the broad ligament. Pulmonary complications developed in 25 per cent. of the cases. Thrombosis was most common in vessels connected with the left iliac vein. There was not conclusive evidence that the entrance of air into the veins was a sufficient cause for death. Gas might form in the vessels from infection. (4) Sudden death occurred in parturient women, and after operation, from reflex nervous shock, without assignable cause; also from disease of the thoracic viscera, from infection of the placental site, and other obscure conditions. Patients having fibroid tumors were especially liable to disease of the heart and vessels.

What is the Present Status of Electricity as a Therapeutic Agent in Gynecological Practice?—Dr. Chauncey D. Palmer, of Cincinnati, Ohio, spoke of the importance of this subject, and referred to its evolution. He referred to the value of measuring current in individual cases, and discussed at great length in what classes of gynecological cases electricity was useful. The possibilities of electricity as a therapeutic agent were by no means limited. The object of the paper was an effort to speak of electricity and place it on its proper basis, not to magnify or misrepresent its virtues, nor to deprecate its powers.

Officers.—The following officers were elected: President, Dr. R. B. Maury, Memphis, Tenn.; First Vice-President, Dr. Howard A. Kelly, Baltimore, Md.; Second Vice-President, Dr. Reuben Peterson, Ann Arbor Mich.; Secretary, Dr. J. Riddle Goffe, New York; Treasurer, Dr. J. Montgomery Baldy, Philadelphia.

Hot Springs, Va., was selected as the place for holding the next annual meeting.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held March 22, 1905.

The President, James M. Anders, M.D., in the Chair.

SYMPOSIUM ON PNEUMONIA.

The Health of the City.—Dr. Thomas Darlington, Commissioner of Health, of New York City, in this paper spoke upon The Pneumonia Commission, saying that it would conduct its investigation along two main lines—clinical and bacteriological—and that information is especially desired on the following points: (1) The occurrence and virulence of the pneumococcus and organisms related to or resembling it, in the human mouth in health and disease. (2) The evidence and the extent of variations in virulence of the pneumococcus under different conditions. (3) The occurrence of the pneumococcus in children's hospitals, homes and asylums, and the bacteriology of the mouth before and after outbreaks of pneumonia. (4) The vitality of the pneumococcus under various conditions. (5) The value of mouth disinfection. (6) The bacteriology of the air of public places, conveyances and buildings and private dwellings, especially in reference to its dust content. The public buildings to embrace stores, factories, large office buildings, public schools, theaters, hospitals, tenements and private houses. (7) The clinical evidence of the communicability of pneumonia as shown by the collection of cases in private houses and public institutions. (8) The seasonal relations of pneumonia. (9) The collection of statistics of pneumonia of the different varieties occurring in hospitals, special attention being paid to terminal pneumonia. (10) The collection of evidence as to the proportion of cases in which pneumonia can be regarded as an autoinfection, and the proportion of cases in which there is evidence of the communicability of the infectious agent. (11) The study of sporadic cases of pneumonia, special attention being given to relationships of the individual to crowds or to exposure to other cases of pneumonia, and the determination of the presence of the pneumococcus in the mouth in those cases and cases associated with them. (12) The evidence for the belief that pneumonia is infrequent in Arctic regions. (13) A statistical study of pneumonia, covering its prevalence in different lattitudes and in different countries and cities, its yearly and seasonal variations and its types and mortality.

The Symptomatology and Diagnosis of Atypical Forms of Pneumonia.—Dr. J. C. Wilson pointed out the fact that the application of the term pneumonia to two conditions clinically and pathologically essentially different, namely bronchopneumonia and croupous pneumonia, has been the cause of misleading therapeutic conclusions and rendered much of the statistical data relating to the prevalence and death rate of croupous pneumonia absolutely worthless. Acute pneumonic phthisis, syphilitic pneumonia, inhalation or deglutition pneumonia, postoperative and anesthesia pneumonias, hyperstatic pneumonias and influenzal pneumonias, as well as pneumonias of measles and pertussis, are not to be regarded as atypical forms of pneumonia, but are properly to be classed with the bronchopneumonias. When the above cases are referred to their proper nosological position there remains to be considered the great group of cases of croupous pneumonia, probably the most important of the acute infectious diseases of the present historical epoch, just as enteric fever was the most important of the last century, typhus of the previous three centuries and the plague the most important of the middle ages. These diseases have lost their terrors for our civilization because our methods of living are hostile to their spread and we have learned, even if we do not universally practice them, the sanitary laws by which they can be controlled.

Croupous pneumonia, it was stated, yet defies the profession, though Preventive Medicine offers some light upon the solution. Dr. Wilson regards it as difficult to draw a sharp line between the classical and the atypical cases. Here, as in other uncertain matters in medicine, it is necessary to be content with conventions. It is generally agreed among descriptive writers upon croupous pneumonia that the cases occurring in infancy, old age and in drunkards are atypical; yet, the majority of physicians have many times seen perfectly typical cases under these conditions. Nevertheless, the following forms are generally regarded as differing sufficiently widely from the type to deserve separate and special consideration: Pneumonia in infants; pneumonia in the aged; pneumonia in the alcoholic—pneumonia potatorum; toxic, so-called typhoid pneumonia; epidemic pneumonia; larval pneumonia.

From the standpoint of the pulmonary lesion the following atypical forms are to be considered: Upper lobe pneumonia, so-called apex pneumonia;

pneumonia migrans; central pneumonia; terminal pneumonia; pneumonia in pulmonary emphysema, hemorrhagic pneumonia. The diagnosis of typical cases of croupous pneumonia it was stated is unattended with difficulty, errors arising much more frequently from carelessness than from ignorance. Too much importance, he believes, cannot be attached to a systematic routine examination of the chest in all cases of acute disease beginning abruptly with chill followed by fever or presenting pulmonary symptoms. The diagnosis becomes difficult in proportion as the departure from type becomes more marked. In the extreme forms of atypical pneumonia—the terminal pneumonias—the clinical diagnosis is very often impracticable. Herpes, which occurs in more than half the cases, is of diagnostic importance. The detection of the pneumococcus in the laboratory reinforces the clinical diagnosis. It can only rarely be utilized in diagnosis except to this extent. Leucocytosis is an almost constant phenomena. Its diagnostic importance is diminished by the fact that it also occurs in most of the conditions in which the question of differential diagnosis arises. Leucopenia is of most unfavorable prognostic significance.

The Medical Treatment of Pneumonia.—Dr. H. A. Hare in a paper by this title dealt chiefly upon the points that the statistics as to the mortality and as to the results of treatment in pneumonia are practically valueless, because different types of this disease are considered under the one heading of pneumonia, when in reality only the most careful differentiation of different types can give reliable statistics. Again, he says, much depends upon the age of the patient and the time at which treatment is instituted. He approved of the use of moderate doses of digitalis and belladonna for a failing circulation and advised a more moderate employment of strychnine, and the rare employment of nitroglycerin, except in cases of definite indication for its use. The subject of venesection, hypodermoclysis and intravenous injection was also considered.

Some Recent Developments in the Etiology and Pathology of Pneumonia.—Dr. Warfield T. Longcope said that in spite of the extensive investigations upon the pathogenesis of lobar pneumonia, bacteriologists and pathologists have added little which aids in the diagnosis, treatment or prevention of the disease. The exciting cause is now known to be the pneumococcus or *Micrococcus lanccolatus*, and the organism is recognized as an inhabitant of the mouth of many normal individuals, where it leads a saprophytic existence. Until recently, the essayist said, observers have not been able to produce lobar pneumonia experimentally in animals, but within the last year Wadsworth has succeeded in producing the typical disease in rabbits by intratracheal injections of virulent pneumococci into animals which had previously been partially immunized. He said further that it is now generally conceded that in the vast majority of pneumonias, if not all, that pneumococci gain entrance into the circulating blood and set up a general infection. Tizzoni and Pacuchi have recently shown that pneumococci may circulate in the blood of immunized rabbits for weeks or months without perceptible harm to the animals. Resolution has been shown by Flexner to occur through autolysis of the exudate. Anti-pneumococcic serum, according to Rimpan and Neufeld, contains a substance which prepares pneumococci for phagocytosis.

Surgical Complications of Pneumonia.—Dr. John H. Gibbon said that of the surgical complications of pneumonia, empyema is the most common, and that the success of the surgical treatment depends largely upon early recognition. Confirmation of diagnosis is made by the exploring needle, which procedure should be carried out with as much care as any surgical opening of a clean healthy cavity. When pus is present the procedure must be followed by thorough drainage. Dr. Gibbon uses chloride of ethyl as an anesthetic, either alone, or as a precursor of ether. In practically every instance beyond the age of twenty he would do a superiosteal resection of the rib rather than simple drainage. Masses of lymph are removed by the fingers. There should be drainage tubes as large as the finger and they should be stitched in. The whole keynote of the treatment of empyema Dr. Gibbon believes to be the early and thorough evacuation of the pus, with the opening made as low down in the pleural cavity as possible. Another condition which is very common, he stated, is lung abscess; due to foreign bodies lodged in the bronchi, to tuberculosis, or to pneumonia. Of the three varieties, that due to pneumonia gives the best results from surgical treatment. The diagnosis in his opinion is attended with more difficulty than that of empyema. Drainage should be carried out exactly as in empyema. In the presence of adhesions between the lung and the chest wall, either of two courses may be followed: The protection of the healthy pleural cavity by gauze packs and immediate drainage of the abscess; or, the stitching of the lung to the parietal pleura, allowing the formation of adhesions before drainage.

Dr. John H. Musser, in opening the discussion, referred to a few points to which his attention had been especially called in his recent observation of pneumonia; first, to the cases simulating abdominal conditions. In deciding whether the condition was one of inflammation in the upper abdomen, or an infection above the diaphragm, attention to a few of the classical phenomena attendant upon each condition aided diagnosis. Of the greater importance were the phenomena attendant upon supradiaphragmatic cases. Here the rusty expectoration or the expiratory grunt was the most valuable sign of pneumococcic infection of the lung; or, the pulse and respiration ratio. Examination of the blood does not aid, because in both conditions there is leucocytosis. In differentiating between pneumonia and meningitis the presence or absence of the phenomena which attend meningitis was more helpful than that of pneumonic symptoms. The slow pulse, the rather slow respiration were among the phenomena indicative of meningeal trouble. In other instances violent hemorrhage at the onset of the disease suggested tuberculosis. The course of the disease offers more help than do the specific symptoms or laboratory signs. In still other instances delirium was so marked in the period of convalescence as to make the case atypical. This delirium, both in hospital and private patients, came on immediately after the crisis and raged violently for from three to five days or two weeks unattended by fever or undue change in pulse rate. The patients recovered without any unusual cerebral complications. In none of the instances had he seen empyema follow as a complication. In one case there was abscess of the lung. It should be remembered that empyema does not always lobulate at the base, the infection often being between the lobes. In the treatment of pneumococcic infection, Dr. Musser thinks it is a mistake to regard it as a self-limiting disease, believing that it

will run its course and the patient recover. While this may be true, no one can tell how quickly the simplest case may become gravely toxic.

Dr. John B. Roberts, in the discussion, said that the surgeon comes in contact with traumatic pneumonia, ether pneumonia, pneumonia due to cold from insufficient clothing (no-undershirt pneumonia) in patients in hospitals, croupous pneumonia, influenza pneumonia and septic pneumonia. It is often difficult to determine whether a given case is one of true croupous pneumonia or influenza pneumonia. He stated that in the incipient stage of inflammation of the lungs, which is shown by dulness on percussion, crepitant râles and rise in temperature, prompt and efficient dry cupping should be used. He never loses time by sending for a cupper, who would probably put on small glasses, but sends for large tumblers, and puts up half a dozen of them himself, by using small pieces of paper dipped in alcohol, to make the vacuum in the glasses. These are left on for half an hour or more, and followed usually by turpentine stupes. In sthenic cases of pneumonia, and particularly in pneumonia following gunshot or stab wounds of the lung, or injury of the lung from fractured ribs, venesection is often of great value. He is confident that he has prevented congestion of the lung becoming pneumonia by efficient dry cupping, and that he has also prevented disastrous results from acute pneumonia following injuries of the lung by phlebotomy. In cases with a great deal of mucus in the bronchial tubes he has seen life apparently saved by inverting the patient in order that gravity might act as a mechanical expectorant. The serous effusion in the pleura which occurs as a complication of pneumonia should be treated by prompt tapping. This may be done as well by the ordinary hydrocele trocar properly sterilized as with the complicated apparatus known as an aspirator. In empyema it is necessary to promptly evacuate the pus and lymph masses. This is easily done by putting the patient in the semi-recumbent posture, freezing the skin with ice and salt, and making a 2½ inch incision with a straight bistoury. It is never necessary to resect the rib in order to get room for evacuation and drainage; and he believes it better not to take the time for resection of the rib when the patient is in the serious condition for which operation is done. If it is found, after a lapse of some weeks, that the lung does not expand and the chest wall does not sink in to close the cavity, resection may be done with much greater safety to the patient than at the time of the original incision. Many cases will never need the rib resected; and even in young children, not over a year old, he has found it easy to get a finger between the ribs and to insert a drainage tube. The incision should be made with a quick thrust of the knife, just as one would open an abcess elsewhere. The wound should then be expanded with two fingers, to allow the pus to flow and the masses of lymph to escape. The latter may need to be hooked out with the finger tip. Two rubber drainage tubes placed side by side should be inserted and stitched to the skin, to keep them from falling out of the wound, and should each have a safety pin in the outer end, to avoid their being sucked into the chest, if the suture threads should cut through the skin unobserved by the physician. Abscess of the lung should be treated in a similar way by free incision and boring between the ribs with the finger to evacuate the pus. No resection of rib is needed here. Irrigation is not needed in cases of empyema, unless the temperature should subsequently show that the cavity has become septic from putrefactive germs. Then it should be washed out once or twice a day with a weak antiseptic solution, or with sterile salt solution. The temperature curve indicates when the intervals between the irrigations may be lengthened.

Dr. James Tyson said that no disease is more treacherous than pneumonia. There is no single treatment which may be said to be in any way curative, although there are measures which cooperate with whatever tendency nature has in the way of self-immunization, or in the way of elimination. He does not believe, however, that treatment is without effect and to be ignored. He emphasized the early and prompt use of dry cups after the manner described by Dr. Roberts, and repeated for a number of days. Certain cases are favorably influenced by the application of the ice bag to the inflamed lung. Where this method has seemed to be lacking in efficiency he thinks it due to the imperfect method of application. He is inclined to think that the best application of cold is by cloths wrung out of ice cold water and kept in place until they become warm. That the ice-cloths induce deep inspiration is an added advantage. They also reduce temperature. When the temperature drops to 100, he has the ice-cloths removed, to be reapplied if the temperature goes above this point. He has found good results to follow the use of creosotol in ten minim doses every four hours. This drug is less irritating than creosote and less dangerous of application. He believes the diagnosis of abscess of the lungs to be more difficult than Dr. Gibbon finds it. Dr. Tyson believes that cases of pneumonia associated with delirium are less apt to be fatal in their termination, although one would naturally think that delirium is an index of the severity of the toxin.

Dr. Judson Daland mentioned dilatation of the right ventricle as an important complication of croupous pneumonia. The use of venesection he finds of special importance. In no condition of the blood with which he is familiar is coaguability of the blood greater than in certain of these cases of croupous pneumonia. In this class of cases the use of alkaline water in large amounts to reduce the acidity of the urine is important. Certain cardiac stimulants are also valuable.

Dr. Frank Woodbury asked that the President speak upon the mode of entrance of the pneumococcus. He thinks possibly the upper air tract may occasionally be a source of entrance for the pneumococcus, though occasionally entrance is through the bronchial mucous membrane. He suggests the possibility that abnormal conditions of the nasal mucosa may afford entrance for the pneumococcus, and that the entrance into the blood from the upper air passags may give some of the atypical forms referred to by Dr. Wilson.

Dr. James M. Anders spoke especially with reference to the treatment of pneumonia, believing that attention should be directed to the limitation of the area of consolidation, to the assistance of nature in the elimination of toxins, and to the meeting of indications as they arise. He agreed with Dr. Musser that water is given too sparingly in pneumonia patients, and not sufficiently systematically. He emphasized especially the support and maintenance of the heart circulation. An important question is the decision of just when to aid the heart, and with what agents; whether to wait until the pulse tension

begins to fall off and the first sound of the heart becomes weak, or to give this aid before that period arrives. In Dr. Anders' experience, after an attack of heart failure in pneumonia toxemia increases, and death almost invariably is the result. On the other hand, when he has given cardiac tonics and stimulants sufficiently early failing circulation has been warded off. Strychnine he has found to be the best agent for this purpose. Nitroglycerin is another valuable remedy. He believes that the pneumococcus often makes its entrance through the upper air passages.

Dr. Githens referred to his experimental work in the injection of adrenalin chloride into animals. The chloride causes punctate hemorrhages throughout the lungs, and if the dose is too large, in a rabbit death is caused promptly by pulmonary edema. It has occurred to Dr. Githens that a similar effect may account for some of the bad results found in pneumonia.

Dr. Darlington, in closing, emphasized the value of the drinking of water in pneumonia. He had lobar pneumonia himself ten years ago, with six others, all of whom died. The other men had been accustomed to a different kind of drink, and it was impossible to get water into them. Dr. Darlington had taken water in great quantities in the course of the disease, and considered himself a monument to the value of the drinking of water in pneumonia. Quinine he gives in large doses, and the result of the remedy, in his opinion, depends upon the particular epidemic. Last year, he remarked, pneumonia was very fatal; this year the mortality was less. In reference to heart stimulants, Dr. Darlington observed that if the heart commences to fail it will go on to failure irrespective of the giving of a stimulant.

ILLINOIS STATE MEDICAL SOCIETY.

Fifty-fifth Annual Meeting, held at Rock Island, May 16, 17 and 18, 1905.

The President, William E. Quine, M.D., of Chicago, in the Chair.

The scientific work of the Society was divided into two sections, medical and surgical.

Medical Section.

The Optional Disease.—Dr. Heman Spalding, of Chicago, discussed the symptomatology and differential diagnosis of smallpox, and showed lantern slides made from photographs taken of patients at the Isolation Hospital, Chicago. He also quoted the statistics of the Chicago Department of Health, showing the incidents and death rate of the disease in vaccinated and unvaccinated persons, and described the methods of vaccination. He emphasized the exercise of caution in using virus which was efficient. Failure to obtain a take was usually due to inert virus, and sometimes to improper technic in vaccinating.

Pericarditis.—Dr. J. H. Bacon, of Cleveland, Ohio, discussed the clinical history of the various forms of pericarditis and described a new method of tapping the pericardium. A small trephine opening was made opposite the fifth intercostal space between the midsternal line and the left border of the sternum. The finger was inserted through this opening, adhesions were broken up, and the pericardium opened. In cases of purulent perdicarditis, to prevent infection of the sternum and a subsequent osteomyelitis, the posterior surface of the sternum was covered freely with ten per cent. iodoform paraffin or wax. He also suggested that in cases of adherent pericardium the patient's life often could be saved by making a similar opening and loosening the adhesions between the two layers of the pericardium in the same manner as uterine adhesions were liberated. He detailed experiments on dogs that were carried on by him, showing the feasibility of this procedure.

The Present Status of Serumtherapy.—Dr. E. R. Larned, of Chicago, defined what was meant by serumtherapy, and then classified the sera as used in medicine under (*a*) curative sera, and (*b*) diagnostic sera. Classification of sera as to efficacy, (*a*) those of demonstrated efficacy; (*b*) those whose value appeared probable, but remained to be proved, and (*c*) those whose efficacy was *nil*. He described the methods used in the elaboration of sera; and gave a brief outline of the present status of the following sera: (*a*) Those of demonstrated efficiency, antidiphtheritic, antitetanic, antiplague, antistreptococcic, and sera for exophthalmic goitre. (*b*) Those whose value appeared probable, but remained to be proved, as serum for hay fever, tuberculin, antityphoid, antirabic, antitubercle, and intivenine. (*c*) Those whose efficiency was *nil*, as antipneumococcic sera, antiscarlatinal sera, antidysenteric sera, antivarioloid sera, antitoxin for cerebrospinal meningitis, serum for rheumatism, serum for syphilis, serum for anthrax, cancer serum, and leprolin.

Scrofula.—Dr. Henry G. Anthony, of Chicago, stated that scrofula was a factor in dermatology, the importance of which was variously estimated chiefly because of the diversity of opinion which existed as to what was meant by the term. He emphasized the fact that scrofula was not tuberculosis. Children with tuberculosis of joints did not present the various lesions which occured in the eye and skin of scrofulous patients. It required nose and throat lesions to produce the clinical picture of scrofula. These nose and throat lesions were not tuberculosis, and the nasal and throat secretions did not contain the bacillus tuberculosis. Clinically and microscopically, the the disease was a pyogenic infection of the nose and throat. Tuberculosis readily developed on the pyogenic infections, but this could never be determined clinically, and that was the reason so many believed that the disease was tuberculous. When a chronic pyogenic infection of the nose and throat was present it spread to the ear, eye, skin, glands, and bronchial tubes. The eruption of the skin which ocurred from this spreading of pyogenic infection was impetigo, and not eczema, of which two varieties were mentioned, one of which was a vericella-like eruption. Eczema might occur in scrofula, but the cases which were usually called eczema were really impetigo. The author had observed that sweating of the hands and feet was an important symptom in the disease. Scrofuloderma was subcutaneous tuberculosis, and lichen scrofulosorum was a tuberculous toxemia occurring in all forms of tuberculosis. The severest of all cases were those in which the infection had extended to the bronchial tubes.

The Educational Treatment of Neurasthenics.—Charles D. Center, of Quincy, Ill., believed that cases of neurasthenia were increasing in number very rapidly. He showed that a rather definite percentage of the symptoms of a neurasthenic were illusory or hallucinatory in character, and also claimed that practically every phase had one symptom, complaint, apprehension, or fear, which predominated over all

the others. This one predominating symptom he called the chief obsession, and stated that when this was overcome or removed all lesser symptoms were either abated or were entirely relieved. A number of cases of neurasthenia from the practice of the writer were cited, giving the chief obsession in each case, and the educational means used to remove this obsession. Reference was made to the use of strychnine in these cases, and it was found that the majority were made worse by its administration. The author emphasized the need of getting hold of the mentality of each case of neurasthenia, believing that it was more essential to treat the mind than the body.

Late Hereditary Syphilis.—Dr. R. R. Campbell, of Chicago, stated that in establishing a diagnosis of hereditary syphilis there were three points known as the triad of syphilis, which had long been looked upon as of the greatest value. These were Hutchinson's teeth, interstitial keratitis, and a particular form of deafness. These points were considered in their order. He reported several cases of late hereditary syphilis gleaned from the literature, and others that had occurred in his own practice.

The Climatic Treatment of Tuberculosis, with Special Reference to Colorado.—Dr. Clarence L. Wheaton, of Chicago, spoke of the mortality from tuberculosis, and the period of life at which death occurred during the last census year. He alluded to the necessity for enforcing laws relating to hygienic and sanitary measures, the establishing of State sanatoria for the care of the tuberculous poor, etc. He referred to the success of the Ottawa tent colony in the treatment of this disease, and said the tuberculosis problem was to be solved at home, based upon a study of conditions in Colorado, Arizona and New Mexico. A knowledge of meteorological facts and climatic data was essential in prescribing climate.

Diet in Tubercluosis.—Miss Adelia Sater, of Ottawa, spoke on this subject, and, among other things, stated that the appetite was no reliable criterion as to the amount of food that might be taken and digested by the patient. Hygiene and diet were the foundation stones upon which might be constructed successful therapeutics in the cure of tuberculosis.

Indormescent Shocks.—Dr. Hugh T. Patrick, of Chicago, called them indormescent because they ordinarily occurred just as the patient was falling asleep. These shocks might be divided roughly into motor, sensory. Mild motor shocks, or simple starts, might be regarded as normal, but in some persons they reached a degree which was pathological, and in others attained a violence sufficient to make them worthy of medical consideration and special treatment. The sensory form might affect general sensation or the special senses. The manifestation occurred as a symptom of functional disease, and in the vast majority of cases was of no grave significance, although the shock was a most alarming sensation for the patient. Illustrative cases were cited, and treatment given.

The Glycosuria of Hepatic Insufficiency.—Dr. Alfred C. Croftan, of Chicago, spoke of the frequency of sugar excretion in functional disorders of the liver, and pointed out the dangers of treating a patient afflicted in this way as a diabetic. He detailed the causes, symptoms, and treatment of this variety of non-diabetic glycosuria.

The Practical Significance of Certain Symptoms in the Upper Abdomen.—Dr. J. F. Percy, of Galesburg, said that the overlooking in this region of the pathology on which these symptoms were based was one of the strange chapters in the history of diagnosis. The common symptoms were pain due to cholecystitis, ulcer of the stomach, and of the duodenum, together with the formation of gas due to inhibited peristalsis. Vomiting was also mentioned; but nausea was a more prominent symptom than the former. Bleeding was also to be noted as one of the symptoms. The significance of these could best be determined by percussion, palpation, and noting costal resistance, especially in the right side. Laboratory methods were of confirmatory value only. Alone they could not make the diagnosis. The periodicity of the attacks from ulcer of the stomach and the duodenum was insisted upon, as was also the fact that the cholecystitis or an ulcer of the stomach would account for many of the chronic lesions of the liver and the pancreas. Both of these facts were new to the literature of this great subject.

The Tuberculosis Problem in Illinois.—Dr. Homer M. Thomas, of Chicago, stated that the main factor in the solution of the tuberculosis problem in this State was to secure for patients an abundance of pure air. It was from the unpierced heights and limitless expanse of the tractless skies came the life-giving ozone. Its presence in the blood brought renewed life and vigor. The flagging forces of nature found in its subtle chemistry the antithesis of decay. The sodden skin, the halting step, the lustreless eye, the clouded brain, under its vitalizing influence were rejuvenated. Tuberculosis in Illinois concerned sources of impure air. These were mainly the home and the workshop. Tuberculosis was a house disease. It depended upon the home for implantation, growth, maturity and propagation. The house was the granary of the bacillus. Houses of one kind and another were the ordinary means of spreading the disease. The house was the most frequent means, and the workshop next. This was so because it took prolonged intimate contact with a person, place, or thing that had been intensely contaminated with tuberculosis matter to give rise to implantation. Probably three-fourths of all cases of the disease conveyed from person to person were contracted in the home, and one-fourth through the workshop and environment. Homes should be made clean, dry, airy and bright. Buildings in which men and women were employed should be made sanitary, and should have a correct standard of air supply and light. The highest conception of medical science to-day was in preventive medicine. The Illinois State Medical Society had taken upon itself the advancement of this great work by establishing the Ottawa tent colony.

Parenchymatous Keratitis, Iridochoroidal Form, with Loss of Both Eyes.—Dr. Charles H. Probst, of Peoria, read a paper with this title, in which he stated that if iridectomy was to accomplish anything it should be performed early in the disease, before iridic adhesions had taken place, or before an advanced iridochoroiditis had a chance to develop. On several occasions he had performed iridectomy in the very beginning of the iridochorodial from of parenchymatous keratitis, with excellent results. In summing up the case he reported there were several interesting features relating to it, which were subnormal temperature from 1 to 1.5° F., and a very slow pulse. The therapeutic agents which were administered per mouth, such as salicylates, mercury, and potassium idodide, exerted no influence on the disease whatever. Subconjunctival injections of mercury and salt solutions had no beneficial effect on the eye until after the constitutional results of mercury

had been attained by deep hypodermic injections. There was a sudden development of a secondary glaucoma after the eye had been doing well for six months. Destruction of both eyes, four years apart, occurred in a similar way. While the history and all other symptoms were negative, he thought the case was undoubtedly one of hereditary syphilis.

Mixed Infection in Consumption.—Dr. Ethan A. Gray, of Chicago, spoke of the necessity of recognizing the presence of more than one infection in pulmonary tuberculosis. Secondary or so-called mixed infections were the chief agencies in producing the symptom-complex, consumption. As to the course of mixed infection, there was danger of mistaking it for grippe, malaria, colds, etc. Occasionally pleurisy and broncho-pneumonia were expressions of mixed infection. Hemorrhage from eroded arteries was a factor in spreading infection. A diazo-reaction did not always mean a fatal prognosis. Treatment should be largely hygienic and climatic but this was uncertain as far as checking the toxemia was concerned. He spoke of the value of streptolytic serum; amount administered, 10 c.c. daily, for six days; treatment was then discontinued until reaction had passed. Usually cough and expectoration would be diminished to a minimum, sometimes altogether. The phenomena of reaction were pointed out, postreactive findings were few or no bacteria. There was diminution in tubercle bacilli unless sputum was greatly concentrated; normal pulse and temperature. Severe cases only approximated the normal. Serum did not cure tuberculosis, but only cleared out bacteria and their toxins, leaving a better field in which to fight the tubercle bacillus. Seven cases were cited, in all of which the septic fever was materially influenced. In once case of advanced consumption fever was reduced from 103° to 99.5° F.; appetite and sleep returned, cough diminished, and expectoration as well. One case died without fever or expectoration three weeks after treatment was finishd. Five cases showed marked improvement with return to normal temperatures and better general condition.

The License and Control of the Practice of Medicine in Illinois.—Dr. George W. Webster, of Chicago, said that during the session of the Forty-third General Assembly a bill was introduced, creating a board of examiners. Owing chiefly to want of harmonious action on the part of the legislative committee of the State Medical Society, it failed to become a law. At the present time the chief functions of the Illinois State Board of Health were the general supervision of all sanitary and public health matters, and quarantine in the State, the examining and licensing of physicians and of other practitioners, the licensing of embalmers, the licensing of midwives, the inspection of lodging-houses in all cities of one hundred thousand inbatitants and over in the State. The board established a schedule of minimum requirements for medical colleges, making a high school education the preliminary entrance requirement, prescribed the length of the term, which must be not less than seven months, no two courses to be given in the same calendar year of time, prescribed the minimum number of hours of instruction in each term, the studies of the curriculum, the character of the college equipment, and all those colleges complying strictly with these rules were considered in good standing with the board. This simply admitted them to the examination. If their credentials were found satisfactory, and if they possessed a diploma from a recognized school and sustained a satisfactory examination before the Board, they were then licened. The "other practitioners" referred to were mostly osteopaths, and this term referred to the licensing of all those who treated human aliments without the use of drugs, or by mechanical appliances.

Some Phases of Disordered Metabolism in Nephritis.—Dr. Ralph W. Webster, of Chicago, said that nephritis was primarily a constitutional disease, with secondary manifestations in the kidney. The close relationship between the findings in the so-called febrile albuminaria, and those in typical nephritis were so marked that a common constitutional condition in each must be granted. All of the causative factors of nephritis produced metabolic disturbances which resulted in the production of toxins, irritant poisons, changes in the properties of the blood, both physical and chemical, and various other pathological abnormalities, which, in themselves, caused irritative and later inflammatory lesions in the kidney resulting in nephritis. A large number of metabolic changes might be directly traceable to the nephritis itself. In this paper the author discussed only the points of chloride retention, edema and urēmia. The retention of chlorides in nephritis was granted, but its relation to edema seemed to the author still debatable inasmuch as present knowledge regarding the pathology of albuminaria and of edema was not sufficient to warrant the ascribing of a specific influence to the chlorides in edema, over and above that of other salts. A discussion of the relation of chloride intake to increased albuminaria was given, in which the author concluded that in this connection NaCl may act as a specific. Concerning the theories of edema, those of Cohnheim, Kövesi and Roth-Schulz and von Koranyi received attention. The author showed the importance of osmotic changes in the production of this symptom of nephritis. The relation of the amount of water taken in had double importance in increasing a hydremia and in increasing the work of the heart. With regard to the uremia, it seemed that one must at present accept the idea of Senator and assume that this condition is purely a group of symptoms brought about through disordered metabolism as a result of lesions in an insufficient kidney, which lesions had, in their turn, been caused by attempts on the part of the kidney to eliminate products of an abnormal metabolism, the result of a specific or non-specific toxemia.

Ocular Manifestations of Chronic Nephritis.—Dr. Leigh E. Schwarz, of Chicago, read a paper in which he drew the following conclusions: (1) An ophthalmological examination should be made in all cases where nephritis existed or was suspected. (2) The non-existence of nephritis must not be inferred because visual disturbance is absent. (3) Ocular manifestations were invaluable where nephritis without albumin existed. (4) The severity of the renal symptoms did not influence those of the eye. (5) Retinal changes might occur before any definite clinical symptoms of nephritis developed. (6) Unilateral retinitis gave a relatively hopeful prognosis. (7) Retinitis might be the first indication of nephritis even in the later stage. (8) Prognostic value of the hemmorrhagic type was not greater than that of other forms of albuminuric retinitis.

Medical Treatment of Nephritis.—Dr. Arthur R. Elliott, of Chicago, presented the subject in the following practical order: (1) Treatment of chronic nephritis without dropsy; (2) treatment of chronic nephritis with dropsy; and (3) treatment of uremia. After discussing the subject at great length under the above heads, the author closed by saying that there was no room for pessimism in our attitude toward this

disease, and while obviously there was no remarkable cure to be performed by any mode of treatment, careful regulation of the life, and attention to little details, would secure results which were unsurpassed in any of the chronic dystrophies. The two most important indications were to protect the patient from intercurrent acute disturbance and maintain the compensatory adjustment in the circulation.

Ideals and Practices of the Medical Profession.—This was the title of the President's Address, delivered by Dr. William E. Quine, of Chicago. He stated that standards differed in different societies and even under different conditions in the same society. It was a fact of familiar knowledge that offences committed by physicians against the public conscience might be easily tolerated by their own organizations; but offenses against the technical standards of the organizations themselves, although quite unnoticed by the community at large, were liable to severe and lasting penalties, especially is the culprit be of humble rank and without friends. Among misdemeanors of this kind he mentioned advertising in the public prints; the exploitation of remarkable cures and operations; the holding of patents on articles used in the practice of medicine; the pretense of possessing an infallible law of cure; and the acceptance by physicians of commissions on their prescriptions, or on needed appliances which they were instrumental in selling, or on the fees of surgeons received for operations on the physician's patients. Such acts were always small and surreptitiousness made them mean; but he failed to see in them convincing proof of gross moral obliquity. Most of them were quite compatible with honorable standing in the community; and yet they were stigmatized, and properly so, by the unanimous vote of the organized profession—and, hence, were subject to penalty within the organization and profession itself. On the other hand, when physicians violated the public's standards of morality and thereby brought upon themselves public disrepute, their professional standing might be saved from challenge in medical organizations. Such discrimination was neither creditable nor defensible. A life sentence of ostracism should never be inflicted for mere technical transgressions, nor for any others except such as constitute *prima facie* evidence of depravity of heart.

What We Must Learn and Unlearn in the Treatment of Tuberculosis.—This was the title of the address in medicine delivered by Dr. J. W. Pettit, of Ottawa. The author said it was now a well-established fact that climate was an unimportant factor in the treatment of tuberculosis. Because the medical profession had learned the utter futility of drugs in the treatment of this disease, their responsibility had not ceased. Physicians should guide patients when they do not treat them. A mistake had been made in regarding fresh air as the *sine qua non* in the treatment of tuberculosis. Nutritious food, regular rest and exercise were each of essential importance. There was much to be learned in regard to the housing of tuberculosis patients. As to the use of tents, it had been demonstrated that the tent was practicable in cold climates. It fulfilled the conditions most perfectly from a scientific standpoint. A practical point essential to success was the importance of an early diagnosis in this disease.

The following papers were also read and discussed: "Air Examinations, Importance and Results," by Dr. Adolph Gehrman, of Chicago; "Typhoid Fever," by Dr. G. G. Craig, of Rock Island; "Cases of Erysipelas Treated with Marsh Purslane," by Dr. H. C. Mitchell, of Carbondale; "Respiratory Oxidation Stimulants in Nephritis, Pulmonary Dyspneic and Allied Crises,' by Dr. George F. Butler, of Chicago; "Syphilitic Meningitis in Children," by Dr. William J. Butler, of Chicago.

Surgical Section.

Surgery of the Stomach.—Dr. Arthur Dean Bevan, of Chicago, said that stomach surgery to-day stood out as the most gratifying surgical field in the process of rapid development. This fact was perfectly patent that the demonstrated value of surgical procedures in treating stomach lesions waranted a much wider application of such methods than were at present practiced. His plea was that the cases must be carefully selected, and the surgeon must be sure that an operation was strongly indicated. Cases that could be cured by a summer's outing or by carefully selected diet should not be operated upon; nor should hopeless cases be operated. He discussed the surgery of the stomach under two head: (1) Surgical treatment of carcinoma of the stomach, and (2) the surgical treatment of ulcer and its complications and sequelæ. If cases of chronic carcinoma of the stomach were early diagnosed and operated upon at a time when the entire focus of disease could be removed, a cure could be effected. As to stomach ulcer, when intelligent medical treatment failed and the symptoms returned and persisted, then and not until then did the uncomplicated stomach ulcer become a surgical problem. The great majority of cases of perforation of the stomach by ulcer could be saved by early surgical interference. The surgery of the stomach was advancing. The profession should keep pace with it and give the patient the benefiits of its demonstrated possibilities.

Dr. Carl E. Black, of Jacksonville, discussed the surgery of the bile tracts; while Dr. Emerson M. Sutton, of Peoria, discussed the possibilities of surgery of the duodenum.

Dr. M. L. Harris, of Chicago, spoke of the surgical treatment of injuries to the spleen due to subcutaneous penetrating wounds; the value of splenectomy in certain anemias associated with enlargements of the spleen.

Surgical Tuberculosis.—Dr. William E. Guthrie, of Bloomington, in discussing this subject, said that while phyisicians should study how to help tuberculosis patients by the proper removal of diseased tissues, they should not forget that vastly more necessary was the conservation of the power of resistance of the patient to disease through suitable hygiene and forced feeding. He who would treat tuberculosis in any form successfully must have for his watchword ever, "Feed, feed, feed."

Tuberculous Nephritis.—Dr. Robert Christie, of Quincy, reviewed the literature with reference to comparative frequency, and alluded to the more recent investigations and observations, discussing the modes of infection, primary, secondary, metastatic atypical cases, without characteristic symptoms, other than localized tumefaction. He reported a case in which he did a primary abdominal nephrectomy, followed by recovery of the patient.

Errors in the Diagnosis of Abdominal Troubles.—Dr. Clifford U. Collins, of Peoria, said that perfection in diagnosis marked the highest development in science and medicine. With a correct diagnosis it was not hard to institute the proper treatment. The development of diagnosis had been a difficult process marked by many errors. While one was endeavoring to approach perfection in diagnosis, it was highly probable that errors would always be made. Although errors

were annoying, each one conveyed a lesson, and, if studied and interpreted correctly, would result in much good to the examiner. The keeping of complete case records would permit of close and careful study of each error and lead to success, because "Success does not consist in not making any mitakes, but in not making the same mistake twice."

Congenital Clubfoot.—Drs. John Ridlon and Charles E. Eikenbary, of Chicago, contributed a joint paper, in which they briefly discussed the varieties of congenital clubfoot; also the anatomy of congenital equinovarus and the theories of its causation. The paper chiefly discussed the subject of treatment by manipulation, by braces, by the Thomas wrench, by hand modeling, with the patient anesthetized, by the Granton osteoclast, by simple tenotomies supplemented by modeling, or the use of the wrench, or the osteoclast by the Phelps open incision and Jonas' modification of it, and by linear and cuneiform osteotomies, and enucleation of the astragulus. The methods of after-treatment by plaster splints and by braces were briefly considered and the statistics of Dr. Ridlon's cases for the past twelve years were given.

Stricture of Esophagus Following Typhoid Fever.—Dr. S. C. Plummer, of Chicago, reported a case of stricture of the esophagus following typhoid fever. The case was one of typhoid fever with severe relapse, symptoms of stricture immediately following. The patient was treated by sound. There was gradual tightening until swallowing even of water was impossible. Under anesthesia an unsuccessful attempt was made to pass the stricture. A gastronomy was performed; there was relaxation of the stricture after four months of absolute closure. Dilation of the stricture was resorted to, and an operation made for closure of the gastric fistula.

Colloid Carcinoma of Cecum.—Dr. Plummer reported this case, in which an operation was performed for appendicitis three years previously. Excision of the cecum and ascending colon was done, with lateral anastomosis by Murphy button of the ileum to the transverse colon. There was recovery from the operation, with restoration of health, followed by recurrence.

Penetrating Wound of Liver.—In this case Dr. Plummer said the injury was produced by a small missile, a portion of a dynamite cap. Laparotomy was done, but the foreign body not found. It was evidently embedded in the liver. The liver wound was closed, and patient recovered without complications.

Gastro-Enteroptosis.—This patient had symptoms simulating appendicitis. The transverse colon was found in the shape of a letter V. The gastrohepatic omentum was abnormally long. The gastrohepatic omentum and transverse mesocolon were each folded upon itself and stitched, followed by permanent relief of the symptoms.

Dr. Fernand Henrotin, of Chicago, made some remarks concerning when and how to treat septic pelvic affections of women by vaginal incision and drainage.

Diagnosis and Pathology of Neoplasms of the Brain.—Dr. Hugh T. Patrick, of Chicago, in discussing the pathology, said that the most frequent tumors were glioma, carcoma and solitary tubercle. He enumerated the less frequent forms. Structure, the manner of growth, and the physical properties of more frequent tumors were pointed out. As to diagnosis, the determination of intracranial neoplasms was generally easy. Exact localization was generally difficult, frequently impossible. He mentioned the classical symptoms of brain tumor and the points of differential diagnosis. Tumor might simulate apoplexy. General paresis, arteriosclerosis, nephritis, migraine, etc., were discussed in connection with brain tumors; also the symptoms indicating the seat of growth.

Insanity Following Skull Injuries.—Dr. E. Mammen, of Bloomington, spoke of contusions, concussions, location of injuries, fractures, and symptoms following skull injuries. The symptoms were sometimes slow in development. He spoke of the changes in tissue at the site of injury, also operation, relief from pressure, relief by the removal of changed tissues and of cirrhotic bone. He cited cases and gave the results.

Cerebral Infection from Middle-Ear Disease.—Dr. Norval H. Pierce, of Chicago, referred to the anatomical paths by which suppurations within the temporal bone reached the contents of the calvarium. He discussed the character of the primary inflammations which produced intracranial complications, as well as the influence of locality of the primary inflammations on the different intracranial complications. Purulent inflammations of the dura and the extradural abscess were discussed. He referred to meningitis and meningo-encephalitis serosa following suppurations within the temporal bone; also to phlebitis and thrombosis of the dural sinuses and the jugular vein. Reference was made to isolated thrombosos of the jugular bulb, also to otitis brain abscess.

Prophylaxis of Syphilis.—Dr. Alfred Schalek, of Chicago, said there was renewed activity in this direction among the medical profession in recent times. The reasons were not an increase in the number of cases, nor a more severe course of the disease, but better statistics, and the present improved prophylactic measures against other infective diseases. The spread of syphilis could be limited by means which applied to the general public and the individual. The former included control of prostitution, but had proven a failure. Impracticable also was the suggested cumpulsory report of cases by physicians. A better measure was the education of the public as to the nature of the disease. Instructions should be given how to avoid infection innocently. He made a plea for increased facilities for treatment in hospitals and dispensaries. The author thought that at the present time the most valuable prophylaxis against syphilis ought to be practiced by the medical profession in their relations with their patients. Since no methods were known to abort the disease after infection occurred, the most important duty was a thorough treatment.

Some Cases Demanding Removal of the Eye of Interest to the Physician and Surgeon.—Dr. J. Brown Loring, of Chicago, discussed the responsibility resting on the physician and surgeon, as well as the ophthalmologist, with regard to the treatment of blind eyes. Reports were given of three cases of sarcoma, one of glioma, and five of iridocyclitis of various origin, causing or threatening sympathetic ophthalmia. The first four cases indicated danger to life, the others danger to sight. Statistics were given as to the frequency of sympathetic ophthalmia. Attention was called to the unsatisfactory and at times contradictory manner in which the subject of treating eyes blind from iridocyclitis was discussed in modern textbooks. A plea was made for a more radical treatment of these cases from every standpoint.

The Commerce of Surgery.—Dr. Fernand Henrotin, of Chicago, in selecting this subject for his address, said he did not wish to apologize for the prevailing forms of commercialism which tended to degrade the medical profession. He spoke for the future, and bespoke an unbiased, calm decision upon the best methods of eradicating or minimizing existing evils.

A considerable part of these might rightly be attributed to the course of life of the very men who condemned them so strenuously. In the keen competition of the battle of life they had forgotten that the ethical function equity should be supplemented by kindness; omission and lack of perception, not commission. Within the bounds of law they had lost sight of negative beneficence. They had often begun by being commercial until beyond want, and now they were moralists. They held more positions than they could fill satisfactorily; they performed more operations than they could do full justice to, or overlooked the care of. They often opposed the rise of their peers and particularly their superiors on their faculties; they boasted of their large fees and their annual income, exciting the cupidity of their fellows, all of which was properly within the law, but was an element in the development of present conditions. Add to that the elements which he had shown and one would have the reason for commercialism. All of this writing was a plea for the exercise of negative beneficence on the part of the profession in regard to this whole question. While proven violations of the law of ethical conduct should be given publicity and be visited by just penalty, wholesome denunciations should be decently omitted as tending to disorganize the ranks and doing injury to men whose mistakes had resulted from force of circumstances and surroundings and the strenuousness of the age they lived in. Let those who were successful make it their duty to help others to a firm footing beyond the need of dubious methods. To eradicate impure commercialism entirely might be impossible, as it was founded on man's inheritance of original sin, and because reasonable commercialism and was an incentive in life, but it was not impossible by harmonious cooperation to cultivate a desire for a higher standard by combining justice and beneficence. The practice of self-restraint and renunciation was not happiness, though it might be something better.

Dr. George E. Stambaugh, of Chicago, discussed the indications for opening the mastoid process in cases of acute empyema of the cells when there was an absence of signs over the external surface of the mastoid.

Dr. L. H. Nickerson, of Quincy, followed with a paper in which he discussed the diagnosis and treatment of laceration of the vaginal portion of the uterus and fornix vaginæ.

Immediate Diagnosis and Treatment of Lacerations of the Vagina and Pelvic Floor and Perineum.—Dr. C. S. Bacon, of Chicago, classified tears as external and internal. In both there were many grades, and either might be simple or combined with those of the other class. Diagnosis concerned both the finding of these lacerations and determining their extent and importance. Both touch and inspection were employed. The pain caused could be disregarded, but the risk of infection was considerable and should be carefully considered. Hirst's proposed delay of all examination and operation till the end of a week was not practicable, and the author favored immediate examination and repair, but only with as careful asepsis as would be employed in a secondary operation. In a non-operative labor, when there was no hemorrhage with the expulsion of the head, and no severe external tear, there would be no internal laceration, and an internal examination was unnecessary. Hemorrhage was rarely an indication for operation in vaginal and perineal tears. The bad results of unrepaired lacerations were generally the reasons for operation. Spontaneous repair was a delusion. Proper preparation was very important in all repair operations. Especial attention should be given to vaginal lacerations that involved the pelvic diaphragm and extended into the central attachments of the accessory diaphragm, but did not implicate the skin surface. Here the skin bridge might be cut and the repair made as in a combined vaginal and perineal laceration, or the internal suture could be applied so as to bring in apposition the divided structures. The perineal sutures of silkworm-gut must not be tied too tightly. In a complete rupture the method of restoring the rectal tube by passing the suture through the rectal mucous membrane was preferred to the passing of the suture from the perineal side. The author preferred cutting the ends of the perineal sutures short, and discarded powders. Catheterization was unnecessary. A wide occlusive dressing, fastened by the four corners to the abdominal bandage was much better than the ordinary dressing held by the T bandage. Chief stress was laid on attention to details in preparation for the technic of operation, without which poor results and total failures furnished grounds for discarding immediate operations.

Pelvic Infections in Women.—Dr. T. J. Watkins, of Chicago, said that pelvic infection was preferable to pelvic inflammation as a name to designate the disease, as infection injured and destroyed tissues, whereas inflammation tended to conserve tissue. The author limited his paper to a discussion of some of the practical points of pelvic infections. He spoke of the importance of the disease, and said that the same principles were involved in pelvic infections as in infections in other parts of the body. He considered the etiology, pathology, symptomatology, diagnosis, prognosis and treatment. The importance of prophylaxis was pointed out. Topical applications were often of little or no value. Conservatism during the acute stage was of great importance. Spontaneous and complete recoveries sometimes ensued.

Bronchoscopy for the Removal of Foreign Bodies from the Lung.—Dr. E. Fletcher Ingals, of Chicago, mentioned previously reported cases, and the removal of foreign bodies by the upper and lower routes. He described the instruments used in removing these bodies, with illumination by electric lamps, as in urethroscopy. There was danger when the tube was introduced into the bronchus of the affected side, owing to the fact that it might shut off the air from the other lung. He spoke of the use of a small opening in the tube to keep the tube free from pus and mucus. He reported recent cases, and exhibited an emergency device for removing foreign bodies.

Dr. James W. Twitchell, of Belleville, reported a case in which recovery occurred following a perforated wound of the intestine without surgical interference.

The following papers were also read and discussed: "The Value and Place of Duodencholedochotomy in Gall-Stone Surgery," by Dr. John C. Hancock, of Dubuque, Iowa; "Inversion of the Uterus, with Report of Cases," by Dr. P. L. Markley, of Rockford; "Pathology and Diagnosis of the Lesions of the Spinal Cord and Peripheral Nerves," by Dr. Frank P. Norbury, of Jacksonville; "Malignancy in Uterine Myomata," by Dr. Henry F. Lewis, of Chicago.

Officers.—The following officers were elected for the ensuing year: President, Dr. H. C. Mitchell, Carbondale; First Vice-President, Dr. W. K. Newcomb, Champaign; Second Vice-President, Dr. M. S. Marcy, of Peoria; Secretary, Dr. E. W. Weis, Ottawa, re-elected; Treasurer, Dr. E. J. Brown, Decatur, re-elected. Springfield was selected as the place for holding the next annual meeting.

ORIGINAL ARTICLES.

THE PROGNOSIS IN SYPHILIS.[1]

BY R. W. TAYLOR, M.D.,

OF NEW YORK.

WHEN a patient has been informed that he is syphilitic he immediately begins to question the surgeon as to his chances in the future. He will inquire anxiously whether he can be thoroughly cured; how long it will take to cure him; will he suffer very much? Will he be as good as he was before he was infected? Can he ever entertain the thought of marriage, and will his children be healthy?

These momentous questions reveal to us the necessity of a thorough knowledge of the prognosis of syphilis. It is therefore important at first to determine what the nature of syphilis is, and from our studies and observations to acquaint ourselves with the course of the infection in healthy and diseased subjects, and of the influence of therapeutics upon this infection.

Syphilis is a chronic infectious granulation tissue disease caused by a specific poison, the nature of which is doubtful, being considered by some (Max Schuller) a protozoa, and by others (Max Joseph Piorkowski and others) a specific bacillus. The first evidence of syphilitic infection is the chancre, which was derived from a previous syphilitic. This chancre shows that the poison penetrates the epithelium, works its way to the blood vessels, infects the perivascular spaces and involves the inguinal ganglia.

The process of syphilitic infection is one of constant growth and diffusion from the beginning. In the very first days of the existence of the chancre the poison is deeply rooted in the subcutaneous tissue; it is in a most active state and progresses along the course of the vessels until it reaches the body, and then infects the whole economy. Reasoning by analogy, we are warranted in assuming that this new, highly infectious and rapidly growing tissue gives off, probably by means of its microbes, a poison which diffuses itself through the system. We have then in syphilitic infection two orders of morbid changes: (1) The heterologous new cells; (2) the diffusible poison.

In many diseases of microbic origin the severity of the attack depends upon the activity and the quantity of the virus inoculated or received. When the microbes are derived from active and exuberant lesions they usually produce an intense disease in vulnerable subjects, but when the virus is attenuated, or when the microbes are in a weakly state (involution forms), then the resulting invasion is less severe. To these features offered by other infectious processes syphilis does not seem to present points of resemblance. In other words, we know nothing of the mildness or malignancy of the syphilitic virus, and extended clinical observations made by many authorities go to show that a virus which produces severe syphilis in one individual may produce only a mild form of the disease in another. Therefore, in syphilis it may be said, without fear of contradiction, that the potentiality of the poisonous dose is about the same whether it be derived from a severe case of syphilis, or from a mild one. For example: Many years ago I had under my care a very strong young man who had a small and insignificant chancrous erosion on the penis. This man, in whom the secondary stage was very mild, contaminated a rather anemic young woman who developed a well-defined vulvar chancre in which there was a slight tendency to sloughing. This woman was attacked by the malignant form of syphilis which resisted intelligent treatment and careful nursing, and she died six months after infection. While she was in a very debilitated state, just before the onset of the malignancy which terminated her life, she had connection with four young men and infected them all with syphilis. Three of these individuals had mild secondary syphilis, and in only one was the disease somewhat severe. In all four patients the initial lesion was small and not much indurated. My belief on this question is in accord with the opinions of many authorities. Clinical observation has also proved that the potency of the virus is about the same whether it be derived from the initial lesion, a secondary lesion, or the blood.

From the foregoing statement of facts it seems warrantable to conclude that there is a well-marked uniformity in the infectious quality of the virus, no matter from whom it may be derived, and that this poison may produce in some subjects a mild and in others a severe form of syphilis. It, therefore, logically follows from what has been stated that the benignity or severity of syphils is determined by the condition of the individual.

Clinical observation clearly shows that in some patients, owing to partial immunity, the syphilitic poison meets with such resistance on the part of the tissues that it makes but a slight impression, while in others a marked susceptibility to its action exists, and a more or less severe form of the disease is produced. It has been claimed that from certain features observed in the chancre and during its course we may draw prognostic criteria as to the mildness or severity of the subsequent course of the disease. It has been said

[1] Read before the New York Academy of Medicine at a Symposium on Syphilis, May 4, 1905.

that a small, slightly indurated chancre is usually followed by a mild attack of syphilis. This statement may apply to some cases, but certainly not to the majority. It is not uncommon to see all grades of severe syphilis follow an insignificant initial lesion which might have undergone involution in ten days or two weeks, and have left little if any trace upon the part attacked. How common it is to see severe and extensive syphilitic lesions in persons who never knew that they had a chancre, and in whom it must have been very small. The truth is that both mild and severe grades of syphilis may follow small initial lesions.

It has also been claimed that large and deep primary lesions invariably lead to severe forms of infection, but this statement is only partially true. I have seen many cases of mild syphilis follow a very extensive chancre, and have also seen instances in which two or three parts of the body were the seat of chancres (penis, lip and finger, or penis and lip, or other part), and yet the course of the disease was not at all severe.

Ulceration, phagedena and gangrene, attacking the initial lesion, have been claimed to be ominous signs of a severe attack of syphilis. Extended clinical observation shows that his assumption is not fully warranted. Destructive ulceration of any form or gangrene attacking the initial lesion is always the result of contamination with pyogenic microbes, usually caused by carelessness and uncleanliness, and also by intemperate cauterization, and they are to be regarded as disquieting accidents, and not as indices of the malignancy of the initial lesion or as forecasting a severe attack of syphilis. In some cases of phagedena and ulceration of the initial lesion a temporary condition of ill health is produced, but careful treatment will soon remove this accidental complication.

It is also claimed by some authors that extragenital chancres are the forerunners of severe syphilis. This view is certainly based on the observation of a few exceptional cases, and is not borne out by extended investigation. I have reached the conclusion, from the statistics offered in over one hundred cases observed and recorded by me, that the course of syphilis averages about the same in cases beginning in genital or extragenital lesions. It not infrequently happens that the nature of an extragenital chancre is not recognized or that it runs its course unobserved by the patient. In such cases the resulting syphilis may not be treated, or it may be improperly treated, and then a degree of severity may result. This view of the malignity of extragenital chancres is in some instances due to the hue and cry raised by infected medical men and nurses who, having innocently contracted the disease, take kindly to the mild form of martyrdom with its resulting sympathy from friends and acquaintances. They usually exaggerate their symptoms and give the impression that they are suffering from a severe form of syphilis.

Fortunately for the human race, syphilis in the great majority of cases is contracted by young men between twenty and forty years of age, in whom the vital processes are active and whose health as a rule is good. Such patients are naturally capable of withstanding attacks of various diseases, but some are more resistant than others. According to my observations, it may be said that syphilis is much less severe to-day than it was thirty years ago. This diminution in the severity of the disease is largely due to our improved methods of treatment, to better sanitary and nutritive conditions, and to the greater attention which is paid to cleanliness and antisepsis. But further than this, there undoubtedly exists to-day in the tissues of many individuals a greater resistance to syphilitic infection than was possessed years ago. In other words, in many people a moderate condition of immunity against syphilis exists, which is due to the changes in the tissues and in the blood induced by syphilis in their more or less remote ancestors.

In a general way it may be stated that the large number of persons who contract syphilis are those who are in average good health and have not grown old. In a smaller number the standard of health is less high, and in many patients certain morbid conditions exist which are due either to disease or bad habits, and which lower their power of resistance. Extended clinical observation shows very clearly that syphilis when untreated by mercurials runs a somewhat uniform course. Following the chancre, in due time the secondary cutaneous and mucous membrane manifestations appear, and remain for a short or long period, and then they seemingly undergo resolution. Next a more advanced form of lesions, such as large papules or papulo-tubercles, are observed, and these may in time wither and later on—in months or years—true tertiary lesions may develop.

Syphilis in healthy persons, male and female as a rule, runs a mild course, and its poison is eliminated from the system if active treatment is instituted at the proper time. Much depends upon the intelligence and docility of the patient who, if he enjoys ordinary good health and will follow up energetic, but very carefully directed treatment, may, I am confident, be cured. This comforting assurance may be given to the majority of patients seen in private practice, who in general, are intelligent, realize the gravity of their condition, and resolve to so conduct themselves and regulate their habits that their vital processes can resist the depressing influences of the syphilitic poison and be able to undergo the strain put upon them by long-continued medication. Many years' study and observation of the nature and treatment of syphilis has convinced me that in most cases a cure is possible, whereas in years gone by, we groped in ignorance, pursued faulty, and even harmful, therapeutic methods, and never felt ourselves masters of this insidious and far-reaching infection.

This vigorous and intelligent treatment more or less promptly influences and attenuates the virulent infection, which will gradually subside, and in most cases in previously healthy persons a cure will result within two or three years, and in some exceptional cases sooner. The mercury destroys the newly formed and nascent cells, and as they die so does their poisonous power wane. In many cases we see no visible lesions or very simple ones after the first rash. Cases thus treated may be called mild, and in private practice it is the rule, when patients are intelligent and docile, and submit fully to treatment, to see this benign course of syphilis. Such cases may, therefore, be taken as the standard of comparison with other forms of syphilis now to be considered.

There are many persons who, though not absolutely sick, are not really well. In this category are included cases of anemia, flabby and poorly nourished individuals, blonds with light reddish hair, persons suffering with malnutrition, and even those who are mildly neurasthenic. In America syphilis in women runs about the same course that it does in men, but the female sex is much less frequently attacked by cerebral and cerebrospinal affections than are men. Women as a rule are less addicted to alcoholics than males, and they are not called upon to overtax the brain as many men are, consequently they present rather infrequently evidences of specific nervous affections.

Syphilis in the poor and ignorant is mild or severe, and sometimes malignant in its course. Perhaps the greatest of all drawbacks in the treatment of syphilis in the poor is the difficulty of establishing in their minds a realizing sense of the gravity of the affection. Consequently, it is in these individuals that we so often see the disease run a chronic and severe course. They are careless in following treatment, and as a rule cannot be induced to remain under medical care any length of time after the disappearance of their specific lesions or the cessation of the discomforts. This is the keynote to the severity and malignancy of syphilis among the lower orders of our population. Then again, many poor people are addicted to alcoholics, which act harmfully upon them and render the course of syphilis severe and protracted.

Severe forms of syphilis are observed in varying grades of intensity. As a rule, the secondary lesions are numerous and distributed symmetrically over the whole body, and the influence of the specific poison is severe (neuralgias, headaches, joint bone, and muscular pains, etc.). One rash runs an indolent course and is soon followed by one of more severity which becomes complicated with pyogenic infection, and thus we come to see ecthyma, impetigo, and variolaform syphilides and rupia. In these cases there is more or less prostration and little reparative tendency, while in very severe cases fever, sometimes head symptoms, great emaciation, and even marasmus may exist. Then again, in unhealthy persons, particularly in the lower orders, we may observe what is called precocious malignant syphilis, which is an entirely different condition from true malignant syphilis. Precocious malignant syphilis is noteworthy for the reason that it usually begins in the severer forms of the disease in which ulceration attacks the various lesions. Then while these degenerating secondary lesions are appearing, ulcerating and cicatrizing, and old are being replaced by new lesions, gummatous infiltration, of the mouth, eye, subcutaneous tissues, bones and joints, and the cerebrospinal system, may develop more or less extensively.

Malignant syphilis is undoubtedly a rare and peculiar form of the infection. Its chief characteristic is that it is essentially a secondary condition and is in no way associated with tertiary syphilis. Patients thus afflicted show evidence of profound systemic poisoning in the high fever, loss of flesh, abject marasmus, insomnia, and pains in various parts of the body. There also may be present such grave symptoms as aphasia, epilepsy, coma, and paralyses. In these cases the nervous affections are not due to gummatous deposit, but rather to the round-cell infiltration around the vessels, chiefly of the membranes of the brain. Malignant syphilis is due to the lack of resistance on the part of the individual to the severity of the infection. It seems that the poison meets in the tissues of the person attacked such a condition of receptivity that it is generated in large quantity and with a peculiar virulence which affects the whole organism.

By far the most potent cause of tertiary syphilis is absence or insufficiency of treatment in the secondary stage. But in addition to this cause there are others which result from lowered nutrition and weak resistence on the part of the tissues. Then, again, certain diseased conditions may act as secondary factors in the development of this late and erratic stage of syphilis.

One of the most formidable complications of syphilis is tuberculosis, and it is only too clearly proven that tissues attacked by syphilis become perfect hotbeds for the fructification of the tubercle bacillus. This destructive and deadly symbiosis is seen in the secondary and in the tertiary periods. In early secondary syphilis, even when well treated and in seemingly healthy subjects, bronchitis or pneumonia may develop and upon them acute miliary tuberculosis may supervene and carry off the patient. Then, again, when syphilis runs a severe course, in some truly malignant cases, tuberculosis supervenes and quickly kills the patient.

Gummatous infiltrations of any or all of the viscera are liable to be attacked by tuberculosis, and syphilitic sarcocele is not infrequently the seat of this second invasion. When considering the factors of gravity in syphilis, we unfortunately must accord to tuberculous infection a prominent place. Chronic alcoholism is a powerful factor in inducing the development of severe

and extensive lesions of the skin and mucous membranes, of cerebral disorders, of a debilitated condition of health, and causes the disease to run into its tertiary stage.

In malarial subjects the course of the disease is frequently severe, the condition of ill-health is well-marked, neuralgias are very frequent and the specific lesions are copious and extensively distributed.

Bright's disease is a factor of much gravity in patients also infected with syphilis, and in many cases its course is very severe. Then again, we sometimes see men and women who have advanced kidney degeneration in whom syphilis runs a surprisingly mild course. Diabetic subjects who contract syphilis are very commonly profoundly influenced by the infective process. Their lesions are extensive and show a tendency to ulceration, and the general depression of health is very marked. The various morbid blood states, such as scurvy, the hemorrhagic diathesis and hemoglobinuria, are serious complications of syphilitic infection, and in patients suffering from them it is common to observe a severe course of the disease. Influenza is frequently seen to be the cause of great systemic depression, and it may become a factor of much gravity in syphilitic patients, in some of whom severe pulmonary affections occur. Rheumatism and gout are not uncommon complications of serious import in syphilitic patients, in some of whom the specific lesions are materially modified by this harmful symbiosis. The debility following various infective processes, such as typhoid fever, diphtheria, erysipelas and the exanthemata, renders the course of syphilis severe for a long or short period.

When it is remembered that syphilis expends its morbid action largely and extensively upon the blood-vessels, the fact strikes one that in old persons the severity of the attack is very much influenced by the condition of the vascular system. Upon the integrity of the patient's blood-vessels, therefore, hinges in a large degree the greater or less severity of syphilis. In old persons arteriosclerosis is common, and may involve more or less of the circulatory apparatus. Besides vessel changes, visceral lesions, general debility, an unstable condition of the tissues, and the systemic morbid effects produced by vicious habits and indulgences, are undoubtedly factors of gravity in syphilis of advanced life. A review of my own experience has convinced me that in many elderly persons of vigorous physique and good habits syphilis runs a comparatively mild course; in less vigorous persons it is more severe; but that in poorly nourished, weakly, and underweight indivduals, in the nervous, excitable, neuropathic, and overstudious (brain-workers from all classes) it is often severe and even disastrous in its effects.

Finally it may be said that early, efficient, painstaking and prolonged treatment is most essential in all cases of syphilis, and by it the course of the disease in the young and the aged may be much modified, may be rendered mild, and in most cases a cure may be produced.

142 West Forty-eighth Street.

PROGNOSIS OF SYPHILIS: RELATIONS TO MARRIAGE AND HEREDITY.[1]

BY PRINCE A. MORROW, M.D.,

OF NEW YORK;

EMERITUS PROFESSOR OF GENITO-URINARY DISEASES IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; CONSULTING DERMATOLOGIST TO THE CITY AND ST. VINCENT'S HOSPITAL.

Syphilis constitutes a social as well as an individual danger. From the standpoint of the individual the prognosis refers only to the risks to his own personal health; from a social point of view the prognosis becomes magnified in importance as the health and life of other individuals may be involved. In determining the prognostic significance of syphilis in relation to marriage and heredity there are two classes of dangers to be considered: first, the personal risks to the prospective husband, which may seriously compromise his health or life and incapacitate him for the responsible position as the head, the material support and breadwinner of the family; second, the contagious risks to the wife and the added increment of danger to the offspring which would come from her infection. Where the question of marriage is concerned, the first order of dangers is apt to be overlooked by the physician who considers only the infective risks to the wife and offspring, but it is to be observed that when syphilis is no longer contagious nor transmissible by heredity, the possible dangers to the health of the husband from his disease are not always extinct.

It is a peculiarity of syphilis that its most dangerous and even deadly consequences are essentially late manifestations. More than 50 per cent. of the most dreaded accidents of syphilis, affecting the brain and end on other organs essential to life occur after the tenth year of the disease. It is further to be observed that these grave lesions of important organs resulting in hemiplegia, paraplegia, tabes, general paralysis, blindness, etc., conditions which are permanent and irremediable, often develop in syphilis characterized by an initial benignity and pursuing a mild course. Their occurrence cannot, of course, be attributed to the mild type of the disease, but to the fact that the patient has been lulled into a false sense of security and has not received a thorough and efficient treatment.

Unfortunately the prognostic indications which point to the development of these late tertiary manifestations of a severe type are often absent. There is nothing more difficult or uncertain than forecasting the future of a given case of syphilis. A favorable prognosis based upon the benignity of secondary manifestations is entirely illusory as a guarantee against the malignancy of tertiary

[1] Read at the Medical Society of the County of New York, March 27, 1905.

lesions, especially when the only solid guarantee —that furnished by sufficient specific treatment —is wanting.

Of all the menaces to the health and life of the individual, lesions of the nerve centers are most to be dreaded. In many cases there are valuable prognostic indications to be drawn from the disease which point to the involvement of the nervous system. The localization of specific lesions in the ocular apparatus, the occurrence of iritis, transient paralysis of the muscles of the eye, the sign of Argyll-Robertson pupillary immobility, etc., are to be regarded as probable though not positive precursory signs of cerebral syphilis.

The second order of dangers refers to contamination of the wife, who may be infected from the contagious accidents which the syphilitic husband bears upon his person or she may receive syphilis by conception.

The prognosis of syphilis from the viewpoint of its infective risks to the wife must be based upon the determination of the duration of its contagious and transmissive periods. Since there is no scientifically accurate test for determining the date of the extinction of the virulent principle in the human body, our knowledge upon this point is based chiefly upon the results of clinical observation. No fact is better established than that when the syphilis is recent and active, conjugal contamination is practically certain; infection may occur even when the husband has no contagious lesion upon his person.

The prognosis is always more unfavorable when there is a tendency to the repeated recurrence of papular lesions localized in the genital and buccal regions, which are the chief centers of contagion.

Clinical observation shows that the contagious activity of syphilis is markedly attenuated, and finally extinguished by time and treatment. Unfortunately the time limit does not admit of exact mathematical expression; it varies in different cases. The elements which constitute a favorable prognosis are the advanced age of the diathesis, a prolonged exemption from specific manifestations, twelve or eighteen months after the completion of the secondary stage and sufficient specific treatment. The arbitrary designation of a period of two and one-half or three years as perfectly safe for a syphilitic man to marry is, medically, an error, and, socially, a danger.

As before intimated, the prognosis of syphilis in relation to heredity is much more unfavorable when the wife becomes infected, as to the relatively restricted influence of paternal heredity there is superadded the much more potent and prolonged influence of maternal heredity, constituting what is known as mixed heredity. The prognosis of syphilis so far as its transmissive power is concerned is based upon the same elements which enter into the determination of the period of its contagious activity. There is a certain concordance but not an absolute identity between those two periods. In general, it may be said that the corrective influence of time upon syphilitic heredity is less marked, since the hereditary influence may be manifest long after the disease has ceased to be contagious; this is especially true of maternal heredity.

On the other hand, the preventive influence of treatment upon syphilitic heredity is more marked but less permanent. If the syphilitic parent is under the active influence of mercury at the date of impregnation, the pregnancy may result in a healthy child, but if the treatment is suspended, the next child may be syphilitic. Specific treatment seems to hold in abeyance, rather than extinguish the influence of hereditary transmissibility. Experience shows that when the syphilitic diathesis has been subjected to the double depurative action of time and treatment during a period of four years its contagious and transmissive qualities are extinguished. We may therefore conclude that the two most essential elements of a favorable prognosis of syphilis in relation to marriage and heredity are time and treatment.

The consideration of the prognosis of syphilis in relation to marriage would be incomplete without reference to the reciprocal influence of marriage upon syphilis. It is well known that marriage favorably influences certain diseases and aggravates the course of others. In a syphilitic individual in whom the preferential infection is especially directed toward the nervous system the prognosis would be rendered much more unfavorable by marriage. It is well established that the sexual excess not uncommon in early married life aggravates the nervous symptoms and may precipitate serious implication of the brain and cord. In many cases general paralysis and tabes are due to the combined effect of syphilis and sexual excess, just as cancer and leucoplasic affections of the tongue and buccal mucous membranes are due to the combined effect of syphilis and tobacco. Fournier has reported a number of such cases and my own inquiries have elicited the information that in the Manhattan State Hospital for the Insane, on Ward's Island, in a large proportion of cases of general paralysis, there is a history of syphilis and sexual excess in married life. The exhaustion of the nerve centers consequent upon sexual excess may explain the development of the paralyses.

66 West Fortieth Street.

Influence of Electricity on Gastric Secretion.—Many experiments have been published, showing that the influence of electricity upon the gastric secretion in man is slight, yet R. FREUND (*Virchow's Archiv.*, Vol. 180, No. 2) has deemed the subject of sufficient importance to repeat the experiments on animals. One electrode was introduced into the stomach through a gastric fistula, the other electrode was applied to the abdomen, with both galvanic and faradic currents, only a slight amount of alkaline mucus was secreted from the gastric mucous membrane, so that the value of electricity in diminished acidity is absolutely nil.

DERMOID CYSTS OF THE MEDIASTINUM.

BY ROGER S. MORRIS, A.B., M.D.,
OF ANN ARBOR, MICH.;
INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF MICHIGAN.

(Continued from Page 410.)

12. *Virchow.* Seltenere Beobachtungen: II. Teratoma myomatodes Mediastini. *Virchow's Archiv*, Bd., LIII, p. 444, 1871.

E. K., artilleryman, aged twenty-two years, was admitted to hospital April 6, 1870. Patient was strongly built, well nourished, did not look sick. For several weeks he had complained of frequent chills in the evening, dyspnea, stabbing pains in the right front of thorax and near the right shoulder blade and slight cough with mucous sputum.

Status Præsens.—Expansion somewhat diminished on the right. Thorax symmetrical. Percussion (see Figure 3) gives absolute dulness on the right from the third rib down, passing into the liver dulness and on the left into that of the heart. The upper border of dulness passes obliquely from the third rib downward, outward, and backward to the inferior angle of the scapula. Over the dull area no breath sounds are heard; behind, above the dulness, roughened vesicular breathing. Pectoral fremitus absent on right front and side. Examination of left lung and heart negative. Lower edge of liver is about two finger-breadths below costal margin in nipple line. Temperature normal; pulse slightly accelerated.

Dyspnea, feeling of oppression, and pain increased as the disease progressed. During May a tumor developed at the end of the third rib, which reached the size of a small fist. Dull area on right gradually increased in extent and the right side of the chest became much larger. On May 27 an edematous swelling developed in the right axilla, which soon spread over the entire right side and abdomen; no fluctuation in it. Death occurred on June 14 after an illness of about two months.

Autopsy.—Marked emaciation. On the third left rib an elastic tumor; the mass consisted of a loose tissue and contained blood clot. On opening the thorax a very large tumor was found in the place of the expected exudate; it occupied the larger part of the right half of the thorax, extending to the left of the middle line, and was adherent to the right lower lobe, pericardium, large arteries and veins; it was rather lobulated. In the tumor were found many cysts, the contents of which varied, hair, bits of epidermoid material, cholesterin plates, and fat droplets being seen; the walls were covered with ciliated or pavement epithelium, and in places contained cross-striated muscle and cartilage. Some parts of the wall presented the appearance of sarcoma, others that of carcinoma; similar changes were found in the mass attached to the third rib. Liver presented many hard nodules on its surface and in the substance. Spleen enlarged; several cysts on the surface, largest the size of a walnut, with bloody fluid contents.

13. *Kückman.* Anlegung einer künstlichen Cystenfistel zur Heilung einer Haarbalggeschwulst im Mediastinum anticum. Inaug.-Dissert., Marburg, 1874. (Cited by Ekehorn and Dangschat.)

Patient was a male, aged thirty-three years, who had been perfectly well till his twenty-ninth year. In March, 1872, he was taken with pains in the left shoulder and in the back of the head. Soon he noticed that a tumor, which grew slowly but steadily, was developing on the left side of his neck anteriorly. On admission to the Marburg clinic the mass was the size of a goose's egg, pushed the sternal end of the clavicle forward and gave fluctuation. The patient had marked dyspnea. Exploratory puncture gave a yellowish-brown fluid with small particles of fat and pavement epithelium. Diagnosis: Dermoid cyst. On incision a purulent fluid with hairs, singly and in tufts, was evacuated. The finger could be inserted through the opening to the second rib under the sternum. Drainage was maintained. Not long after this the patient passed through two attacks of pneumonia; during this time he expectorated a large quantity of foul-smelling sputa in which many strands of hair were found. Drainage being insufficient, an opening was made through the sternum 2 x 3 cm. The condition of the patient was greatly improved, the expectoration diminished, the putrid odor decreased, and he was discharged from the hospital. In February he returned to the clinic and said he had been entirely well for four months; the opening into the bronchus was no longer evident, as he had no cough at all. Examination with a sound showed that the sac was in reality much smaller and was freely movable.

14. *Foà.* Ciste ateromatosa del mediastino in un' alienata cronica emofiliaca. *Il Morgagni Giornale Indirizzato al Progresso della Medicina*, XVI, p. 498, 1874.

B. B., female, aged sixty-one years, had suffered from no illness excepting intermittent fever for fourteen years, according to the statement of a relative. Occasionally she had had myodynia and pleurisy, and there was marked tendency to hemorrhage after the slightest abrasion of the skin. No palpitation nor dyspnea. For the last few weeks there has been edema of the feet and legs. Death resulted from pneumonia.

Autopsy.—Upper, middle and lower lobes of right lung showed red hepatization. Between the pericardium and the visceral pleura of the lower one-third of the right lung could be seen a glistening, white body, loosely adherent to pleura, pericardium, and posterior mediastinum. The tumor was rather round, of pasty consistency, and on section, a quantity of clotted yellow material escaped. Microscopically the latter consisted of numerous more or less de-

generated epithelial cells, fat droplets, and some pigment crystals. The cyst wall was formed of connective tissue covered by pavement epithelium.

15. *Gläser.* Mentioned by Danzel. Geschwulst mit Haaren im Rectum. *Langenbeck's Archiv*, Bd. XVII, p. 443, 1874.

At autopsy hairs were found in the lung.

16. *Smythe.* Dermoid Cyst of Lung. *The American Practioner*, Vol. XIX, p. 313, 1879.

January 31, 1879, an unknown woman died at a boarding house where she had been only a few hours. No history was obtainable. From those who had talked with her, it was learned that she appeared greatly exhausted, breathed with much difficulty, and suffered severely from paroxysms of coughing. Her hands and lips were of a livid, almost purple hue. She said she had been suffering from what physicians told her was consumption for about three years.

Autopsy.—Slight emaciation. Hair light, age about thirty or thirty-five. Lower and middle lobes of right lung hepatized. Moderate serous effusion of left pleura. Entire upper portion of left side of chest was filled with a mass extending from above downward to the lower margin of the sixth rib and just beyond the middle line. The tumor was cystic, and from its wall hair, some of which was fifteen inches long, grew and thoroughly mingled with the sebaceous contents, which were about of the consistency of Dutch cheese. Imbedded within the thickened wall of the cyst was a genuine bone; it was very irregular, horseshoe shaped, and weighed 120 grains.

17. *Marchand.* Beiträge zur Kenntniss der Dermoidgeschwülste. Zweiundzwanzigster Bericht der Oberhessischen Gesellschaft für Natur und Heilkunde, p. 235. Giessen, 1883. (Cited by Ekehorn and Dangschat.)

A woman, aged twenty-seven years, married, well advanced in pregnancy, became suddenly ill with pneumonia of the left lower lobe; there developed a gradually increasing pleuritic exudate of the left side. The upper lobe also became infiltrated. In addition there was a small exudate on the right side, and finally peritonitis, which caused death.

Autopsy.—In the upper part of the mediastinum is a tumor the size of a child's head, round, tense, which extends from the second rib to the fifth, and, to the left, beyond the sternal margin and fills the entire upper part of the right pleural space anteriorly. The tumor is cystic and adheres to the upper lobe of the right lung. Heart is forced downward and to the left. In the left lung there are compression and fresh hepatization. The cyst wall is formed of firm fibrous tissue, calcified in several places; the inner surface is in general smooth with several small prominences which are covered with numerous blond hairs. The cyst contained about one-half liter of thick, bright yellow, very turbid fluid with larger fragments and masses in which hairs are embedded. From the outer surface of the cyst two tongue-shaped prolongations pass upward on the anterior surface of the trachea almost to the lower border of the thyroid gland. They look like fat and on microscopical examination resemble thymus tissue.

18. *Butlin* (Paget). A System of Surgery, by Holmes and Hulke, 1883, Vol. II, p. 259.

"I have lately seen one of these cysts (dermoid), situated deep down behind the first bone of the sternum in a young man who was brought to Sir James Paget, and in whom it had commenced to grow during adult life. It contained masses of connective tissue, covered with skin and fine hairs, and beneath the skin were numerous sebaceous glands. The cyst was freely opened by Mr. Taylor (of Coltishall), the solid growths removed, and the cavity allowed to fill by granulations."

19. *Pinders.* Ueber Dermoidcysten des vorderen Mediastinums. Inaug.-Dissert., Bonn, 1887. Also *Finkler* and *Ribbert. Berliner klinische Wochenschrift*, Bd. XXIV, p. 250, 1887.

Autopsy.[1]—In the anterior mediastinum between the first and fifth ribs there is a nodular tumor close against the sternum and adherent to the second and third left costochondral junctions. Lungs are pushed backward by the tumor. In the apex of the left lung there are discrete, grayish white nodules. Anterior part of upper lobe is firmly united to the tumor, which apparently has grown into it, forming a large mass softened in the center. Upper right lobe is adherent to tumor and contains similar but smaller mass, with many small ones. Aorta free; there is a large lymph gland near the esophagus. Heart is pressed downward; fibrinous pericarditis. On section the tumor consists of an upper solid portion with a cyst the size of a goose's egg in the lower right side. The inner surface of the latter is smooth, and large calcified areas are found in the wall. The cyst is filled with a grayish brown, fatty material. Microscopical examination showed that the solid part was lymphosarcoma, which had metastasized and undergone fatty degeneration. The cyst contents were seen to consist of fat and cholesterin crystals, and nuclei resembling those of epithelial cells. The liver was one finger breadth below the costal margin.

20. *Pinders. Ibidem.* Male, aged fifty-three years, died of bulbar paralysis.

Autopsy.—Between the pericardium and the left primary bronchus is an encapsulated tumor the size of a goose's egg, whose walls are in part calcified. On its posterior surface a soft tissue is attached; this extends upwards as far as the upper aperture of the thorax, decreasing in thickness as it ascends, and finally becomes inseparable from the adipose tissue. On section the tumor is shown to be a multilocular cyst. The largest space is uneven on the inner surface, and its contents on microscopical examination cor-

[1] Clinical findings by Strauscheid in his Inaugural Dissertation. (This I could not obtain.)

respond with those of the previous case (19). Because of defective preservation the histological examination was difficult. In places the wall resembled hyaline cartilage. The smaller cysts contained cells chiefly. The prolongations from the posterior wall of the cyst resembled thymus tissue.

21. *Loewenmeyer.* Demonstration eines Präparats (Dermoidcyste des Mediastinums). *Berliner klinische Wochenschrift*, Bd. XXV, p. 135, 1888.

The patient, a male, entered the hospital in 1884 because of hemoptysis and left sided pleurisy with effusion with moderate exudate. He recovered soon. There was quite marked bulging of the left half of the thorax, with impaired resonance, which extended from the clavicle to about the sixth rib. Apex beat could not be felt in the normal position, but there was a rather diffuse impulse on the right side and pulsation in the epigastrium. In the following years the patient worked quite hard, was in relatively good condition, and had no pressure symptoms. Recently attacks of dyspnea have come on, which have become frequent and severe. After admission suddenly extreme dyspnea and marked cyanosis set in, lasting till death.

Autopsy.—A tumor about the size of a child's head, with smooth, tense walls, occupied the greater part of the left side of the thorax. Its anterior surface was free against the chest wall, otherwise it was adherent to the neighboring parts, especially to the pericardium, which lay in the right half of the thorax, to the diaphragm and the left lung. Adherent pericardium. Apex under sternum. The tumor contained cavities, the inner surface of which was lined by ciliated epithelium. In the cysts were blond hairs in tufts, with epidermis and fat.

22. *Sangalli.* Grossa ciste colloidea composta del polmone destro con peli, glandole sebacee e lamine ossee nelle sue pareti. Rendiconti del R. Instituto Lombardo. Serie II. Vol. XXI, p. 662. (Cited by Pflanz and Ekehorn.)

A woman, aged fifty years, died in 1880 after a long illness, during which the attending physician had considered the condition one of chronic pulmonary tuberculosis with large serofibrinous effusion into the right pleura.

Autopsy.—No tuberculosis was found, no pleuritic exudate. The right half of the thorax was occupied by a large tumor which had compressed the right lung markedly. The tumor was adherent to the middle lobe of the right lung and extended downward to the diaphragm. It proved to be a multilocular cyst with bloody, atheromatous contents in which many fine blond hairs were found. In the wall were hairs, hair follicles, sebaceous glands, bone, and cartilage. Pavement epithelium lined the cysts.

23. *Buyvid.* Fibrous Mediastino-pericarditis, Adhesion of Heart to Pericardium, and Dermoid Cyst. *Medizinskoje Obosrenje*, Mosk., XXXII, p. 97, 1889.

E. K., male, aged twenty-three years, a Co sack, entered the hospital December 13, 188 with the diagnosis of pleurisy. February 2 1889, the patient was discharged from the arn because of anasarca. He re-entered the ho pital March 4, 1889. Respiration harsh, on t left, in the axilla, bronchial. March 23 the was noted ascites, considerable dyspnea, a swelling of the feet. Sputum bloody. Pain the region of the heart and in the chest in fro and behind. March 30, considerable fluid in t pericardium and pleura. Apex invisible, not p pable. Dyspnea extreme, face swollen and cya otic. Orthopnea. Marked ascites. Exitus c curred April 3, 1889, with severe dyspnea.

Autopsy.—April 4. Posterior surface sternum adherent to underlying tissues. A lar amount of fluid in the left pleural cavity. L pleuropneumonia. Anteriorly the entire space occupied by a saccular tumor which was ac dentally cut into on removal of the sternum, thick yellowish mass escaping. The tumor firmly adherent to the left lung and all t mediastinal structures, the heart being in t middle. The right half of the tumor is a d moid cyst the size of two large fists, which co tains two tumblerfuls of thick, granular, yello ish, fatty fluid with many concrements from pea to a hen's egg in size, also roundish mas containing hair. The microscope reveals pa ment epithelium, cholesterin, fat and detrit Fibrous bands extending from the cyst embra the great vessels, the bronchi, and the esophag in part.

24. *Godlee.* Dermoid Cyst of the Right S of the Chest Communicating with a Bronch Medico-Chirurgical Transactions (Londo LXXII, p. 317, 1889.

Mrs. C., aged twenty-nine years, had not s fered from any symptoms referable to the ch during her childhood. Except that she had b a little short of breath previously, the onset f her illness was sudden, and consisted in an ac pain in the right side of the chest in May, 18 followed rapidly by the development of ac right pleurisy with effusion. This develo d into an empyema. Tapping was postponed, d the diagnosis was confirmed by rupture i bronchus. Cough and expectoration diminish d, but never disappeared entirely. Slight clubb g of the fingers. The patient was first seen the author in June, 1887. At this time th was a slight swelling in the right axilla, c center of which was a little tender. A cert n amount of pain was also often felt shooting p to the right infraclavicular region. Percuss n gave dulness at the base with peculiar out e (see Figure 4): it was most marked in the ax l, but extended towards the middle line in fr nt and in this situation reached the level of c third rib, but behind it was abruptly limited by a line passing in a curved direction downwa ds and upwards, and then vertically downwa ds below the angle of the scapula. Over the all

rea little or nothing to be heard. The patient
as anesthetized, and with an exploring trocar
us was hit at the tender spot, just outside the
namma in the sixth interspace. A portion of
ie rib and dense pleura were incised and a small
avity was found, from which about one ounce
i pus escaped. At the back of the pleura a firm
ounded mass was felt, which was thought to
e a piece of the lung adherent to the thoracic
alls. Expectoration stopped at once; a thick
opurulent discharge remained, and drainage
as difficult. The patient had coughed up two
airs since the operation, and one or two had
en noticed on the drainage tube. They re-
mbled the axillary hair which had been shaven.
he patient now said she had on two occasions
ughed up a hair, which she thought at the time
ie must have inspired. August 9, 1887, the
ening was enlarged. At least two handfuls of
ir and fatty stuff were removed; then strange,
hite, finger-like processes were observed, which
oved to be thick masses of fibro-cellular tissue
vered with skin, from which hairs were grow-
g. A drainage tube was introduced and the
scharge became slightly offensive. September
, 1887, the opening was again enlarged. Three
ger-like processes were removed. The cavity
as found to extend right up to the apex of the
orax, and the wall of the cyst was most in-
nately connected with the surfaces of the lung
d diaphragm. Removal of the cyst was con-
dered too dangerous. Improvement from the
eration was rapid. Discharge still copious and
ther sour smelling. The opening, which it
as intended to have large, contracted so that
ly a small drainage tube was admitted. The
pectoration showed that the bronchial open-
g still remained.

A letter from Mr. Godlee, written November
1904, conveys the information that "the pa-
nt died October 26, 1891, that is, four years
ter my first operation, after a week's illness
om 'pyemia.'"

25. *Koenig.* Lehrbuch der speciellen Chirur-
e, Bd. II., p. 45, 1889.

Roser incised a dermoid cyst presenting in the
prasternal fossa and later trephined the ster-
m to secure evacuation of the contents.

26. *White.* Dermoid cyst attached to the front
the pericardium. Transactions of the Patho-
gical Society of London, Vol. XLI, p. 283,
89-90.

The specimen consists of a dermoid cyst about
e size of a large Tangerine orange. It was
ached to the anterior and right surface of the
ricardium and by a few adhesions to the right
ng. It was filled with dirty yellowish fluid
ntaining cholesterin and oil globules. There
as also a large quantity of solid sebaceous
terial, and some hairs which seemed to be
losely attached to the interior of the cyst.

27. *Sormani.* Un Cas de Kyste Dermoïde du
Poumon Gauche. *Gazetta degli Ospedali*, No.
4, p. 314, 1890. (Cited by Foucher.)

A. O., female, aged twenty-four years, entered the hospital at Milan July 17, 1887, complaining of attacks of dyspnea, cough and pain in the left side of the thorax. According to the parents, the patient displayed a great susceptibility to pulmonary trouble from the earliest months of infancy; it was necessary to hold her in the upright position when she was feeding from the breast because of attacks of dyspnea and cough. Her health was fair during childhood except for frequent paroxysms of cough and dyspnea. At the age of sixteen years the patient noticed for the first time brown hairs in her mucous expectoration, to which she paid no particular attention. They continued to be present. During the last two years of her life dyspnea and cough became more severe.

Autopsy.—Patient was cachetic and emaciated. The upper lobe and two-thirds of the lower lobe of the left lung contained a cyst about the size of a child's head. Its lining resembled skin; to it hairs were attached. On the inner surface there were projections. The cyst contained a grayish-yellow, foul-smelling, atheromatous pap in which brown hairs were found. The surrounding lung tissue showed interstitial pneumonia with bronchiectases at the base. In the upper lobe a second, smaller cyst similar to the first was found; this was completely separated from the latter, and in its atheromatous contents were small black hairs. The inner surface was like that of the larger cyst. Microscopical examination of the lining of the cysts revealed all the characteristics of true skin, including hair follicles, sebaceous glands and sweat glands. No cartilage was demonstrable.

28. *Marfan.* Kyste dermoïde du médiastin antérieur. *Gazette Hebdomadaire de Médicine et de Chirurgie*, t. XXVIII, p. 394, 1891.

A coachman, aged thirty years, entered the Hospital Necker July 17, 1891. Examination of lungs showed nothing abnormal. July 23 the patient became comatose and a marked inequality of the pupils appeared; the pulse was infrequent. Exitus took place during the night.

Autopsy.—July 25, 1891. On opening the thorax, there is found behind the upper part of the sternum a large whitish mass the size of two fists in front of the great vessels of the base of the heart. On incision this mass presents numerous white hairs and a very thick sebaceous matter. It forms a cavity having for its lower limit the anterior surface of the pericardium, posteriorly the great vessels, anteriorly the sternum and ribs. Between the anterior edges of the two lungs and the tumor there are loose adhesions: somewhat more firmly adherent to the pericardium. The cyst wall is very thin and its inner surface is uneven. Microscopical examination of the wall shows only connective tissue; no epithelium. Recent tuberculosis of the lungs, tuberculous ulcers in the intestine and tuberculous meningitis are found.

29. *Kocrte.* Berliner medicinische Gesellschaft. Sitzung am 11. November, 1891. *Berliner klinische Wochenschrift,* Bd. XXVIII, p. 1204, 1891.

The patient, a male, entered the hospital with a fistula of the anterior chest wall. He said he had had marked pressure symptoms in the chest a short time before, then the fistula formed; since then there had been improvement. A part of the anterior chest wall, the second rib, and a piece of the sternum were resected and a small sac, the size of a fist, was met with; this was filled with characteristic dermoid contents, including hairs. In time only a small fistula, 4 cm. long and as thin as a lead pencil, remained. The patient, who also had pulmonary tuberculosis, felt so well that he left the hospital. Several weeks later he died of hemoptysis. No autopsy.

30. *Harres.* Ueber Zähne in Dermoidcysten. Inaug.-Dissert., Zürich, 1892, p. 45.

The specimen showed a dermoid cyst of the anterior mediastinum the size of a fist lying between the heart and the left lung. In the wall, which resembled skin in many places, bits of bone and cartilage, as well as hairs, were found.

31. *Bastianelli. Riforma Medica,* May 20, 1893. (Cited by Pflanz.)

A female, aged twenty years, had had a fistula on the left side of the neck above the sternoclavicular articulation for four years, resulting from incision of a tumor in this region with the evacuation of fat and hairs. The fistula was opened, its walls excised, and the edges of the wound approximated. Union by first intention; after several weeks rupture with escape of pus. After two similar attempts the manubrium sterni was resected, and behind it a tumor the size of a nut was discovered. This was dissected free from a large vein, the pericardium, and the esophagus; it was less firmly adherent to the aorta. Total extirpation of the tumor was done. Uninterrupted and permanent cure resulted.

32. *Kraus.* Ein Fall von ausgedehntem linkseitigem Pleuratumor. (Malignes Sarcom und Dermoidcyste.) Inaug.-Dissert., Bonn, 1893. Autopsy findings also reported by *Jores.* Ueber die Verbindung einer Dermoidcyste mit malignem Cystosarcom der linken Lunge. *Virchow's Archiv,* Bd. CXXXIII, p. 66, 1893.

N. K., male, aged thirty-nine years, entered the medical clinic at Bonn, August 23, 1892. Family history negative. Three years ago the patient was taken with febrile symptoms, acute pain attributed to left-sided pleurisy, and moderately severe catarrh of the smaller and larger bronchi. After two months he returned to work, but occasionally had stabbing pains in the left side, his general condition remaining good. Since May, 1892, he has had continuous pain in the left lower part of the chest. Cough with considerable expectoration, never bloody, has been present since July. During the last three weeks there has been severe dyspnea, which causes him to apply for relief.

Status præsens.—August 23, 1892. Frame is strong; muscles well developed. Expansion of lungs equal. Percussion gives marked dulness (see Figure 5) above and below the left clavicle the same being continuous with the heart dulness and extending into the left side as far as the posterior axillary line. Left back and entire right side clear on percussion. On auscultation there is practically no breath sound over the dull area; strong vesicular over the right front. Vocal fremitus is absent in the left front and side. Behind there is relative dulness on the left above with prolonged expiration; a few râles over lower left with bronchial breathing at the angle of the scapula; over lower right bronchial breathing. Heart dulness extends to right parasternal line. Over the base there is a prolonged systolic murmur. Left jugular fuller than right. There is diffuse sytolic heaving on the left side of the chest. August 24, 1892, exploratory puncture yielded a hemorrhagic exudate; the operation was repeated on September 19 with like result, only a small amount being obtained. Soon dulness appeared behind, puncture giving a serous fluid. About the middle of October complete paralysis of the left recurrent laryngeal. Soon the right pupil became wider than the left. In November edema of the left leg came on, less marked on right. The dyspnea became much worse, and on November 11, 1892, exitus occurred.

Autopsy (Jores).—November 12, 1892. Fairly well nourished body, rather marked edema of left arm. Left half of thorax very prominent especially in the upper four interspaces. In the left half of the thorax there is a large grayish-red tumor. It is firmly adherent to the diaphragm and the left pleural cavity is filled up by it. The lower part is composed chiefly of a grayish-yellow, pulpy material, in which cheesy particles and numerous blond hairs lie. Removal of this exposes a cyst 19 cm. broad and 6 cm. high. Smaller cysts are also found. Cartilage is found in the wall. Anteriorly, forwards the heart, a cyst the size of a fist is found. The wall presents many prominences, on one of which are two small teeth. In the right lung solid tumors are found in all lobes. Microscopical examination showed that the cyst wall in places had the structure of the skin, with sebaceous glands and hair follicles. Cubical and cylindrical epithelium was found in some of the smaller cysts. Unstriped muscles and sweat glands present in the wall. Malignant changes (sarcomatous) were found, the tumors in the right lung being metastases.

33. *Kretz.* Beitrag zur Casuistik der Dermoïde. *Wiener klinische Wochenschrift,* Bd. VI, p. 861, 1893.

The patient was a man, aged thirty years, in whom a diagnosis of pulmonary tuberculosis with bronchiectasis in the left upper lobe was made. He entered the hospital eight days before death and during this time no hairs were detected in the sputum, nor was there any history of this.

Autopsy.—Body large and thin. Adherent pericardium. Tuberculosis of both upper lobes. In the upper lobe of the left lung a cavity about the size of an apple was found, filled with hair, pus, and fatty material. It lay in front of, and below, the hilum of the lung. The cyst communicated with the bronchi, and the wall resembled epidermis. Near the opening there were light blond hairs. In the wall sweat and sebaceous glands were found, but no adherent hairs were made out. Death was due to tuberculosis.

34. *Dardignac.* Tumeur dermoïde du médiastin antérieur. *Revue de Chirurgie,* t. XIV, p. 776, 1894. First reported for Dardignac by *Peyrot.* Kyste dermoide du médiastin. Bulletins et Mémoires de la Société de Chirurgie de Paris, t. XX, p. 414, 1894.

N. W., a soldier, aged twenty-two years, entered the military hospital June 18, 1893, because of dyspnea and swelling in the thorax. In May, 1889, the patient, then sixteen years old, had an unaccountable feeling of lassitude, accompanied by persistent pains localized in the right supraspinatus fossa. One and a half months later a prominence was noted in the upper one-third of the right side of the thorax anteriorly. Towards the end of November, 1899, the patient was compelled to stop work on account of dyspnea. Hydatid cyst, probably arising from the liver, was diagnosed. The patient entered St. Antoine Hospital. Dyspnea and retrosternal pain were severe. Exploratory punctures in the hepatic region were negative. Towards the end of February, 1890, the needle was inserted inside of, and at the level of, the right nipple. Eight hundred grams of a cloudy, yellowish liquid came away. Relief was immediate. A few days later five hundred grams were withdrawn. March 5, 1890, the patient left the hospital in good general condition, but weak. In the following autumn he returned to work and was without symptoms during 1891 and 1892. Early in January, 1893, the patient noticed difficulty in performing gymnastic exercises. Each morning there was paroxysmal cough for five or six minutes. June 19, 1893, the following notes were made: Patient is slightly emaciated. There is a bulging of the right front of the chest, most marked about the nipple; it is over the fourth, fifth and sixth ribs, between the parasternal and anterior axillary lines. No pulsation here. Percussion (see Figure 6) gives absolute dulness from the third rib to the base. In the right axilla and back dulness in the lower third, otherwise clear. Over the dull area there is absence of breath sounds. The interscapular space on the right gives weak blowing breathing; no sound over the base. Neither egophony nor pectoriloquy is present. Left lung is negative; heart negative. The liver is two finger-breadths below the margin of the ribs. Exploratory puncture into the most prominent part of the tumor yields a thick, opaque, greenish fluid; microscopically, no blood or pus. Blood examination shows no leucocytosis. August 3, 1893, the patient was operated upon. Part of the fourth rib was resected, and a whitish tissue, intimately adherent to the periosteum, was exposed; fluctuation was obtained over it and, after inserting a trocar, about 1½ cm., fluid similar to that previously obtained was evacuated. As the cavity was almost emptied, a large tuft of white, curly hairs escaped. The walls of the cyst were rigid. Digital exploration showed that the diaphragm formed the base, the upper part being adjacent to the pleura. On the left the heart was felt. About 1,800 grams of fluid were removed. In it red blood cells, matter analogous to sebum, and hairs were found. The patient made a good recovery; the cyst gradually decreased in size, vesicular breathing returning over the entire right back and in front, except immediately about the fistula. April 6, 1894, the patient had gained considerably in weight and felt perfectly well.

35. *Pflanz.* Ueber Dermoidcysten des Mediastinum anticum. *Zeitschrift für Heilkunde,* Bd. XVII, p. 473, 1896.

D. A., male, aged twenty-one years, a baker, had always been well up to the onset of the present trouble. For several years he had suffered occasionally from pains in the right ear, and for about one year in the right shoulder. In August, 1894, he noticed difficulty in swallowing, especially solid food. In November pains in the ear and shoulder increased and dyspnea came on with exertion; at the same time the patient noticed a swelling above the right clavicle. In the following weeks this was unchanged. The pains became more severe, especially over the tumor, and radiated through the entire arm. Bulging of the upper part of the chest was also noticed.

Status præsens.—February 23, 1895.—Patient is quite large, well nourished. Neither edema nor distention of the veins is present. There is a considerable bulging in the region of the manubrium sterni, the sternal end of the right clavicle, and the first two ribs on the right side. Skin normal over this. Absolute dulness is obtained in an area sharply circumscribed, extending 4 cm. to the right and 2 cm. beyond the left sternal margin, below in the middle line to the level of the second interspace. Over this region there is no sound of any kind, no pulsation. Above and outside the right sternoclavicular articulation there is found a movable, plainly fluctuating tumor about the size of a nut, and partly covered by the sterno-mastoid. It shows pulsation, which apparently arises from the vessels lying beneath it. Lungs are normal. Heart dulness normal in size and position, separated from the area described above by a clearer note. Radial pulses synchronous and of equal tension. Laryngoscopic examination negative. Temperature normal. Pupils equal. Exploratory puncture of the tumor above the clavicle yielded pus. It was incised and drained. Patient felt better and was discharged March 10. March 13 he returned with a swelling in the same place the size of a hen's egg. Status otherwise as before. April 12

this tumor was opened by Dr. Neugebauer. A cavity the size of a pigeon's egg was opened; it contained pus. Downwards and inwards communication was found into a larger cavity situated in the thorax. On washing this out pus escaped with the fluid, together with many short brown hairs and masses, which, under the microscope, were seen to consist of fat droplets and epithelium. The sinus became too small for efficient drainage and an opening was made in the sternum April 25. By the end of June the secretion was greatly diminished, and the cyst had shrunken. There are no longer any subjective symptoms, such as shortness of breath, cough, or pain in shoulder and arm. Early in October, 1895, the fistula was only 3 cm. deep (in June 10 cm.) and very narrow. Secretion slight, purulent, with no epithelial cells. The patient left the hospital at this time.

36. *Ogle.* Dermoid Growth in the Lung. Transactions of the Pathological Society of London, Vol. XLVIII, p. 37, 1896-97.

The patient was a man, aged twenty-eight years, who died from profuse hemoptysis. He had been ill with cough and occasional hemoptysis for five years intermittently. The physical signs suggested empyema. The temperature was of hectic type and the sputum offensive, so that bronchiectasis was discussed.

Autopsy.—Right lung contains a cavity about four inches in diameter in the lower lobe, separated from the chest wall by a thin layer of fibrous tissue. The cavity communicated freely with the middle division of the left bronchus. Many secondary bronchi open into it, and the contents are offensive, dark red material, looking like pus mixed with blood, and five or six bodies of a cream color, firm but flabby, of a pear shape, with the rough aspect of skin, and with hairs growing from their surface. In addition the contents consist of material like cream cheese and a quantity of hair. Embedded in the core to which the stalks are attached is a large tooth.

37. *Ekehorn.* Die Dermoidcysten des Mediastinum anticum. *Archiv für klinische Chirurgie*, Bd. LVI, p. 107, 1898.

M. H., female, aged twenty-one years, entered the service of Prof. Sahli in the Inselspital, Bern, January 30, 1893, and died September 14. The present trouble began with pleurisy five years ago; since then constant cough with mucopurulent expectoration. Three years ago hemoptysis occurred six times in as many weeks. Each time considerable blood was lost; it was of bright red color, fetid odor, and frothy, and was brought up with severe coughing which always led to copious expectoration, a mouthful being raised at a time. Sputum from entrance has been purulent and since the hemorrhages of a marked fetid odor. Cough is usually paroxysmal, the attacks being ushered in with moderate dyspnea. After raising a large quantity of sputum the patient feels entirely well. Between the paroxysms there is constant cough, and lying on the right side seems to bring on an attack. There are palpitation and dyspnea on exertion. The patient's father died of phthisis.

Status Præsens.—February 1, 1893. Slender frame of medium size. Muscles and panniculus very small. Marked clubbing of the fingers. Temperature and respirations normal. Left supra and infraclavicular spaces deeper than right; no difference below. Expansion good on both sides. Apex beat in the fifth interspace extending beyond the nipple line. Percussion (see Figure 7) gives a loud, deep note in the right apex and infraclavicular region. From the fourth rib in the nipple line there is absolute dulness. In the axillary line it is on the sixth rib. Over the left lung, the median part, dulness is found. Auscultation over the dull area gives greatly diminished vesicular and diffuse, scanty, fine, moist râles; bronchial breathing in the axilla, elsewhere vesicular. Over the apex of the heart there was a soft systolic murmur, otherwise negative. In the back there is dulness on the right below the seventh rib; aboye this hyperresonance. On auscultation on the right there is a sound resembling friction with blowing breathing near the median line and sonorous and moist, partly ringing râles. Pectoral fremitus is greatly weakened over the dull area. The upper border of dulness does not change with change in position of the patient. The edge of the liver is three finger breadths below the costal margin. Exploratory puncture in the back and axilla on February 21 negative. The sputum separates into three layers; bacilli and cocci present; no tubercle bacilli, no elastic tissue. After July the patient complained of headache, stabbing pains in the chest, dyspnea, and severe paroxysms of coughing. On September 14, 1893, the patient died suddenly in a fit of dyspnea.

Autopsy.—Bronchiectases in both lungs. Right lung markedly compressed by a tumor adherent to the anterior thoracic wall and to both lungs. In the middle lobe of the right lung there is a cavity from which contents similar to those of the tumor escape. On section of the latter there is seen in the upper part a whitish mass containing pieces of bone. There are several cysts, most of which contain hairs and fatty material; one such opens into a bronchus. The cavities communicate with one another. The cysts are lined with skin, some of the smaller ones with ciliated epithelium. In the solid part of the tumor cartilage and teeth are found in addition to bone.

38. *Ekehorn. Ibidem.*

The patient is a male, aged twenty-two years. He had pleurisy with effusion early in 1885. The exudate suddenly disappeared with coughing. In July, 1885, Dr. Fogman exhibited before the Society of Swedish Physicians at Stockholm a few unusual concrements which the patient had coughed up, consisting of fatty clumps of hair, thought to arise from a dermoid cyst. Early in 1886 the patient died with symptoms of severe dyspnea.

Autopsy.—A large dermoid cyst containing bone and teeth was discovered in the anterior mediastinum (Svenska lakaresallskapets forhandlingar, July 14, 1885, and March 30, 1886). The tumor, somewhat larger than a fist, is above, and somewhat to the left of, the heart. It is firmly adherent to the pericardium. From the inner wall of the cyst polypoid growths extend, as in the previous case. Fatty material, epithelial cells, and hairs form the contents of the cavity, which communicates with the bronchi. In the lower solid portion bone, cartilage and teeth are found. The lining of the cyst resembles skin in all respects. A few smaller cysts are present, lined with cubical and ciliated epithelium.

39. *Bergmann.* Ueber einen Fall von Dermoidcyste des vorderen Mediastinum. *Prager medicinische Wochenschrift*, Bd. XXIII, p. 100, 1898.

V. P., male, aged thirty-eight years, was taken ill in the latter part of December, 1896, with influenza bronchitis, returned to work before recovery, and early in the following month had typhoid lasting three months. On coughing there was pain over the second and third ribs on the right side and the adjacent part of the sternum; a swelling of the periosteum developed here, with subsequent rupture. During convalescence, which was protracted, blood appeared in the sputum after each coughing fit. The patient attributed the swelling to severe pressure on the front of the chest while tightening a screw in October, 1886. The patient is of medium size, moderately strong build. He has frequent cough, with a small amount of frothy sputum. Signs of catarrh over both lungs; no dulness. There is a swelling, as above; skin bluish red over it. In its center there is an opening the size of a pea from which an opaque secretion escapes. The tumor is of doughy, soft consistency and painful.

Caries of the bone was diagnosed and operation was performed July 14, 1897. The skin was turned back and the broken down granulation tissue and softened contents curetted away. The latter had the appearance of atheromatous matter. A movable, smooth tumor about the size of a hazel-nut presented in the midst of the contents. The tumor had a projection into the anterior mediastinum from a smooth, round opening in the sternum the size of a lead pencil. Parts of the sternum and second and third ribs were removed, and a cavity about the size of a goose's egg was exposed, which was filled with a soft, glistening, pultaceous material and a tumor. On removing the contents a well formed tooth was found, and soon a second. The tumor just mentioned consisted of four polyps of varying size. The cyst was drained. For the next few days the patient coughed and raised a bloody sputum mixed with caseous material similar to that found in the cyst. Expectoration decreased and the patient made an uneventful recovery. Examination of the tumor showed that the covering of the polypoid growths had not only the appearance but the structure of skin. Many downy hairs about one cm. long and two more teeth were discovered.

(To be Continued.)

THE SOCIAL STATUS OF TUBERCULOUS PERSONS.[1]

BY WILLIAM W. PENNELL, M.D.,
OF MOUNT VERNON, OHIO.

ASIDE from the dozens of remedies and the numerous sanatoria and other means offered the person with pulmonary tuberculosis for the management of his disease, practically nothing is offered for the management and control of the patient himself—the individual who is the victim of the disease and who goes where he wills and expectorates where he pleases.

This individual generally compels his partner in marriage to sleep by his side, perhaps for the reason that she may follow him to the land of spirits in less than three years. As long as he is able to do so, he visits his relatives and friends because he is unfit for labor, and he is accorded the privilege of his host's house because of invalidism. He sleeps in the guest chamber, lounges in the rocker and on the sofa, depositing his sputum in a vessel provided for his convenience or he ejects it outside the door at one end of the stoop.

At the advice of his physician and desiring to rid himself of his disease, he determines to visit the health resorts; he rides in the railway cars and sleeps in their berths, his offensive breath contaminating the air and his sputtering, recurrent cough atomizing his infecting sputum upon all that it touches, he disdaining the use of a handkerchief to catch the dangerous materials. He sleeps at hotels where you may occupy the same room the succeeding night; dawdles in the office, loiters in the lobby, mingling his spittle in the cuspidors with that of the healthy. He spatters into the telephone transmitter where in the succeeding hour you may inhale the dried, noxious sputum. He drinks from the public watercup while his lips are covered with bacillus-laden saliva, and he drinks from the same glass at breakfast that you may use for dinner. He spits on the sidewalks where the sole of your shoe may be set or where the hem of your lady's garments will sweep and catch a smear of purulent material, and the shoe and garments are put in their keeping place at home to dry. At the church he mingles his outer garments with the others in the vestibule, and takes communion out of the same cup that his elbow neighbor must place to his lips the next moment. His laundry is thrown into the general wash, and his cast-off rags go into the junk dealer's bag along with Mr. Healthyman's.

He courts and becomes engaged to our daughters while he swings around the social circle, a menace to the health of all and, so far as my

[1] Read before the Ohio State Medical Association, Columbus, Ohio, May 11, 1905.

experience goes, a sure death to the victim of his affections if the engagement ends in marriage, because he usually compels his wife to share his bed to the last. In fact, so far as he is able or desires, he enjoys the same privileges, honors and social emoluments as his healthy and uninfecting neighbor.

These are some of the things that he does, and yet we wonder where all the cases of tuberculosis come from in persons who are supposed to be stout, and in families where the disease has been unknown.

These matters are not as they should be because, as in the case of smallpox or diphtheria, no mitigating or immunizing agency can be employed to hinder or lessen infection after exposure. This statement may have to be modified later because of the work being done to discover an antituberculous serum. Recently, Lathrain in the *Lancet* reports cases of this disease that improved under such a serum, as also did Richer in the *Montreal Medical Journal*. But the most interesting and encouraging reports of the work comes from Friedman, in Germany. This scientist isolated a culture of tubercle bacilli from a tuberculous lung in a turtle that produced a fair degree of immunity against human and bovine tuberculosis, and he has hopes of producing an anti-tuberculous serum of great clinical value.

Until these ideals are reached, however, it might be well to have every physician report all his cases of tuberculosis along with those of other infectious diseases, that a practically rigid quarantine or rather segregation as to methods of traveling, visiting, railroad lodging, hotel accommodations, public drinking and expectoration as well as church communion, for each case could be established. The question of marrying an infected person requires no argument. Full publicity in each case of pulmonary tuberculosis should be required and the attitude of the patient toward the public should be such as to insure its safety; besides, it should be a just cause for refusal to keep a marriage engagement should the healthy party so desire it.

The tuberculous person should sleep in a room by himself, his attendants being in the adjacent room. He should be in nowise neglected or forsaken by those who love and honor him but for self-preservation they should refuse to subject themselves to almost certain infection.

There are no grounds why he should be permitted to make social visits to a greater extent than is accorded other persons afflicted with infectious and deadly diseases. When he travels it should be under such restriction as to make him acceptable to others, or his seat in the railway cars should be isolated and prepared for the convenience of the tuberculous, the same being kept clean and properly disinfected. Hotels that shelter him should lodge him in rooms reserved for such invalids, and should be required to disinfect tableware and linen used in such rooms before they are sent to the laundry. Along this line, it would be well for everybody when traveling to carry his own drinking cup.

A township, city and village ordinance should place a prohibition upon the public expectoration of purulent material, and these ordinances should be enforced so far as possible until the dangerous and disagreeable habit is stopped.

Every church communicant should refuse to drink after the tuberculous person for reasons of health, urging the cleanliness of individual cups for each communicant and insisting that each cup be made aseptic after use.

Where a marriage agreement exists and one of the parties is unequivocably tuberculous, no damage should accrue to the healthy party for refusing to have the marriage solemnized until the tuberculosis is cured; and the mere attainment with the disease should operate as a hindrance to marriage and discharge the healthy party from his obligation if desired.

The tuberculous person should be taught that it is outdoor air and nourishing food and not change of climate that he needs; hence the practice of sending the tuberculous hither and thither in the vain quest for health has no value outside of the outdoor air that comes with the traveling; the same outdoor life at home would produce the same results.

These are my conclusions in this matter: The public should understand that tuberculosis is infectious to susceptible people; that it requires intimate and continued contact for others, but that daily contact with many different tuberculous persons may act as continued contact with one person; that houses in which tuberculous persons have lived or died are infected houses, therefore unfit to live in until thoroughly fumigated and cleansed.

Where persons are suspected of having tuberculosis and refuse to employ a physician, a health board should send a competent medical man to examine such invalids; upon the filing of such examiner's report, if the persons prove to be tuberculous, the movements of the affected individuals should comply with the regulations made for the restriction of those maladies are dangerous to others.

Having been in the practice of medicine long enough to see whole families fall victims to tuberculosis, and numerous families where two or more members were claimed by this destroyer, through infection, I have now put upon paper what is told the friends of the tuberculous. Although these conclusions may seem heartless and needlessly severe, there appears no other alternative for protection against the "great white plague." The sooner the State assumes a defensive attitude against tuberculosis the more rapidly will its encroachments cease. While it is not proposed to place the tuberculous person in the position of the ancient leper who was compelled to cry, "Unclean! unclean!" to the passers-by, yet it is intended that a just, humane and adequate segregation of all cases of (at least) pul-

monary tuberculosis should be instituted for the protection of the uninfected, and the Ohio State Medical Association can confer no greater boon upon the thousands that look to its members for protection and guidance in all matters pertaining to disease and its prevention, than to labor to this end.

MEDICAL TREATMENT OF NEPHRITIS.[1]

BY ARTHUR R. ELLIOTT, M.D.,
OF CHICAGO;
PROFESSOR OF MEDICINE, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

MANY excellent recent contributions fully discuss the nutritive problem of Bright's disease and leave little to be said regarding its dietetic treatment. Among notable contributions may be singled out for mention and commendation the work of Von Noorden and his associates. As an outcome of these and other investigations, we find that the dietetics of Bright's disease is to-day on an unquestionably more advanced and rational basis than in former years. If any criticism is to be passed on the correctness of the conclusions of Von Noorden and others who have worked along similar lines, it is that in their investigations attention has been too exclusively focused on the kidneys. Undoubtedly the principle of economy of work to diseased organs is scientifically a sound one, but in the disease under discussion the fact must not be lost sight of that we have to deal with a widespread nutritive perversion of which nephritis is but one manifestation. Although we must admit that in most cases the kidney lesion in the end vindicates the claim to first importance, other organs demand attention during the progress of the disease, and contribute very largely to the symptom group which characterizes this affection. These other considerations, oftentimes of equal importance with renal demands, must be taken into account in the framing of a dietary, and for this investigators have made little allowance. Among important indications which must be taken under consideration are the digestive powers of the patient, the functional capacity of the liver, especially its toxin-destroying power, the presence of anemia or plethora, and, often most essential of all, the cardiac condition and the degree of blood pressure. No routine diet can, therefore, be laid down for the patient with chronic Bright's disease. If he be a confirmed dyspeptic, our measures for diagnosis of the gastric and intestinal states must be as careful and exact as are employed to determine the urinary condition. Such a patient may perhaps be best dieted for his dyspepsia, without regard for the nephritis, the latter being thus most benefited by measures directed to control of the digestive toxemia.

In the presence of marked anemia, a certain disregard of circulatory and renal consequences may be justified in our efforts to improve the blood state. With low tension a comparatively full diet, rich in proteids, without restriction of fluids; in cases with high tension, a low diet, poor in animal proteids and restriction of ingested fluids is indicated.

In cases marked by cardiac irritability and signs of circulatory failure, the indications for diet must be taken from the heart and circulation more than from the kidneys, such cases becoming in effect cases of heart disease more than renal disease. In short, each patient coming under observation for chronic Bright's disease should become an individual study, and the indications for its management must not be interpreted according to any fixed rules of procedure, but be founded on the results of careful and complete clinical investigation, the lines of treatment being directed in the order of their importance, according to the patient's complete organic needs.

To discuss fully the treatment of chronic nephritis with its wide range of associated defects is a task too great to accomplish in the short space permitted. I have thought best to present the subject in the following simple and practical order: (1) Treatment of chronic nephritis without dropsy; (2) treatment of chronic nephritis with dropsy; (3) treatment of uremia.

The existence of dropsy in chronic nephritis cannot be taken as a basis for classification, and it is even a rather arbitrary procedure to attempt to develop clinical distinctions from this point. As a rule, however, cases coming under observation fall naturally into two groups—those without and those with edema.

Cases of the first class—those without dropsy—are principally examples of the type of chronic interstitial nephritis during the stage of cardiovascular compensation. It is true that chronic diffuse nephritis may occasionally display no dropsy, but, as a rule, more or less edema is manifest. The main indications in the management of this type of chronic nephritis may be summed up in the protection of the kidneys from irritation, especially the strain imposed by intercurrent acute toxemias, and the maintenance of cardiovascular compensation.

The first of these two indications is fulfilled by careful regulation of the patient's diet and personal hygiene. The question of the diet suitsuitable to these cases I will not enter into, owing to the elaborate care which has recently been expended on this subject by eminent authorities. The personal hygiene of the patient is hardly a less important matter. In order to engage the full cooperation of the patient, it will be well to state his case fully to him, emphasizing its necessities and the importance of strict obedience. In submitting our advice as to diet and hygiene, the patient is to be informed that the directions are for his permanent guidance, and to prevent misunderstanding we should furnish him with full written particulars of the course to be pursued. The proper clothing, baths, etc., for these patients will not occupy our attention now, owing to the

[1] Read before the Illinois State Medical Society May 17, 1905.

familiarity of such details. We should urge these patients to such a regulation of their lives as will enable them to spend a large share of their time in the open air—especially in the country, where simple diet, pure air and primitive physical environs simplify the nutritive problem and furnish immunity from accidental infections. The open-air treatment is well-nigh as striking in its beneficial effects in nephritis as in tuberculosis. Exercise is of vital importance to these subjects. A good gauge of the patient's endurance is found to be a feeling of oppression and fulness in the chest, and instruction must be given against walking so far or so fast as to produce this uncomfortable sensation. It is well to advise our patients with this disease to avoid high altitudes, the limit of safety for residence purposes being 3,500 feet above sea level. Oliver's blood pressure observations show that above that point the circulatory pressure rapidly increases. Medium altitudes—about 2,000 to 3,000 feet—will lower mean arterial pressure, and this may be considered in sending patients with plus pressure to the mountains.

In directing our patients regarding the amount of water to drink, our advice must run counter to popular prejudice. The execretion of urinary solids cannot be materially increased by copious water drinking. Moreover, arterial pressure is raised and the mechanical burden of the heart is increased thereby. Our advice must, therefore, be in favor of a strictly moderate indulgence in fluids and against overindulgence, and the patient is to be especially warned against the injurious effects of the immoderate use of mineral waters, of which sanitarium and "spa" treatments so largely consist.

The doctrine of "moderation in all things" is to be preached in season and out of season to these patients, the end in view being to suit the amount of work required to the capacity of the diseased organism for its performance—in short, to avoid hyperfunction.

Two indications of vast importance to the case of chronic nephritis require special mention. They are the care of the bowels and the maintenance of cardiovascular equilibrium.

The nephrolytic action of the toxic products of disturbed digestion is now well recognized. Constipation undoubtedly favors the formation of these bodies. In addition to their renal effects, they increase arterial tension. Our utmost care should consequently be directed toward securing regular evacuation of the bowels. The action of aperient drugs should be supplemented by high rectal enemata, administered in the knee-chest or recumbent position at regular intervals to prevent fecal stasis in the colon.

In chronic nephritis there develop sooner or later during its progress certain well-marked cardiovascular changes, consisting of sclerosis of the arteries and cardiac hypertrophy. The essential feature of the circulatory state is high arterial tension. Not only is this true of so-called chronic interstitial nephritis, but even when chronic nephritis follows acute infective nephritis, the change is marked by development of increased blood pressure and cardiovascular sclerosis. The majority of cases when they come under observation manifest typical high pressure symptoms, but if no edema is present we may infer that the compensatory cardiac hypertrophy is still secure. The cardiac compensation is, however, one of tense adjustment, becoming constantly more sensitive to disturbing influences. The changes in the arteries are progressive and the increased blood pressure permanent, so that it is only a question of time when increasing peripheral resistance will outstrip the power of the heart to cope with it, and dilatation of the ventricles result. When that time arrives, the diminishing urine, increasing albuminuria, and uremia will leave us in no doubt as to which organ has conserved the life of the patient. Kidneys which can amply maintain their function under increased cardiac force and high blood pressure become miserably inadequate when such support is removed. The clinical history of the large majority of cases at their termination is that the excretion of urine was sufficiently good for the maintenance of life, and that death originated in cardiac failure or resulted from one of the cerebral accidents of excessive arterial tension. This being the case, it is a matter of the first importance to direct our efforts toward the regulation of the circulatory effects of the disease. The *indicatio causalis* for the preservation of an adequate heart is to regulate within safe bounds the arterial blood pressure. We must not, however, lose sight of the fact that a certain degree of increased arterial pressure is necessary for the comfort and safety of the patient. Samuel West has said: "The patient is best without granular kidneys, but if the kidneys be granular it is better that the tension be high than low." The experience of the writer is that no cases are so hopeless and unresponsive to treatment as those marked by low tension. In the treatment of cases of chronic nephritis some instrument for the estimation of the blood pressure is necessary, and the sphygmomanometer should be employed to conduct routine observations from time to time. The physician who depends upon his stethoscope only for information as to the circulatory state of these cases is apt to be more a detriment than a help to his patients.

In the treatment of high pressure cases the basic indication is the removal of the underlying toxemia which causes the widespread vasoconstriction. This is accomplished best by careful dietetic and hygienic regulation, and assisting the kidneys by securing free elimination from the skin and bowels. When these requirements have been fulfilled and the tension remains persistently elevated, we must have recourse to vasodilator medication to mitigate the exhaustive conditions imposed on the heart. We must real-

ize the limitation of such medication, and as it constitutes purely symptomatic treatment, never depend upon it to the neglect of hygienic and dietetic measures. It is a comparatively easy thing to reduce the systolic blood pressure a number of points within a few minutes by means of the administration of an active vasodilator, such as nitroglycerin. The effect of such a dose is unfortunately very transitory, and notwithstanding the striking temporary effect, the fact remains that it is a difficult thing to produce a permanent reduction of blood pressure by means of vascular drugs. Persistent routine medication will alone effect such a result. At what point in chronic nephritis are we warranted in commencing vasodilator medication? Much will depend on the patient's general sense of well-being and absence of symptoms, but it may be stated that when cardiac irritability or evidence of disturbed cerebral circulation (dizziness, tinnitus, etc.) appear, interference is warranted. For the rest, we must depend upon the readings of the sphygmomanometer. As a rule, a systolic blood pressure of over 160 m. of Hg. is necessary to produce symptoms. At this point hypotensive medication may be instituted. The patient should take a morning saline laxative of magnesium sulphate, Rochelle salts, or one of the aperient mineral waters. A mercurial purge at intervals of a week or ten days is often of the greatest benefit, exercising a double effect both as a peripheral dilator and by increasing the toxin-destroying function of the liver. A vasodilator excellent for its permanent influence is a combination recomended by Brunton (*Deutsche med. Wochenschrift*, Leipzig, Von Leyden number, 1902). This consists of:

Potas. bicarb.	1.8
Potas. nitrit.	1.2
Sodii. nitrit.	.03

The potassium salts are said to have a paralyzing effect on the heart. This effect is desirable in cases requiring less energetic heart action and increased permeability on the part of the arteries, thus lowering pressure at both ends of the circulation. A decided diuretic effect is also secured by the potassium salts. The writer has employed this combination in a number of cases with the greatest benefit, giving it twice daily, well diluted. Another excellent vasodilator for continuous use is erythrol tetranitrate. It may be administered in one-fourth grain doses several times daily, until a mild headache is produced, when the dose is slightly lowered. This drug may be used for weeks and months with good effect, discontinuing it for a week during each month. Another vasodilator of which I hesitate somewhat to speak is aconite. This drug is enthusiastically lauded by W. H. Thomson (*Medical Record*, May 16, 1903) for its effects on excessive arterial tension in Bright's disease, and he reports some striking examples of its efficacy in cases marked by asystole, with high tension. He orders it in five minum doses every three hours. Although it is difficult to explain the vascular effect of this drug, since it is not a direct vasodilator, but rather a cardiac sedative acting through the vagus mechanism, the empirical fact remains that it will lower blood pressure in an astonishing manner. In a recent case of my own a blood pressure of 247 mm. (Riva-Rocci, 9 cm.) was reduced 50 points in a few days by aconite, with great benefit to the patient's condition, the maximum dose employed being seven minums every three hours. In using the drug, I prefer to begin with small doses in order to guard against idiosyncrasy, and afterward gradually increase to five minum doses, or higher. It is hardly necessary to state that so powerful a depressor drug as aconite should be used with every care, and only in cases marked by excessive tension and threatened heart failure.

Iodide of potassium is another means of lowering tension of which the writer can speak with satisfaction. It is difficult to say in what manner it exerts its effect, as iodide is not a direct vasodilator. Recent observations would indicate that it acts by diminishing the viscosity of the blood, and in this way reduces capillary friction, and so lowers peripheral resistance. I know of few medicinal effects more satisfactory than the manner in which prolonged iodide administration will protect the heart from the ill consequences of high tension. It must, however, be given more or less continuously for long periods, covering in fact months and years. In the presence of high tension some restriction of fluids is indicated, and the patient's habits are to be carefully revised to avoid physical and nervous overstrain.

In the stage of sustained blood pressure and adequate heart without edema, digitalis is to be withheld, as its use is unscientific and harmful. The other cardiac tonics come under the same ban. Diuretics are unnecessary, and do no good. In fact, no medication is indicated other than cardiovascular regulation, and such measures as may become necessary to overcome intercurrent functional troubles. Intercurrent illnesses, however slight, during chronic Bright's disease should be followed by prolonged convalescence, owing to the circulatory strain constituted by effort in a reduced condition.

Whenever the heart, which has hitherto performed its work satisfactorily, suddenly displays vagaries of action, it should not be taken unreservedly as a sign of failing compensation. Some underlying reflex cause will usually be found, the correction of which will avoid serious damage to the heart. Early evidence of genuine cardiac incompensation calls for positive action. This need not necessarily consist of digitalis or other cardiac tonics, for rest in the recumbent position, restriction of fluids and general tonic measures will often restore the working capacity of the heart. Should the derangement of the cardiac action threaten to produce or actually result in dilatation, digitalis is indicated.

When the patient with chronic nephritis has become edematous, one of two things has happened: He has either developed diffuse inflammatory changes in the kidneys, or the heart has dilated. The nephritis may, of course, have been a chronic diffuse process, marked by dropsy from its inception. On the other hand, it is quite as likely to be a case of chronic interstitial nephritis, which has become converted into a diffuse nephritis by means of acute renal irritation from cold, excesses or acute intercurrent infection. It is also a fact that a large number, if not the majority, of cases displaying dropsy are chronic nephritis with failing heart, the dropsy developing as a result of ventricular dilatation. Dropsy in the course of chronic renal disease is not necessarily renal dropsy. It is quite as frequently cardiac dropsy. A better word would probably be cardiorenal dropsy. The distinction is important, especially from the standpoint of treatment. When we can decide that the dropsy, suddenly occurring during the progress of chronic nephritis, is due to an acute exacerbative inflammatory attack, the patient should be put to bed, placed on a light milk-farinaceous diet; sweated and purged until the renal congestion subsides. Baccelli (*Münchener med. Wochenschrift*, L., No. 52) has recently recommended in this form of renal congestion the withdrawal of 300 c.c. of blood from the vena pedidia. He reports great benefit and his results have been verified by others. By this procedure he seeks to lower blood pressure in the ascending vena cava, and so by creating a suction force in the venous channels relieves the congestion in the kidneys. The results are neither so prompt nor so energetic when the blood is withdrawn from the arm. After the renal engorgement has subsided, and the edema disappears, it is important to insist on a long gradual convalescence, to ensure a full return to former conditions.

When the dropsy is extensive and due to established diffuse nephritis, we are forced to rather roundabout means to relieve the renal blockade. Diuretics have next to no influence over purely renal dropsy, and their use will prove disappointing. Prolonged rest in bed is often of the greatest benefit, and should be enforced. These cases should be treated on the "little water and no salt" plan. Fluid intake should be restricted to the lowest possible amount compatible with comfort. The principle of dechloruration is to be enforced. Time will not permit of a discussion of this interesting contribution to our treatment of edemas. Since its introduction two years ago, it has earned for itself an established place in physiologic therapeutics as solving one of the underlying factors of dropsy, both cardiac and renal. In severe cases of anasarca the patient is to be entirely deprived of salt. In moderately severe cases the degree of diuresis may be taken as a criterion of the amount of salt we may permit the patient. As the normal percentage of chloride of sodium in the urine is about .5 per cent., we can safely permit as many half grams of salt as there are 100 c.c. of urine. For instance, when the daily urine amounts to 1,000 c.c., the patient can ingest 5 grams of salt. As a diuretic in renal dropsy we possess no better measure than colonic irrigation. The effect on the renal gland activity of this measure is often remarkable. Large volumes of solution at a high temperature are to be used. Decinormal salt solution is a violation of the dechloruration principle, consequently bicarbonate of soda solution of the same strength is to be preferred. From two to four gallons of this solution, at a temperature of 110° to 120° F., are allowed to flow into the bowel through a Kemp's rectal irrigator or double-flow rectal tube. The single precaution necessary is to provide against a further increase of tension in high tension cases by simultaneous use of a vasodilator.

When the degree of dropsy is such as to produce severe tension of the skin, the legs and scrotum may be drained by punctures under aseptic precautions. Hydrothorax, if the amount of fluid in the chest is such as to embarrass the heart's action, should be relieved by tapping, and ascites of high degree will require paracentesis. These latter measures may be repeated as often as the indications are renewed. I cannot say that I have seen the anemia increased or the patient's condition prejudiced in any way by repeated paracentesis. On the contrary, by temporarily relieving pressure on the venous trunks, we exert a favorable influence over the renal engorgement. Energetic diaphoresis offers us a valuable means of relieving renal engorgement, and assisting the kidney in its eliminative function. Bendix (*Deutsche medicinische Wochenschrift*, XXX, No. 7) found that when the freezing point of the blood was normal (56° C.), the most energetic sweating process failed to influence it. When, however, it was pathologically low, as in chronic Bright's disease, sweating raised the freezing point almost to normal, showing that more solid substances were eliminated under these circumstances than when the freezing point remains at a constant level. This is particularly noticeable in cases of uremia. These experiences emphasize the value of energetic sweating processes in nephritis. If the blood count shows the patient to be anemic, some form of iron should be administered, although it is well to remember that the anemia, being of a toxic production, is not so readily influenced by hematinics as under other circumstances. Valuable as iron is in the anemia of Bright's disease, its indiscriminate use in the form of Basham's mixture has unquestionably done a good deal of mischief. Basham's mixture is prescribed with a freedom in all forms of Bright's disease, as if it were regarded as a specific for nephritis. It never was suggested that it possesses any curative value, but is rarely a remedy for anemia, as under other circum-

stances. Not every case of Bright's disease is anemic, and it is clearly not indicated in non-anemic cases. In chronic interstitial nephritis it may do positive harm by helping to raise blood pressure. It is most useful in chronic diffuse nephritis, because that form is most frequently associated with anemia.

In cases of dropsy from dilated heart occurring in chronic nephritis, the treatment will differ materially in some essentials. Simple rest in bed will often bring about a restoration of heart function and subsidence of dropsy. Unfortunately many patients with high tension and failing hearts are very uncomfortable in the recumbent position, suffering from asthmatic symptoms and dizziness. These symptoms are the result of elevation of blood pressure in the lying position. Vasodilators may serve to control this, but often one is compelled to compromise on the sitting position, even allowing the patient to spend the nights in a chair. These are cases which display the inverse pulse, and paradoxical rise of blood pressure on lying down. Prolonged rest in bed, even for patients who can do so without discomfort, is hardly desirable in cardiac hypertrophy of Bright's disease. The dynamic forces of the circulation being lowered by bodily inactivity, a rise of blood pressure in the vena cavæ throws still more upon the already weakened heart —the work of maintaining the failing circulation.

The drug *par excellence* in cardiorenal dropsy is digitalis. Any reliable preparation of the drug may be employed. I have never been able to satisfy myself of the superiority of the infusion in these cases. In giving digitalis in Bright's disease it is necessary to guard the patient against the vasoconstrictor influence of the drug by means of the simultaneous use of a vasodilator. The only exceptions to this rule are constituted by those rare cases in which the blood pressure is low throughout the disease, and in cases where the cardiac weakness has caused secondary low blood pressure. A drug of great value in cases of cardiorenal dropsy is theobromine and its salts, the salicylate and sodiosalicylate (diuretin). Very remarkable results are sometimes secured by the administration of these preparations in dropsy, with underlying cardiac causes. There is evidence accumulating which tends to show that theobromine acts upon the heart by stimulating the elimination of retained chlorides, and so secondarily improves the heart's action by lessening the circulatory load. When the heart is weak, the patient must be well nourished, and receive a fair proportion of proteid food. Severe and restricted diets are to be avoided in nephritis with bad hearts.

The patient with chronic nephritis is never entirely free from the danger of uremia. Although its development is usually a progressive and gradual affair, it not infrequently falls suddenly upon the patient without warning. We sometimes see a case in which uremic coma or convulsions are the first symptoms to betray the presence of chronic Bright's disease. Any acute intercurrent disturbance, such as a simple cold or diarrhea, may serve to precipitate a violent uremia. Gastro-intestinal disturbance especially favors the development of the uremic toxemia, often, no doubt, by inducing *Bacillus coli communis* invasion of the kidneys. This fact emphasizes the importance already referred to of keeping a clean bowel.

In the presence of uremic manifestations, however slight, purgatives are to be employed without hesitation. It should be one of the rules of treatment in nephritis to give a purgative each time the patient complains of headache, dizziness, mental hebetude, dyspnea, etc., all of which may prove to be precursors of uremia. At the first appearance of uremic symptoms all proteid food should be withdrawn. Strubell (*Wiener klin. Wochenschrift*, July 8, 1901) found that dogs with experimentally induced uremia lived twice as long when fed with carbohydrates as when fed on proteids and fats.

Our blood pressure observations will enable us to gauge in some measure the imminence of uremia, the intensity of the uremic toxemia being accurately expressed by the arterial pressure, which rises steadily as the toxins accumulate. An increasing blood pressure should, therefore, put us on our guard. In acute uremia an important point is gained by lowering blood pressure. Our best and speediest vasodilator to relieve the high tension of uremia is venesection. This measure exerts its best effects in uremia complicating acute nephritis. It is of less dependence in chronic nephritis, and is only to be used in sthenic cases with high tension. It is to be avoided in asthenic and far-advanced cases. The relief following venesection is transient, but may serve a good purpose when supplemented by other active measures, such as sweating, enteroclysis, catharsis. Sweating should be carried out vigorously and as soon after onset of the uremia as possible. As soon as free diaphoresis has been induced, the sweat may be temporarily interrupted, as its persistence for too long a time may become a harmful influence. Enteroclysis by continuous irrigation of the colon with large volumes of hot bicarbonate of soda solution constitutes one of our most active measures for inducing diuresis and diaphoresis. Subcutaneous saline infusions, although beneficial in the uremia of acute nephritis, are much less effective in uremia of the chronic disease.

Time will not permit of further discussion of measures employed to combat uremia. Reference may, however, be made in conclusion to lumbar puncture. Seiffert (*Münch. med. Wochenschrift*, LI, No. 10) has employed this measure extensively in acute uremia, with great benefit. It may be employed in uremic coma and convulsions of chronic nephritis, although probably with less likelihood of success. Le Grain and Marie speak highly of the effects of this procedure in uremic headaches.

There are many important points which are not touched upon in the foregoing brief consideration of the treatment of chronic nephritis, and the writer is compelled to forego from lack of time any reference to the treatment of complications, and special phases of the disease.

The ability of the organism to adjust itself to the disturbed equilibrium of impaired organic health is marvelously displayed in many incurable diseases of important organs, and we often stand amazed at the length to which the thread of life is spun, notwithstanding the gravest organic lesions. Under no circumstance is this faculty for adjustment so wonderfully illustrated as in chronic kidney disease. Despite the most serious defects, nature's compromise not only preserves a balance of fair health, but does so for astonishing periods. A realization of this fact should be a warning to us that nature needs our assistance only, seldom our interference.

There is no room for pessimism in our attitude toward this disease, and although obviously there is no remarkable cure to be performed by any mode of treatment, careful regulation of the life, and attention to little details, judging nothing unimportant, will secure results which are unsurpassed in any of the chronic dystrophies. The two most important indications, in the estimation of the writer, are to protect the patient from intercurrent acute disturbance, and to maintain the compensatory adjustment in the circulation.

103 State Street.

THE CARE OF THE PERINEUM, WITH A DESCRIPTION OF A NEW METHOD OF DELIVERY OF THE SHOULDER.[1]

BY H. KAY KERR, M.D.,
OF HAMMOND, N. Y.

Most of what has been written about the care of the perineum refers to the delivery of the head. With regard to the delivery of the head, I will mention only two points. Both of them are old, and are mentioned not because they are old—although perhaps nothing the worse for that—but because in my experience at least they have been found good.

The first is hot fomentations: cloths wrung dry out of hot water, just as hot as the hands can stand, and held in contact with the perineum during the acute pain. These do good in two ways. They relieve pain, or at least render pain more easily endured, and if we doubt it all we have to do after using them a few times is to withhold them, and see if the patient does not call for them again. They also render the perineum more elastic, so that it will stretch easier and farther without tearing, and in this way make laceration less likely.

There is a time coming, however, in the progress of the labor, when hot fomentations have to be dispensed with, when the perineum needs supporting. This brings us to the *second* point concerning the delivery of the head, the choice of a method. The particular method employed is doubtless of less consequence than the actual support given the perineum, no matter by what method. My own plan is: With the thumb on one side and the fingers on the other, reaching well out over the perineum, laterally, to make pressure from without inward toward the center, and with the ball of the palm resting well back on the posterior part of the perineum—the center of the palm not touching the anterior part—also to press forward toward the fourchette. In precipitate labor, where more resistance is needed, the fingers of the other hand may be substituted for the thumb: but for the purposes of description and in most cases it is better to place the thumb on one side and the fingers on the other, reaching out far over the deep lateral structures of the perineum, where the perineum is thick and strong and cannot tear, and with each pain press toward the central, weaker part of the perineum, the part where the great strain comes and the part that will tear, and with the ball of the palm resting well back on the perineum, posteriorly, to press also downward and forward in the direction of the outlet of the pelvis. In this way the perineum is stretched *from its circumference*, laterally and posteriorly, where the muscular development is strong and will stand stretching, while the weaker center and anterior are protected. And I keep this up just as long as I can, until the occiput has engaged, passed under and has emerged outside the pubic arch. Even then I press toward the center and forward in the direction of the outlet of the pelvis because the longer we keep the perineum from slipping over the chin the more, of course, the perineum is stretched and the roomier it becomes, and, as we all know, the more the head elongates and the less becomes the anteroposterior diameter that does the mischief. In other words, by delaying within reasonable limits the birth of the chin there is a more thorough conversion of the long occipito-bregmatic-frontal-mental diameters into the shorter suboccipito-bregmatic-frontal-mental diameters, successively, as presenting parts—the difference between danger of laceration and very little danger of laceration.

Most of us who have had some experience can, I think, take fairly good care of the perineum during the delivery of the head, the text-books to the contrary notwithstanding. It occasionally happens—has happened to me and probably to some of you, and may happen to any of us again—that after we have delivered the head without injury to the perineum, and have congratulated ourselves on that fact as we have a perfect right to do, we make an examination before leaving and are surprised by the discovery that there is a very considerable laceration. Or, if we fail to make the discovery ourselves, perhaps the nurse makes it for us, and that does not improve matters. Now, this proves, if it

[1] Delivered before the St. Lawrence County Medical Society, Potsdam, N. Y., April 18, 1905.

proves anything, that the head is not the only factor in laceration of the perineum. I think we can take a step farther and take the position that the head is not even the major factor in serious laceration; but that in many cases, after the head has been delivered with the perineum still intact or practically so, the damage is done by the ploughing through of the shoulder afterward.

In order to obviate this difficulty, or, as some put it, "to minimize the tear," I will try to describe a method of delivery that I have been using for the past nine years, and which I think well of. Ordinarily, during a considerable part of the progress of labor, my patient may assume any position that she pleases, and I often encourage the squatting position which at certain times makes for progress; but when it comes to the point of delivery I want her on her left side with back to edge of bed. After the birth of the head there is usually a short pause, during which time, or at the beginning of the pains which follow, rotation usually occurs. In this case we do not wait for rotation, but regarding it as a first presentation—the face looking backward—by placing a hand on each side of the head and making gentle pressure in the direction of rotation, rotation is easily effected. Now that rotation has occurred, what is the situation? The face looks upward toward the mother's right thigh; the occiput is directed downward toward the mother's left thigh; the right shoulder presents against the pubic arch in front; the left shoulder presents against the soft structures of the perineum, behind, *but, at least, one and one-half inches from the outlet.*

As soon as rotation is effected, and all this is but a momentary affair, I place my left hand on the right side of the child's head and press back firmly. There is no danger of doing harm here as the point where the left shoulder presents against the perineum is too high up to lacerate, so I press back as far as it will go. What does this do? First, it stretches the perineum once more *from its circumference*, laterally and posteriorly, toward the center and anterior. Muscular contraction is thereby almost entirely overcome. The perineum is now temporarily paralyzed and is elastic like rubber and can hardly be made to tear. Second, every inch or fraction of an inch that the left shoulder can be carried back into the perineum, *we gain that much* in lowering the right shoulder into the pubic arch. Now, when a pain occurs, what takes place? The left shoulder cannot descend because it is held well back and high up in the perineum. Not so with the right shoulder, which does descend. As it does so, it describes part of a circle around the left shoulder, held as a fixed point high up in the perineum, so that the course of the right shoulder is downward and slightly backward, bringing the prominence of the shoulder well back into the vulvovaginal outlet and the right arm, below the shoulder, into the pubic arch. One pain is usually enough to bring down the right shoulder and cause it to bulge well out of the vulva. This accomplished, I close the fingers of the left hand, with which backward pressure is being made, low down on the back of the neck or upper end of the spine and raise up. This increases the space between the back of the child and the maternal soft parts on the left side below and also opens the right axilla. Through this opening in the axilla, I pass the forefinger of my right hand and hook it around the arm, close to the shoulder, bring it down behind the child's back out of the vulva and sweep it over the pubic arch. Then, before relaxing my grip with the left hand, I place my right hand on the left side of the child's head and, with my left supporting the perineum, by a downward, forward and slightly upward movement, effect delivery. Thus, before there is the slightest strain on the anterior part of the perineum, we have exchanged the long diameter—from the tip of one shoulder to the tip of the other (bisacromial)—for the shorter diameter—from the axilla to the tip of the opposite shoulder (axilla-acromial) as a presenting part, the difference again between laceration and practically no danger of laceration.

This procedure is mainly applicable to uncomplicated cases, which are in the great majority. It can be employed in most forceps cases by removing the instruments in accordance with modern practice before complete delivery. A previously repaired perineum is no hindrance. The chief difficulty is in precipitate labors, and these are rare in primiparæ in which the preservation of the perineum is of such vital importance. With a thorough familiarity with the technic, the cases are few in which it cannot be successfully employed.

MEDICAL PROGRESS.

PHYSIOLOGY.

The Oxidative Processes of the Tissues.—Marked differences in the oxidative capacities of the various tissues have been observed by W. ZANICHELLI (*Arch. Ital. de Biol.*, March 21, 1905). Thus, in the dog the spleen has an oxidative power which is at least ten times as great as that of the other tissues with the blood. The second place belongs to the pancreas, and next come the kidneys and the lungs, then the liver, and lastly the blood, whose power is quite limited. The high degree of oxidative power possessed by the lungs corresponds to its marked degree of autolysis observed by Jacoby, and indicates that the pulmonary parenchyma is not only the seat of passive gaseous exchanges, but is also the seat of metabolic processes not less active than those of other parenchymatous organs. The high degree of oxidative power of the spleen is probably associated with its hematologic function. The author finds that the age of the animal has no effect in its oxidative powers.

Researches in Heat Regulation.—It has been found that special substances are formed in the blood of animals subjected to abnormal temperatures, and that

it is also markedly toxic if injected into other animals. A. MONTUORI (*Arch. Ital. de Biologie*, March 21, 1905) made a special investigation along this line, with the object of isolating these toxic substances, and of determining whether they produce the same effects in the animal in which they are generated. He transfused certain dogs with the blood of other dogs kept in baths of hot water (40° to 48° C.) or of cold water (0° to 6° C.). The results were as follows: The transfusion of the ordinary or of the defibrinated blood from the heated or refrigerated dog causes in the transfused animal a diminution or an augmentation of the quantity of heat produced. These thermic effects are proportional to the amount of blood transfused, and also to the degree of heating or refrigeration of the animal from which the blood is removed. The effects are always transitory and cease at the end of not more than twenty-four hours. The transfusion of large quantities of blood from heated dogs is fatal, which is not the case with blood from refrigerated animals. The administration of the blood by way of the stomach or intestine has no thermic effect, while the transfusion of blood from an animal kept at the ordinary temperature has also no thermic influence. These results reveal a form of heat regulation that has been hitherto unknown, indicating the production of thermo-inhibitory substances in heated animals, and of thermo-excitatory substances in refrigerated animals. This mechanism applies only in the case of the heating or cooling of the cutaneous surface of the body, and does not apply to the same condition in the lining of the alimentary canal. It is interesting to note that animals heated by general faradization furnish a blood that causes hyperthermogenesis and elevation of temperature in other animals. If an animal be injected with antipyretics (quinine, antipyrine), its blood will not cause any thermic changes in another animal, which proves that the antipyretics do not act by the production of thermo-inhibitory substances. The author next sought to discover the effects of these transfusions in the other bodily functions. They do not cause any change in the respiratory and cardiac rhythm, and produces no vasomotor effects. This shows that the thermic polypnea and tachycardia, and the vaso-constriction produced by cold are not the result of the elaboration of specific substances in the blood. Transfusions from a refrigerated animal cause, besides an increase of heat production, also an exaggeration of the respiratory exchanges. On the contrary, the transfusions from the heated animals had no effect on the gaseous exchanges. The transfusions from a heated animal cause an increased production of sweat in the animal transfused. This action is evidently a central one. Likewise, there is also an increased secretion of saliva, which is similarly a central effect, since section of the chorda tympani annuls it. There is also increased secretion of pancreatic juice. Hence, the elevation of an animal's temperature causes the production of a substance or of substances which may be compared to pilocarpine. The transfusion of blood from a heated animal or even heating an animal directly causes an increase in the muscle-glycogen. The hepatic glycogen does not suffer any marked variations. One naturally concludes that there is a transformation of the glucose of the blood into the glycogen of the muscle. The results of an investigation into the nature of the thermo-active substances were very incomplete. They are not volatile, for blood subjected to the mercury-pump preserves its thermo-activity. This evidently resides in the morphologic elements, for the serum is inactive, while defibrinated blood is active. The thermo-active substances are destroyed by a temperature of 55° C., but they are apparently not of the nature of enzymes, for the thermic effects are quite proportional to the amount of blood transfused. These substances can not be extracted with glycerin or ether. The author next studied the site of formation of the thermo-active substances and the mechanism of their activity. Heating or cooling normal blood outside of the organism does not conflict with thermo-activity. These substances are formed neither in the spleen, pancreas, nor liver, for removal of the two former or ligature of the blood vessels of the latter does not interfere with the formation of the thermo-active substances. Curarization also does not inhibit their formation. If the spinal cord of an animal be destroyed, the heating or cooling of the animal always gives rise to a thermo-inhibitory substance. The conclusion is readily drawn, that for the production of hyperthermo-active substances the integrity of the nervous system is necessary. The facts discovered by the author have a great deal of importance and permit the following conclusions to be drawn: In the struggle against high temperatures, the thermo-active substances play a predominating rôle. The method by which the thermo-inhibitory substances operate is explained as follows: Accompanying the lowering of the bodily temperature, it has been seen that there is an increase in the synthetic processes of the organism, such as the increased formation of glycogen. The freezing-point of the blood also rises, indicating a greater molecular concentration; that is, a diminution in the number of ions in the blood. These synthetic processes, which are necessarily accompanied by a diminution in the number of molecules of the blood, since the simple ones are built up into more complex ones, are therefore also accompanied by a transformation of some of the heat of the body into latent potential energy. This change of the manifest heat into potential energy is called the "endothermic reaction." This represents an admirable economic disposition in the organism. At the same time that the bodily temperature is lowered, there is a rebuilding of the tissue whose oxidation was the cause of the excessive heat. The choice of people in torrid climes of a diet of carbohydrates instead of one of fats supports this hypothesis, since the carbohydrates, by the simplicity of their constitution and the mobility of their molecules, furnish a more ready material for the synthetic processes of the organism, and therefore furnish a ready means for the cooling off of the body by the endothermic reaction. The thermo-inhibitory substances, by stimulating the production of sweat, furnish another means of lowering the bodily temperature by the evaporation. It has been found that muscles which have been made to contract vigorously furnish substances which, if injected into other animals, increase the production of heat, and that the genesis of these substances is dependent upon the integrity of the central nervous system. Now, it is known that the application of cold to the exterior of the body causes an increase of muscular tone. The conclusion is drawn that the effect of external cold causes reflexly a contraction of the muscles, and it is by means of these contractions that substances are formed which have the power of accelerating the oxidative processes with a resulting thermo-genesis. The muscular origin of the thermo-active substances indicates that the muscular apparatus represents the heat-regulating mechanism of the animal economy *par excellence*.

OBSTETRICS AND GYNECOLOGY.

Vaginal Hysterectomy for Cancer of the Cervix in the Gravid Uterus.—In cancer of the cervix in pregnancy the interest of the fetus, as well as that of the mother, is to be considered. The fetus is constantly threatened by abortion, which may be due to hemorrhage, or by the progress of the rapidly developing neoplasm involving the body of the uterus. The development of cancer is more rapid in the soft and vascular tissues of the genitals during pregnancy, therefore if the pregnancy goes to full term the consequent dystocia endangers the fetus. A. COUDAMIN (*Annales de Gynecol. et d' Obstet.*, March, 1905) reports 30 cases which show that we may expect good results if the patient is operated on sufficiently early, and quotes statistics to show that the fetal mortality is 25 per cent. to 30 per cent. in cases allowed to go to term. In 71 cases already reported 11 had had no recurrence after four years, and were thus considered cured. Although the results are less satisfactory than where the disease is not complicated by pregnancy, they are not sufficiently bad to warrant the sacrifice of the mother for a fetus whose viability is uncertain. During the first six months of pregnancy, with an operable cancer of the cervix, radical operation should be performed at once. After the sixth month the problem is more complex because the fetus is approaching the age of viability and its interests must likewise be considered. If the cancer is seen early the surgeon may wait a month or six weeks for a viable child, but if the neoplasm has already advanced it should be operated on at once, sacrificing the interests of the child to those of the mother. An anesthetic may be of great use in determining the extent of the neoplasm. At the eighth month the child is viable, and an abdominal Cæsarean section should be performed, followed at once by an hysterectomy. After the eighth month vaginal Cæsarean section should be the exception and reserved for those cases where the fetus is very small. The contra-indications for operation are the same as those for a non-pregnant uterus. Any invasion of the parametrium would not justify a vaginal hysterectomy, as interference in these cases is likely to be followed by a recurrence. In such cases palliative treatment should be employed. In cervical cancer coincident with pregnancy the vaginal hysterectomy is no more difficult up to the sixth month than when uncomplicated by this state, there being compensation for the increase in size of the uterus in a more easily dilatable way of access, more elongated uterine ligaments, which permit more easily the descent of that organ. The uterus may be emptied first by making an incision in the median line, rupturing of the membranes and delivering the fetus. Another advantage of the route is that the limits of the neoplasm may be better appreciated and the incision made well outside of the cancer zone. The lessened risk of infecting the peritoneum from the cancerous stump speaks also in favor of the vaginal route. The vaginal hysterectomy, without preliminary incision of the posterior and lateral culs-de-sac, may be performed as follows: (1) Excision of the salient parts of the cancerous growth, followed by use of Paquelin cautery or a strong caustic to the cut edges. The anterior lip of the cervix is then seized and drawn well downward and forward. (2) The anterior vaginal cul-de-sac is incised on the anterior lip of the cervix and the tissues separating the vagina from the bladder liberated. (3) An incision following the median line of the anterior lip of the cervix is continued along the anterior wall of the uterus, the edges of this cut are held open by forceps which are advanced as the incision is carried higher up. The membranes are ruptured as soon as reached, the child is extracted, usually by version. The median incision is continued upward till the fundus uteri can be delivered into the vagina. Bleeding is easily controlled in this procedure. (4) Large curved clamps are placed upon the broad ligaments from above downward which meet at the level of the posterior cul-de-sac. (5) The broad ligaments and the posterior vaginal wall are cut within the clamps. These clamps may be left in place forty-eight hours or replaced by ligatures. An advantage of the procedure is the ease of hemastosis and small loss of blood during the operation. It avoids the incision of two vascular parts, the lateral cul-de-sac and the point of union of the lateral with the anterior cul-de-sac. When the seat of the cancer is on the posterior lip it frequently extends to the posterior or lateroposterior vaginal walls. In such a case the wall should be separated from above downward and the entire cancerous mass removed *in toto*. The objection to this operation is that when the neoplasm is on the anterior lip of the cervix and extends to the vaginal mucous membrane it is inapplicable. But when the mucous membrane is invaded to a slight degree it will be possible to incise in front of the tumor and reach the anterior peritoneal cul-de-sac. More advanced lesions involving the cellular tissue separating the bladder and cervix contraindicate any attempt at vaginal hysterectomy, since a portion of the bladder must be resected near the ureters, which would be particularly hazardous. In such a case death would follow more rapidly than if the growth were not interfered with.

Paravaginal or Abdominal Operation in Carcinoma of the Uterus.—In a discussion on the relative merits of the two operative routes, G. GELLHORN (*St. Louis Med. Rev.*, June 3, 1905) comes to the following conclusions: (1) The radical abdominal operation, as far as the routine ablation of the lymphatic organs of the pelvis is concerned, has thus far failed to yield the desired results. (2) On the other hand, the eradication of the parametria has been found to reduce greatly the percentage of cures (3) Consequently, the simple abdominal and vaginal operations which do not include this procedure must be discarded. (4) For the extirpation of the parametria, Wertheim's method is the best of the abdominal operations. (5) It has, however, certain advantages compared with the paravaginal method of Schuchardt. (6) Considering the encouraging results of igniextirpation, a combination of thermocautery with paravaginal extirpation gives promise of further improvement in operative results.

Sudden Death During or Immediately After the Termination of Pregnancy or Operation on the Pelvic Organs in Women.—E. P. DAVIS (*St. Louis Med. Rev.*, June 17, 1905), from a study of twenty-five cases, arrives at the following conclusions: (1) That sudden death may occur after abortion, labor or operation from undemonstrable causes. (2) Death may follow abortion, labor or operation, from the rapid formation of a pulmonary embolus. Pulmonary embolism may develop before the placenta has been delivered, or when delivered by Credé's method. It is not frequent after Cæsarean operation or after the more complicated obstetrical operations. Predisposing and probably exciting causes are bronchial infection and abnormal conditions of the blood. (3) Primary thrombosis and secondary embolism may cause death after the termination of pregnancy or operation. Causes: pre-existing infection, mechanical violence, altered con-

ditions of blood serum, and lesions in the walls of the valves. (4) Sudden death occurs in parturient women and after operation from reflex nervous shock without assignable cause; also from disease of the thoracic viscera, from infection of the placental site and other obscure conditions.

PATHOLOGY AND BACTERIOLOGY.

Agglutination of Typhoid and Paratyphoid Sera.—The observation has frequently been made that the serum of patients suffering from typhoid will also agglutinate the paratyphoid germs, and it may be difficult to say whether the patient suffers from typhoid or paratyphoid. D. Korte and B. Steinberg (*Münch. med. Woch.*, May 23, 1905) point out the necessity of always determining the highest dilution in which agglutination will still take place. It may also happen that the typhoid bacillus will not be agglutinated by typhoid serum in low dilution, while with high dilution clumping will be perfect. In a case mentioned a dilution of 1 to 80 was tested against both typhoid and paratyphoid. The latter was clumped actively, the former not at all. A diagnosis of paratyphoid therefore seemed probable, yet on further testing the serum, active agglutination was obtained with typhoid at 1 to 640, while the paratyphoid was not at all agglutinated in this dilution. The microscopic test is always more delicate than the macroscopic.

The Bacillus Coli Communis as a Cause of Septicemia.—The rôle played by the *Bacillus coli communis* leads T. G. Moorehead (*Practitioner*, June, 1905) to consider whether or not it is ever the cause of septicemia. It has been long known that the bacillus has pyogenic properties, and while its presence is always suspected in abscesses near the alimentary canal, the author considers that there are cases in which the symptoms point to a sapremia being present, due to the absorption of the colon bacillus toxins, and that also there are cases in which the organism assumes a septic or septicemic rôle, as distinct from a pyogenic one, and produces an actual septicemia. He bases this statement upon the following facts: (1) Its known power of producing a septicemia in animals, and in connection with this fact it may be stated that Lésage and Macaigne have shown that the organism, isolated from the intestines in cases of diarrhea, is much more toxic than that obtained from the healthy alimentary canal. They, in fact, believe that the bacillus of the normal intestines can only exert a local pyogenic toxicity, while that from diseased intestines has septicemic powers. It may also be stated that Ferranini has shown that the *Bacillus coli communis* exerts a much more powerful effect on ill-fed animals than on well-nourished ones; that, in fact, its toxicity increases with the diminution in resisting power of its host. (2) Cases in which the *Bacillus coli* was found in the blood during life. (3) Cases of general sepsis reported by Schenck, Gebhard, Kerr, Eisenhardt and others, in which the *Bacillus coli* was found universally throughout the body in pure culture after death, and along with these may be mentioned Kamur's work on Winckel's disease. (4) The occurrence under natural conditions of infectious diseases in the lower animals apparently caused by the colon bacillus. The power of the *Bacillus coli*, in modifying the course of, or preparing the way for, other forms of septicemia, is indicated by the following facts: (1) Motta Coco, experimenting on animals, found that the *Bacillus coli* assumed very virulent properties in company with streptococci; (2) Widal and Besançon, working with the streptococci of the mouth, ascertained that many which were harmless when injected alone into animals became virulent when mixed with the colon bacillus; (3) Blasi and Russo-Travali reported, in 1896, a case of mixed infection with the *Bacillus coli* and diphtheria bacillus, and found experimentally that a mixture of the two bacilli was much more poisonous than either organism singly. Schenck also reported, in 1898, a case of combined coli and streptococcal infection, and makes the statement that the *Bacillus coli* is always very virulent when combined with streptococci, while, as showing that the opinion that the *Bacillus coli* might combine with other organisms to produce a septicemia has been long held, it may be added that in 1896 Sims Woodhead said that he believed many so-called streptococcal infections to be really secondary to colon infections. From the above reasoning the author concludes that the existence of a *Bacillus coli* septicemia is probable.

Vaginal Cysts.—From an examination of 53 specimens of vaginal cysts, T. S. Cullen (*Bull. Johns Hopk. Hosp.*, June, 1905) classifies them into the following varieties from an etiological standpoint: (1) In 26 the origin was clearly the result of a perineal tear or a perineal operation. (2) Four seemed to originate from vaginal glands. (3) Eleven were apparently derivatives of Gärtner's duct. (4) Three were situated near the external orifice of the urethra. (5) In eight it was impossible to determine the mode of origin. The inclusion cysts are due to small portions of the vaginal mucosa being included in the stroma. Such cysts are small, and are naturally found in the posterior or in the lower lateral wall of the vagina. In three of the cases of this series the cysts probably originated from the vaginal glands. In 11 of the cases a dilataton of a portion of Gärtner's duct appears to have been responsible for the cyst. The most common situation was in the anterior vaginal wall just behind the urethral orifice. In two cases it was probable that the cysts owed their origin to urethral glands. Several of the unclassified cysts probably had their origin from Gärtner's duct. The author considers that various gas cysts which are at times found in the vagina of pregnant women are analogous to those found in the liver and other organs, due to gas-producing microorganism, and suggests as a causative factor the *Bacillus œrogenes capsulatus*. In countries where the echinococcus is prevalent, some vaginal cysts may be due to them.

Pathology of Gastric Ganglia.—If dogs are treated with a dilute mixture of ethlyic and amylic alcohol, gastritis of varying severity may be induced. In the most acute type, L. Amato and P. Macri (*Virchow's Archiv*, Vol. 180, No. 2), found marked hyperemia, involving all the layers of the stomach and extensive changes in the nerve-ganglia (chromatolysis, vacuolization, karyolysis, atrophy). In the less acute types, the hyperemia was less advanced, particularly in the muscular layers, but both here and in the subacute cases the nerve-cells were seriously altered. In man the following changes could be detected: in pyloric cancer, the ganglia were either destroyed directly, or else the seat of interstitial changes of advanced degree. Chronic interstitial and parenchymatous inflammation was also found in the various types of chronic gastritis. The poisons which set up the gastritis probably have a particularly strong affinity toward the nerve-cells, and there can be no doubt that the changes in the latter are responsible for many of the symptoms.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 2, 1905.

A NEW HOPE IN THE BATTLE WITH QUACKERY.

FROM its earliest inception the medical idea has been a reaching for truth and a denial of falsehood in the sphere of physiological functioning. Since the days of Hippocrates the medical profession has been fighting superstition, within its ranks as well as without. Now that a wider education is in a small measure enabling the masses to reason instead of following blindly, it would appear that there is less hope than ever of dealing the death blow to quackery; for this very reasoning power, this newly awakened belief in one's ability to choose and discriminate has been seized upon by the modern descendant of the ancient quack, and the specious appeals to the patient's intelligence which appear in the advertisements of the daily papers are far more seductive than the cruder forms of quackery that advertised universal panaceas. The survival of the unfit goes hand in hand with the survival of the fit.

The blatant contempt which the quack expresses for what he calls the physician's obstinacy and indifference to all but his own views prevents the ethically-minded among us from replying in kind. We cannot place ourselves in the quack's shoes and denounce others while insisting on the superiority of our own treatment, and they know it, such knowledge having ever constituted stock in trade. Hence the quacks, and by these we mean the propagators of every form of cure that has the credulity or ignorance of patients for its basis, the quacks skilfully put forth practically all the medical literature that meets the eye of the average layman.

It is therefore with a feeling of positive pleasure that we find published in the *Popular Science Monthly* for September a paper on quackery, read before the Yale Biological Club. It is a layman's study of a layman's grievance. It is a comprehensive but brief protestation that such a state of things should exist, that there should be twenty thousand quacks in New York City to six thousand physicians, that quackery in such a city as Berlin should have increased 1,600 per cent. in thirty years, and that the vendors of quack medicine should be among the largest customers of wineries and distilleries.

"Given," says the author, "on the one hand, the limitations of scientific medicine, the pain and dread of disease and the power of auto-suggestion, and on the other hand, depraved humanity, hard-driven in its struggle for existence, but cunning in the knowledge of men, and you have the essential parts which, with a few minor pieces, make up the smooth engine of quackery. Psycho-therapeutics and knowledge of human nature constitute the quack's entire outfit; all he really needs is moral atrophy and the instincts of a cheap drummer."

Clearly and logically the fraud perpetrated upon the people through the medium of the daily papers is exposed. "With a few notable exceptions, such as *The Outlook, Life, Ladies' Home Journal, The Evening Post* and a few others, the whole secular press unblushingly sprinkles its columns with the charlatan's cards."

Very cleverly is it hinted that "it is not bare accident that America is at once the home of quackery and the home of the free," for the passion for personal freedom is, as one writer has savagely described it, the attitude of "jealously safeguarding to every citizen the sacred right of going to the devil in his own way."

We as physicians have for the most part resigned ourselves to helpless silence, for whenever we attempt to raise our voices, even the disinterested have seen an attempt at extending the "Medical Trust." But now that the public has been given rope enough there is a possibility that they may suddenly realize that there is sufficient with which to hand itself.

It is perfectly true that "quackery is a seated evil which the community in self-defence ought to weed out." Such papers as have not prostituted themselves should agitate the matter. Mr. Bok has made a strong stand, and in the last issue of the *Ladies' Home Journal* has contributed a forceful page, silent yet emphatic, as to the frightful extent of the evils in question. Other editors, it is suggested, would secure more of the necessary sensational effect by the free exploitation of the ills resulting from the use of patent nostrums than they could from exposing a gas or a beef trust; and once the public realized that they were being duped, and could only be kept in that state of mind, they would have at least a different point of view of the men who advertise their prowess in the healing art.

In Germany the public-spirited men of all professions have organized a systematic campaign against quackery. Is it possible for us to do the same? Cannot we at least endeavor to bring the matter before the public school authorities as a subject for some of the free lectures, and one deserving a small place in the curriculum along with the matter devoted to the dangers of alcohol and tobacco?

The hope lies in the layman who is the sufferer. We have known for centuries that he has been duped and defrauded, but he has thought our warnings were made purely in self-interest. From the tenor of the address referred to and other signs of the times, we hope that the worm is nearly ready to turn.

THE AMBULANCE SERVICE OF THE AMERICAN METROPOLIS.

In the evolution of the modern municipality the inauguration of a highly efficient organization for the safeguarding of life and health is, strangely enough, a very late development.

The government first concerns itself with the protection of private property, and to this end a powerful police force, at least potentially, and a magnificent fire department are evolved. In the meantime the increase and congestion of the population necessitate a closer regard for the health and comfort of the masses. Hence, in due time, are established large public hospitals, alert Boards of Health, sanitary water-supplies, small parks, scientific methods of street-cleaning, etc. Far-seeing publicists are beginning to realize the economic gain resulting from governmental expenditures that tend to diminish disease and save life.

In every community there is a body of citizens who are better adapted even than medical men to point out the deficiencies in public systems of relief. These are the practical sociologists. The physician is too deeply engrossed in concrete instances of disease and suffering to note the general aspect of sanitary problems as well as the busy charity-worker or the interested citizen. It is quite natural then that a timely suggestion for remodeling and improving the ambulance service of New York should come from a layman. At the recent Portland Conference of Charities and Correction Mr. Nathan Bijur referred to the poor ambulance service of the metropolis, and advocated the appointment of a commission to investigate the subject. He suggests that temporarily a central ambulance bureau might be looked after by the Police Department, which, working in connection with the various hospitals, would be able to render speedy relief. A system of instant response to calls for aid, such as the splendid Fire Department of New York affords, is imperative. The solution of this problem is rendered difficult by the irregular distribution of hospitals over the city.

It does not require a long residence in the heart of the metropolis to become familiar with the inadequate facilities for rendering first aid to the injured. An enumeration of a few concrete instances will serve to emphasize the truth of this statement.

A child is run down by a trolley-car. Grabbed up by some spectator, and followed by a sympathetic crowd, it is carried to the corner drug-store. A police officer has probably arrived on the scene by this time and, calling up Police Headquarters, asks that an ambulance be summoned. Accordingly one is dispatched from the nearest hospital that maintains an ambulance service. In some parts of the city the nearest hospital may be located a distance of several miles. In the meantime the victim either receives no care or else must submit to the crude ministrations of the amateur surgeon. Rarely is any effort made to summon a nearby physician, for no one cares to assume the responsibility of paying the fee.

Not long ago a lady fell while alighting from a Broadway car. She was carried to the sidewalk, where she lay unconscious, surrounded by the usual crowd, in the center of which stood the stalwart policeman who had already telephoned for an ambulance. A physician who at that moment was passing by edged his way through the

crowd. His proffer of aid was insolently refused by the officious guardian of the peace, and as a reward for his pains he was actually told to mind his own business.

In the eyes of the public the ambulance surgeon is a sort of hero. The prestige conferred by the hospital uniform and the settled air of nonchalance with which the young tyro in surgery usually lies outstretched on the rear seat of the ambulance have a tendency to create an exaggerated opinion in the popular mind of his attainments and skill. In many instances the junior interne who responds to the call is fully deserving of this good opinion. It is needless to refer to the numerous examples recently recorded in the press of personal daring and self-sacrifice displayed under the most trying circumstances by the young surgeon. Yet hardly a week passes but some instance of poor judgment or reckless self-confidence on the part of the embryo surgeon is brought to one's attention. Many a time in cases in which the physician of mature mind and experience would hesitate to make a diagnosis, the ambulance surgeon is quick to decide that the case is one of alcoholism, shamming, hysteria, etc. The unnecessary frequency of these mistakes has naturally called forth the indignant criticism of the public.

There is a class of cases which, while not particularly urgent, nevertheless require prompt removal to a hospital. It is frequently difficult to locate a hospital that is willing to admit the patient, and under these circumstances days may elapse before the patient is removed. An instance of this is afforded by the following experience in the Borough of Brooklyn during the recent epidemic of meningitis. A physician desired to have a child under his care, suffering from a severe form of this disease and unable to receive the proper care amid its poor surroundings at home, removed to a hospital. After communicating in vain with over half a dozen hospitals, which would not admit a case of meningitis, he finally telephoned to the King's County Hospital, corresponding to Bellevue in Manhattan; he was told that the case would be admitted, but that an ambulance could not be sent that day, as it was Sunday. In fact, a period of forty-eight hours elapsed before the ambulance arrived.

The needless delays, the unnecessary mistakes, the fear displayed by the ambulance surgeon of being harshly criticized by his superiors for bringing an unsuitable case to the hospital, the summoning of an ambulance from a distant hospital when one from a nearer hospital might be obtained, and the lack of sufficient ambulances to supply the large territory of New York—all these are elements which require attention in reforming and perfecting our ambulance service. A few of the broad features of such an improved system might here be considered.

First, there should be a central bureau, as suggested by Mr. Bijur, which would receive all calls and would cooperate with the various hospitals. It is questionable whether anything would be gained by maintaining this bureau in connection with the Police Department. The high degree of supervising efficiency demanded, the utmost familiarity with the conditions in the various hospitals, the preservation of records, the investigation of complaints, and the preparation of periodical reports showing the work accomplished and the various needs of the system all require the maintenance of an independent branch of the public service, which would be as reliable and as ready to meet every demand for instant aid as the Fire Department.

Second, the number of ambulances should be increased, and in sections of the city that are remote from a public hospital and in which the population is large enough to warrant such relief, ambulance stations should be established. In lieu of the latter, local physicians might be appointed in various parts of the city to respond in case of emergency, and to care for the injured person until the ambulance arrives, or to remove him, if necessary, in a hired vehicle to the hospital. In fact, a system of public compensation for services that might be rendered by any local physician called to the scene, might be devised. These measures would obviate the painful delays and unnecessary scandals associated with the crudity of the present system. The precarious conditions of life in a large city, particularly one like New York, which is continually in a process of transformation, with its congested traffic, uptorn streets and innumerable other dangers, demand that a fair assurance of quick relief be accorded to the citizen who may be injured or suddenly stricken in the street.

Cholera at Manila.—Cholera has appeared in Manila in a sporadic form. One American woman and a man died on August 25. Two privates at Camp McKinley have also died of the disease. The surgeons of the Board of Health anticipate that the appearance of the disease will not have serious results.

ECHOES AND NEWS.

NEW YORK.

Cerebro-Spinal Meningitis.—The report of the contagious diseases in New York last week shows that cerebro-spinal meningitis is still present in the city. There were 14 new cases last week and 15 deaths. This is the time, if ever, while the new cases are so few, that isolation may be effectually practised and an attempt made at minimizing the danger of the recurrence of the disease that otherwise will be sure to take place next winter.

Typhoid Fever Situation.—There were 324 cases of typhoid in Greater New York last week. Of these cases 210 were in Brooklyn, 95 in Manhattan, 12 in the Bronx, 3 in Queens and 4 in Richmond. In the week before last there were 252 cases, of which 150 were in Brooklyn, while three weeks ago there were 259 cases. These figures would seem to indicate a big increase last week, but the Health Board officials say that of the 324 cases reported, 110 were old cases that had not been reported by the physicians, who have been very negligent about the matter. As a matter of fact, most of these 110 cases should be included in the reports of the previous two weeks. That would show that the disease is on the decrease, and this the department officials think is actually so.

Health Department Laboratory.—The fine new laboratory building of the Health Department will be opened and occupied in the very near future. This ornamental building has been in process of construction some time at the foot of East Sixteenth Street. It is attached to the old Willard Parker Hospital for contagious diseases, and simultaneously with its erection, several adjoining buildings have been put up, one a new scarlet fever hospital, and the other an administration building for the executive officers of the contagious disease hospitals, and for the accommodation of physicians and nurses attached to these hospitals. The laboratory is one of the finest municipal institutions of its kind. It is almost axiomatic to say that in all progressive cities it is recognized that the value of a Health Department is its ability to safeguard against contagious and infectious diseases and this is largely dependent on the efficiency of its bacteriological workers. New York City was among the first to establish a bacteriological laboratory. From an insignificant back room with a microscope and some cultures, the institution will be housed in an imposing six-story building. Every floor has been constructed so as to be adapted to research or chemical work. The laboratory is being thoroughly equipped. The chemical laboratory will be moved from its old quarters in the Department of Health Building, at Sixth Avenue and Fifty-fifth Street. Upon the methods of New York City's bacteriological laboratory have been modeled those of many similar laboratories in the United States and other countries. The first impetus given to the establishment of such an institution was in 1892. Cases of cholera had been brought to this port, and there was great public apprehension manifested. Dr. Hermann M. Biggs, the pathologist of the Health Department, urged upon the department the necessity of bacteriological diagnosis as the only certain method of identifying cases of this disease. After doing some singularly successful work in diagnosis of cholera, the laboratory began further investigations. Its facilities were cramped. Housed, as it has been, in a part of an old building at the foot of East Sixteenth Street, it could not undertake too ambitious a program, for want of adequate equipment. Nevertheless, it made great strides in research work. In 1893 it investigated the bacteriology of diphtheria, and adopted methods for the bacteriological diagnosis of that disease. In the next year, it began work upon the bacteriology of tuberculosis, and also established the necessary plant for the production of diphtheria antitoxin. The free treatment of diphtheria in tenement houses, and the free distribution of antitoxin were begun in 1895. The effect of this work was instantaneous. The mortality from diphtheria was greatly reduced. In 1894, the number of deaths from diphtheria per 100,000 of population, in Manhattan and the Bronx, had been 158.4. In 1895, the number went down to 105.2; the next year to 91.2, and yearly has been proportionately going down. For the seven years before the free distribution of antitoxin in diphtheria cases was begun, about 37 per cent. of the cases in Manhattan and the Bronx were fatal; since then the proportion of fatal cases has been less than 11 per cent. The laboratory has also carried on investigations of the bacteriology of typhoid fever, rabies, and dysentery, bubonic plague, and other diseases; and is now, among other work, investigating the bacteriology of cerebrospinal meningitis. The research laboratory has done other important work. It found out from its studies that the virus of smallpox and vaccine could not be of a bacterial nature. It has studied tuberculosis cultures obtained from human beings and cattle. It has made great progress in methods of disinfection. One of its staff devised a machine by which formaldehyde gas could be generated with great rapidity and cheapness. These machines were installed upon the boats and at the ambulance stations of the Health Department. The laboratory prepares its own material for the enormous number of vaccinations the department makes yearly. This branch of the Health Department necessarily has always been in the hands of scientific men, and is not affected by political influences or changes.

PHILADELPHIA.

No New Case of Diphtheria Reported.—The fact that no new case of diphtheria was reported for last Wednesday has created some interest at the Bureau of Health. According to one of the inspectors, such an instance has not occurred in seven years.

To Investigate the Epidemic of Typhoid Fever.—Dr. F. C. Johnson, chief medical officer of the Department of Health, of Philadelphia, has been detailed by Dr. Dixon, Health Commissioner, to investigate the epidemic of enteric fever at Dundaff, Susquehanna County, and to limit its spread.

Antitoxin to Be Distributed Free.—Dr. Dixon, Health Commissioner, has decided to create two stations in each county of the State at which diphtheria antitoxin can be obtained free upon the presentation of a doctor's certificate. This step is regarded by physicians as a very important factor in the reduction of the mortality of this disease.

New Milk Law Necessary.—As the milk law stands at the present time it is necessary to prove that the dealer has personal knowledge that the milk which he is selling is impure; the food and dairy agents have found it very difficult to convict under those conditions and as a result have ceased to work. It is to be hoped that the Council will think it necessary to draw up and pass a bill which will en-

able inspectors to bring the dealers to a wholesome respect for authority.

Smallpox Hospital Destroyed.—The first move to occupy the new smallpox hospital was evinced by the burning of several of the buildings, once a part of the Municipal Hospital. Should more cases of smallpox be received than can be accommodated in the buildings remaining, they will be taken to the new hospital, although not completed. It has been suggested that the new hospital may never be used for the purpose designed, provided that these patients can be housed in temporary sheds, which can be destroyed from time to time.

Fire Destroys Part of the University's Buildings.—As a result of a fire the University of Pennsylvania has sustained a loss of $40,000. The damaged buildings are in such condition, however, that repairs can easily be effected; at first it was thought that the microscopes and other scientific apparatus were destroyed, but investigation showed that the anatomical and surgical preparations which were lost can be replaced without much difficulty. The cause of the fire is not known, but crossed electric wires are thought to have given birth to the flames.

Additional Precautions Against Yellow Fever.—Dr. Henry Heller, of the State Quarantine Board, has adopted a method similar to that instituted by Dr. Quitman Kohnke, health officer of New Orleans, which consists of allowing barrels of stagnant water to stand around the quarantine station, assuming that the mosquitoes on board vessels will make for these to deposit their larvæ on the stagnant rain water. The barrels and their contents can be destroyed from time to time. The quarantine hospital of this city, and all of its beds, are screened so that it is almost impossible for mosquitoes to reach the patients, should they be attracted from the vessels by the stagnant water, thus provided for them.

Sanitary Expert Chosen.—Dr. Samuel Dixon, Health Commissioner, has announced the appointment of F. Herbert Snow as head of the sanitary engineering division of the Department of Health. Mr. Snow is a pioneer in the work of devising sanitary systems of sewage disposal, and Dr. Dixon believes his experience and his knowledge will be of inestimable value to the department in its dealings with municipalities and corporations to prevent and to remedy the pollution of the State water in the most efficient and economic manner. Mr. Snow is a member of the American Society of Civil Engineers, has had twenty-three years' experience, and has served more than fifty municipalities as consulting sanitary engineer. Atlantic City is about to rebuild and extend its drainage system under the plans mapped out by Mr. Snow.

Russell's Vegetable Compound as a Cure for Tuberculosis.—While many of the physicians of this city are sceptical in regards to the curative value of the compound, Dr. J. Solis Cohen has determined to give it a fair trial at the Chestnut Hill Hospital for Consumptives. He has no knowledge of the compound, but he has used Dr. Russell's emulsion of mixed fats extensively, and is able to say with good results. Vegetables are prescribed extensively by all physicians, but the mere fact that they are cooked may make them less efficacious. The *Bulletin*, in an editorial commenting upon the value of the compound, suggests that, owing to the fact that we so often see temporary improvements in patients who have at different times tried the "cures" for consumption, it would perhaps be better to wait longer than six months before expounding its value as a cure.

CHICAGO.

The Chicago Health Department Laboratory.—In his annual message to the City Council, April 10, 1905, Mayor Harrison showed the Health Department Laboratory to be a "money-maker," turning into the city treasury annually from $40,000 to $50,000 more than the cost of its maintenance, and urged upon the Council that some share of this excess, if not every dollar of it, should be used for its further development. The laboratory is more than a "money-maker!" Its value to public health and life in its supervision of food supplies—milk, cream, meats, water, ice, etc.—in its safeguarding against impure vaccine, inert antitoxin and other remedies; in its assistance to physicians in the diagnosis of the contagious and infectious diseases, and in many other ways, cannot be estimated in dollars and cents.

Pharmacists Pass a Resolution for New and Drastic Legislation.—The twenty-sixth annual meeting of the Illinois Pharmaceutical Association was recently held in this city. After a vivid presentation of some of the present evils of the pharmaceutical profession by George P. Engelhardt, Editor of the *Western Druggist*, the following resolution was adopted unanimously: *Resolved*, That we favor such legislation as shall require the proper public officer, in case of death ensuing from disease, or otherwise, under medical attendance when the physician has himself dispensed his own medicine, shall issue the death certificate instead of the attending physician, as now permitted by law. A second resolution was also unanimously adopted. This resolution was as follows: *Resolved*, that we deem the dispensing of pure drugs vital to the life and welfare of pharmacy and therefore approve any and all measures calculated to suppress the adulteration of drugs and medicines, and we most earnestly commend the relentless prosecution by the proper authorities of all druggists and others who shall be guilty of these subversive practices.

Tetanus Successfully Treated.—Dr. John B. Murphy reports the case of an eight-year-old boy who was admitted to the hospital with trismus, some contraction of the neck muscles with opisthotonus, seven days after cutting his foot on a piece of dirty glass. Under anesthesia some glass and pus were found in the foot wound, but cultures did not reveal any tetanus bacilli. The convulsions continued, so that on the following day he was given three full doses of antitetanic serum without effect, the convulsions becoming almost continuous. Two days later 16 c.c. of cloudy cerebrospinal fluid were withdrawn by lumbar puncture, and through the same needle there were injected 3 c.c. of the following solution, sterilized by boiling:

B-eucaine	0.09
Morphine sulphate	0.02
Sodium chloride	0.18
Distilled water	105.00

The patient slept four hours following the injection, and through the night slept one and one-half hours at a time. The spasms became shorter in duration, and there were only eight in the succeeding twenty-four hours. Then 15 c.c. of cerebrospinal fluid were drawn off and 4 c.c. of the above solution injected. Similar injections were made daily for six days, then on alternate days for six days. The spasms gradually ceased, the trismus relaxed and the boy was discharged cured three weeks after ad-

mission, or four weeks from the date of injury. Dr. Murphy considers eucaine much less dangerous than cocaine, and was particularly struck with the muscular relaxation that followed the morphine eucaine injections.

To Aid Insane Consumptives.—It has been decided to fight consumption in the insane asylums of Illinois, and two cottages for the isolation of tuberculous patients are now in the course of construction at the Watertown Hospital. These structures will effectually aid not only in the general care of the 1,200 patients, but in more humane treatment for those who in addition to their mental affliction are victims of the dread disease. The cottages were not provided for in the State appropriation, but this additional building was made possible by the economical expenditure of the general funds of the institution, it is said. One of the two cottages will be for male patients and the other for female. While the proportion of the tuberculous patients in insane hospitals is not high, the white plague is manifest sufficiently to warrant precautionary steps for the isolation of the disease. Every modern preventive and aid will be employed at the Watertown institution. The buildings will be well ventilated and absolutely sanitary. On all sides of each cottage will be a broad porch. Sections of the porches will be screened off so that the sufferers may sleep in the open air and gain the benefit of outdoor life. For sleeping outdoors in winter, provision will be made for tempering the extreme cold. A room fitted up in tiling will be used for spraying patients, and through the use of a huge atomizer the air will be impregnated with the fumes of Norway pines. Part of the porch will be enclosed with glass to gain the violet light which has proved an aid in the treatment of tuberculosis. A tent colony will be provided. Large yards will surround the cottages and provision will be made for six to ten tents in each. The amusement hall now being built at Watertown has dimensions 100 by 300 feet and is capable of seating 1,200 people, the present population of the patients. It will have four bowling alleys, billiard and pool tables, a swimming pool and a platform eighty feet wide. There will be a wide area within for general amusements for the patients. This hall is to be a retreat for the patients in stormy weather and entire wards will be entertained at one time.

Poisons and Druggists.—More care and discrimination in the sale of poisons and harmful drugs are necessary in this city. At present the conditions governing the drug traffic are notoriously lax since it is possible for a child to purchase morphine or cocaine wherever a druggist is unscrupulous enough to sell it can be found. To the discredit of the pharmaceutical profession it must be said that too many of these unscrupulous druggists abound. Realizing the need for maintaining public confidence in the profession, the Illinois Pharmaceutical Association is beginning a campaign for the passage of a law that will make the order of a responsible physician virtually necessary before harmful drugs can be purchased. This law, if effectually enforced, will undoubtedly serve to keep many people from obtaining drugs they had better be without. But if the druggists would but see and acknowledge the fact they have in their own hands the power to do much to remedy the drug evil in Chicago. The *Chicago Daily Tribune* in commenting on this proposed law editorially remarks that: "It depends on a druggist whether a man, woman, or child can buy harmful drugs of him. In the better class of drug stores at present it is impossible to buy poisons without a physican's order. The reason why it is impossible to buy them at all without such an order is that all druggists have not the same high code of business morals. The remedy is obvious. The druggists must elevate the standard of their profession. So long as there are druggists who will take the drug-fiend's money, so long will the drug evil exist. When no druggist sells drugs except on a carefully investigated order it will cease. By adhering themselves strictly to the first principles of humanity and decency, by exposing those who are guilty of improper drug selling, and by prosecuting them with a relentlessness that will affect reform or drive them out of the business, the better class of druggists will more quickly and more effectively rid their profession of an odium and the public of a menace to health than by working for the passage of laws whose efficacy depends upon the manner in which the municipal authorities enforce them. A more stringent law is needed, but that alone will not suffice."

GENERAL.

Bubonic Plague in Panama.—A fatal case of bubonic plague in Panama was reported to the State Department Monday last. Some months ago one death by bubonic plague was reported from the Isthmus.

The American Roentgen Ray Society.—The sixth annual meeting of the American Roentgen Ray Society will be held at Johns Hopkins Hospital, Baltimore, September 28, 29 and 30. The Stafford Hotel has been selected as headquarters. The program includes foreign as well as American workers in this special department of medicine. All regular practitioners are eligible to membership, and are invited to attend the scientific sessions and view the exhibition of apparatus. Further information can be obtained from Dr. Russell H. Boggs, Secretary, Empire Building, Pittsburg, Pa

Mississippi Valley Medical Association.—At the next meeting of the Association, to be held at Indianapolis, Ind., October 10, 11, 12, the annual addresses will be delivered by Dr. Arthur R. Edwards, of Chicago, and Dr. W. D. Haggard, of Nashville, Tenn Dr. Edwards has chosen for the subject of his address, "Certain Phases of Uremia; Their Diagnosis and Treatment," and Dr. Haggard will discuss in his address, "The Present Status of Surgery of the Stomach." In addition to these addresses there will be the annual address of the President, Dr. Bransford Lewis, of St. Louis. A cordial invitation is extended to every physician in the valley to attend this meeting, for which a large number of interesting and valuable papers have been promised.

Lectures on Inebriety.—Dr. T. D. Crothers, of Hartford, Conn., Superintendent Walnut Lodge Hospital, has accepted an invitation to deliver the first oration in the Norman Kerr memorial lectureship, at London, Eng., October 10, 1905. Dr. Kerr will be remembered as an eminent London physician who has made a special study of inebriety, alcoholism and other drug disorders. He has written several excellent books on this subject, and has been instrumental in securing the enactment of laws for the control of inebriates and the promotion of hospitals for their care throughout Great Britain. He founded the British Society for the Study of Inebriety, in 1884, and this society and his friends have organized

a memorial lectureship for yearly orations on his life and work.

Tropical Medicine School.—Sir Patrick Manson, medical adviser to the British Colonial Office, in a speech before the board of directors of the Merchants' Association of San Francisco, outlined his theory that yellow fever may yet become a source of worriment there in the changed trade conditions which will follow the completion of the Panama Canal. He urged the futility of what now passes as quarantine either in yellow fever or the bubonic plague. Owing to the advantages that San Francisco possesses over London for the study of tropical diseases, an advantage due to the fact that it has a colony of ten thousand Chinese as well as many Japanese, Filipinos and Hawaiians, he suggested that a school should be established here for the study of tropical medicine. Sir Patrick is in San Francisco giving the Lane Lectures this year.

Cholera in East Prussia.—The official *Reichs-Anzeiger* of Monday last said that since August 16 seven cholera cases, three of which were fatal, have occurred in the Weichsel District, East Prussia. Traffic from Weichsel has been placed under medical and police control. Dispatches from Danzig say that the cholera bacillus appears to have spread further than the health authorities on Saturday supposed possible. A raftsman has died of supposed cholera, in the hospital at Bromberg, and two laborers of Fordon who drank of Weichsel River water suddenly became ill. One of them died later, supposedly of cholera. Three rivermen from Galicia have been attacked, presumably by cholera, at Graudenz. Apprehension is felt at Thorn and Bromberg and in the small river-towns, from the Russian frontier to Danzig, although nothing like a panic can be said to exist. The medical authorities are tightening their dictatorship, multiplying the stations along the river to prevent bathing or the use of water in any form, examining searchingly every person complaining of the least illness, and are urging upon all families within the district to use the recognized precautions. These measures have been effective enough so far as Prussian territory is concerned, but the physicians ask each other what is taking place beyond the frontier boundary stones. The water of the River Weichsel flowing out of Russia is contaminated, but no one knows whether few or many cases of cholera exist up the stream, or whether proper precautions are being taken. The situation in East Prussia is compared with that of the United States and Cuba in the case of yellow fever epidemics, but instead of a wide ocean channel flowing between Russia and Prussia, the latter's territory is conterminous, and Prussia is powerless to enforce sanitation over the border.

Thomas Wilson Sanitarium, Baltimore.—The difficulty in establishing the use of cows' milk for infant feeding among the poorer people of the large cities is due to their inability to obtain a supply of good milk at a reasonable price and the trouble of keeping it fresh in their homes. It is a disgraceful fact that much of the milk bought by the poor is inferior in quality, lacks in freshness, is full of dirt and micro-organisms and contains chemical preservations. What the Nathan Straus Pasteurized milk depots are doing for the New York babies is being done for the babies of Baltimore by the milk dispensary of the Thomas Wilson Sanitarium, writes *Charities*. They are now entering upon the tenth month of the second summer of their service, and the results have been exceedingly gratifying. The dispensaries will be maintained throughout the coming year. All the milk is Pasteurized during the warm weather, and it, therefore, keeps sweet for twenty-four hours, even where there is no refrigeration in the homes. The milk is produced at the Burnside Farm, bottled at the Walker-Gordon Laboratory, and contains less than 5,000 bacteria to the cubic centimeter when delivered to the various stations. There are at present five of these milk depots for dispensing at a minimum charge (somewhat less than actual cost) several modifications of milk, suitable for infants during their first year. The charge for a day's feeding for each of the modifications—five to eight bottles, according to the age of the child—is ten cents, payable daily on delivery at the station. This milk is not only for those infants who are already sick or ailing, but it is also, and quite as much, intended for any children whose circumstances prevent their securing a proper diet. An experienced nurse is in charge of each station, and wherever possible she keeps a record of the baby's weight and condition, and where it is desired she will visit regularly in the homes. The first summer five hundred babies received milk through this charity, and the results have been exceedingly gratifying. But four children on the rolls were lost during the winter —three of these from pneumonia and one phthisis. The Thomas Wilson Sanitarium has for many years been maintained each summer at Mount Wilson, on the Western Maryland Railroad, ten miles from Baltimore, where the children of the poor suffering from intestinal disorders have been treated. This year the sanitarium opened June 6, and will continue through August.

Fever Situation in the South.—The yellow fever has apparently improved in New Orleans, while the disease is reported to be gaining renewed energy in Louisiana outside New Orleans. The present total number of cases that has occurred in New Orleans is about 1,700, the number of deaths being about 230. In the city of New Orleans new foci are less numerous, but none the less evident. Surgeon White, Chairman Janvier, of the Citizens' Committee; Dr. Beverly Warner, in charge of the ward superintendents, and Dr. Souchon, President of the State Board of Health, went to Baton Rouge last week for a conference with Governor Blanchard. The trip was made at the suggestion of the Governor, who desired to know at first hand the exact status of all departments of the work. Since the beginning of the yellow fever, the Governor has been unable to put foot in New Orleans. Quarantine has penned him up in Baton Rouge, and he has been compelled to confine himself to telegraphic and telephonic communication. A feature of the situation that is attracting attention is the fact that what are termed centers of infection now exceed the number of cases under treatment. It is an encouraging feature because it is an indication of a slow extension of the fever, which is particularly true of the quarter above Canal Street. It is hoped soon to reduce the number of disease centers. Ordinarily, it would be assumed that a center would become extinct in twenty days, the length of time within which the *Stegomyia* should furnish fresh cases in any neighborhood which has been infected. In order to take no chances, health officers will not cancel any disease centers until thirty days have elapsed. Large quantities of rock salt have been purchased by the Federal authorities with a view to salting stagnant gutters and pools. The salt is intended to destroy the pools as breeding places for mosquitoes. A freshly infected spot in St. Bernard parish was announced last Wednesday. It is at Terre aux Boeufs, the parish seat. Health Officer Meraux found five genuine cases and three that were suspicious. The town and its vicinity were invaded

by Italians after the fever appeared at New Orleans. In Leeville, near the mouth of Bayou Lafourche, nearly two-thirds of a settlement of three hundred persons have been infected and several deaths have taken place. Dr. Devron is the only physician there, and his difficulties are increased by the fact that the settlement lies on two banks of a rather wide stream. Assistance is being asked by other points in the matter of physicians and nurses. There is a steady increase of disease in Hanson City. In St. Charles parish the infection is increasing and is beyond the control of the force thus far sent there.

Hospital for Constantinople.—In the city of Constantinople, writes the *Evening Post*, with 1,250,000 inhabitants and surrounded by a district containing a population of 24,000,000, the trained nurse is practically unknown. Nor do the native physicians practise surgery, as the consequences of a case that ends fatally are too unattractive for a doctor to take the chances. The American Hospital and Training School for Nurses, in Constantinople, is endeavoring to awaken the city to the necessity of caring for the sick scientifically. Dr. Thomas Spees Carrington, the physician in charge, received recently from John G. A. Leishman, United States Minister to Turkey, a letter indicating the high opinion of the movement entertained in American circles there. Mr. Leishman said: "I am very glad to learn by your letter of July 18 that you have made substantial progress in your efforts to establish an American hospital and training school for nurses in Constantinople. An 'up-to-date' American hospital will prove a boon here, and I am sure that all your friends will welcome your return to Turkey as chief of the hospital staff; and I am quite of the opinion that no greater humanitarian or philanthropic enterprise could be undertaken than the establishment of a training school for nurses, as the customs of the country render the nurse in most cases a more important factor in the family than the doctor, and while there are many doctors, a nurse of any kind is rare and a good one almost impossible to find. The only criticism I venture to offer is that I think you are starting out upon too modest a basis, as an institution of the kind mentioned should, in my opinion, be placed at the beginning upon a good solid basis, not only with enough money to erect and equip the necessary building, but also with a sufficient endowment to guarantee its proper conduct." To foreign residents, as well as the natives, is the training of nurses in the city a matter of vital concern, and the school has among its trustees men whose names guarantee its sincerity of purpose. They include William Ives Washburn, of New York, president of the institution; Dr. Henry O Dwight, missionary and author; Edwin H. Baker, junior partner of the New York firm of Bliss, Fabyan & Co.; the Rev. Dr. Charles H. Richards, secretary of the Congregational Church Building Society; John Beverley Robinson, and Dunham Wheeler, the New York architects, and Ernest Hamlin Abbott, associate editor of the *Outlook*. Checks sent as gifts to the hospital and training school should be made payable to Brown Brothers & Co., bankers, No. 59 Wall Street, New York.

The Modern Juggernaut—The *Railway Gazette*, writes the *New York Times*, tabulates twenty-three collisions of railway trains and twenty-five derailments during July. There was no notable disaster, yet there was an average of a death every day in a month, which compares favorably with its predecessors. One collision was caused by a train being ahead of time. A misplaced switch threw one train into another, and many deaths were averted only by the chance that a "dead" locomotive took up the shock. Many will compare these figures with the annual reports in England and the United States, which have just appeared simultaneously, and with the mortality of battles. According to the Inter-State Commerce Commission, more were killed and injured on railways last year than at Gettysburg or Mukden. The fatality ratio of passengers to accidents was 100 times higher here than in England. We have seventeen times more employees and 600 times more casualties among employees. In England yast year the collisions and derailments totaled 217, which happened to be the precise average for twenty-four years. Last month there were forty-eight collisions and derailments, and there will be over 600 this year in the United States. We have more miles of road, and more trains, to be sure, but the disproportion is not creditable. We would not minimize the facts. They speak for themselves. Americans think there are too many such occurrences in the United States, while the English are well satisfied with their record. Something may therefore be said about the comparison. Most of the English facts are taken from a report by Consul Mabin, at Nottingham. He accepts the official Board of Trade figures without examining or criticizing them. It is hard to find fault with him for that, but we find in *The Press*' London letter an analysis of the figures more to our liking. It seems that in 1901 one person was killed to each eighteen miles of track in England, and one to each eighty-four miles in the United States. One was killed to each 924,000 passengers on British railways, and one to each 2,129,382 on American. Moreover, the figures in England are treated to a process rather putting our own able Mr. Holmes to shame as a manipulator. It seems that the facts are first made up in a "preliminary return," which is not published. This return for 1904 showed 1,158 deaths and 18,749 injuries. But the returns as published show six passengers "killed through train accidents." This is the basis of Consul Mabin's statement that the deaths were 1 in 199,758,000 journeys. But there were 109 other deaths of passengers, nevertheless. No less than thirty-three lost their lives through an accident impossible on American railways. That number, 1 in each 39,000,000, fell out of compartment doors. They were killed all right, but they were not killed in "train accidents." The report told the exact truth, but it is as misleading as diplomatic reports, which are so phrased as to deceive without enabling the diplomat to be called a liar. For some obscure reason the British reports do not include commuters. Upon the average of thirty years British railways kill twenty-three passengers yearly. It is a shameful comparison with the American record, but then our figures include commuters. It would almost seem as though our accident statistics were made up by yellow journals for purposes of their own and as though British statistics were made up by and for British railways, also purposes of their own. For our own part, and with this opinion the Medical News most emphatically coincides, we think too many are killed in either country. We have not the slightest tolerance for grade-crossing horrors, nor for overworking single-track systems, nor for parsimony productive of inferior apparatus or employees. We think any comparison unfair under conditions so different as between England and the United States, or as between our own older and more thickly settled communities and our crude railway enterprises in the West. We cannot believe that our apparatus and administration are inferior upon any fair comparison,

and we should not shrink from placing equally truthful figures side by side. We do not question the good faith in which the British figures are compiled or presented to us, but it would seem that the methods are so different that unwarranted conclusions are suggested. Our figures are dreadful, but not so dreadful as they seem. The British figures lull into a false security. The great crime is in the killing. It boots little what the percentage per mile is.

SPECIAL ARTICLE.

BYWAYS OF MEDICAL LITERATURE.—XXV.

MEDICINE AND MEN OF LETTERS.

It is a curious fact, writes the *British Medical Journal*, that great writers, speaking generally, have been no lovers of the medical profession. This is doubtless the reason why doctors for the most part cut so sorry a figure in literature. Scribes of all sorts take a special pleasure in girding at them. Shakespeare, indeed, used them gently, as though he loved them. Although the medicine of his time was a tempting subject for the satirist, his large mind saw the nobility of its aim, which to less penetrating and sympathetic eyes was disguised by the poverty of its outward apparel, and divined the possibilities of development that lay hidden in the mass of error and superstition of which it mainly consisted. But Petrarch wrote treatises against medicine and its professors; Montaigne laughed at them; Molière put them on the stage as fixed figures for the scorn of time to point its finger at; Rousseau vilified them; Voltaire is the author of the famous saying that the healing art consists in pouring drugs of which the physician knows little into a body of which he knows less; and Carlyle said he might as well confide his sufferings to the hairy ear of a jackass as to that of a physician.

Is this attitude of mind due to intellectual superiority or simply to the conceit and egotism which are pretty constant ingredients in the composition of genius? To the doctor all men are equal; they are simply cases, and the case of a costermonger may be more interesting than that of a poet or a philosopher. Yet philosophers and poets probably think that their ailments should be treated as exceptional because they who suffer from them are exceptional persons. Flaubert—himself, by the way, the son of a distinguished surgeon—is said to have hated doctors because they treated him as a *bourgeois*.

It is, indeed, the literary people who are largely responsible for the distrust of the medical art that so many persons who, in Beatrice's phrase, "profess apprehension," pretend to feel. Whether he be moved, like Molière, by resentment at the failure of medicine in his own case, or like Swift, by fierce indignation which tears his heart, or like Carlyle, by what the old physicians called "black bile," the writer speaks *urbi et orbi;* the doctor in his secret ministry has only the few anxious watchers by the sick bed for an audience. The contest being conducted on terms so unequal, what wonder is it that the doctor gets the worst of it?

We have lately come across a passage in the *Journal Intime* of Frédéric Amiel, in which the Genevan professor of esthetics and philosophy admired of Matthew Arnold and so many other superior persons, expresses his views on doctors. "Why," he asks, "do doctors too often give bad advice?" His reply to his own question is that it is because they do not sufficiently individualize their diagnosis and their treatment. "They class all their patients in an allotted drawer of their nosology, and yet every patient is a *hapax*" [in grammatical terminology a ἅπαξ λεγόμενον is a word or a construction of which there is only a single example.] How, he goes on to say, can so rough a sifting lead to judicious treatment? "Every disease is a factor simple or complex multiplied by a factor which is always complex, namely, the individual who is the subject of it, so that the result is a special problem, always requiring a special solution, especially the further removed one is from childhood and from rustic life." To us, of course, all this is the merest commonplace, but Amiel gives forth his platitudes as if he were Sir Oracle proclaiming a new gospel. He goes on to say that the chief fault he has to find with doctors is that they disregard the true problem "which is to grasp in his unity the individual who needs their care." Their methods of investigation are, he complains, much too elementary; "a physician who does not read one to the bottom does not know the essential." A doctor after his heart should have a profound knowledge of the life and the soul, divining intuitively a disorder or suffering of any part of the being, and restoring peace by his mere presence. Such a doctor, we are assured, is possible, but most practitioners lack the higher and inner life; they know nothing of the transcendental laboratories of nature To Amiel's mind they are "superficial, profane, strangers to the divine, destitute of intuition and of sympathy." He concludes that the model physician should be at once a genius, a saint, and a man of God.

All these noble sentiments and fine language translated into common speech mean nothing more than that Amiel had been treated by his doctor as a man of mould like other folk; he doubtless gave the sensitive philosopher mere vulgar pills and potions, whereas he should have seen by intuiton that there was a disorder of the finer feelings, for which more ethereal medication was indicated.

We hold strongly that there is in the practice of medicine, in the highest sense, much more than pills and potions, more even than the wisest physical therapeusis. We quite agree that the practitioner will find much to learn in the transcendental laboratories of nature; to him more than to any other, nothing human must be foreign. It often falls within his province to treat the spiritual or mental condition of his patient. But he must not on that account neglect the humbler, but equally essential, part of his art. If in trying to influence the soul he forgets to treat the body, he will find himself in the position of the astronomer who, in gazing at the sky, fell into a ditch. If all doctors are to be geniuses, there will be no ground for further complaints as to the overcrowding of the profession. But will the last state of sufferers from disease be better than the first? It would assuredly be well if all doctors were saints and men of God, but genius is as much out of place in the sick room as Sir Frederick Treves holds it to be in the operating theater. Genius is of its very nature soaring and cares nothing for the small things that make up the greater part of human life and that are of such infinite importance to the sick. On the other hand, medicine, which, unlike the law, must concern itself about the least, is patient, plodding, and pedestrian. Genius practising medicine would be like Pegasus between the shafts of a milkcart.

CIGARETTES.

In De Quincey's essay on "Murder as a Fine Art," it will be remembered, it is pointed out that a murderer is likely to descend to almost any depths of criminality. Let him overindulge his desire to kill people and soon he finds himself tempted to commit robbery. From robbery he descends to drinking and Sabbath-breaking, and in time he becomes a victim to incivility and procrastina-

tion. So far almost any one is sure to agree with De Quincey. The Indiana Legislature, however, has imagined a blacker depth into which your skilful murderer might, unless checked by law, descend. He might become a cigarette smoker. It is no news, of course, to say that one may not smoke cigarettes in that State without breaking the law. What may prove of interest are scraps of evidence from the heap piled up before the lawmakers to hasten the passage of the law. Judge Stubbs of the Indianapolis juvenile court read a paper on "The Evils of the Cigarette" before a recent meeting of the Indiana State Teachers' Association which throws De Quincey's conceit far into the background as a real thriller. He wrote after an experience of twenty months on the bench of the juvenile court. "In that time," he said, "I have had before me 1,208 boys and girls—mostly boys—all of whom have been charged with offenses against the law. These charges have covered the entire list of offenses known to the law in Indiana from the most trivial misdemeanor to the greatest of crimes, including petit larceny, grand larceny, housebreaking, burglary, arson, forgery, assault and battery with intent to kill, assault upon girls with criminal intent, manslaughter, murder, and that other nameless crime for which negroes have so often been burned alive in some of the Southern States.

"In inquiring into the causes that have brought about such a great increase in the number of offenses against the law in the last few years by boys, I have reached the conclusion that, aside from the frailties and weaknesses that afflict our common humanity, and which are likely to blossom and develop into crime, especially where there is a lack of parental control, or where the parents themselves belong to the ignorant or vicious classes, by far the most potent factor is the cigarette habit."

It is a grave charge to bring against the cigarette, but the judge seems to have had no trouble in supporting it with plenty of evidence outside his own courtroom. In the campaign against the "coffin nail" the teachers in the lower schools "from Michigan to Georgia, and from New England to California" were appealed to for testimony. The speaker singled out the reply of a young woman teacher in an Indiana high school as representative. She wrote that the boy who is a victim to the cigarette habit "is frequently late and irregular in his attendance. He is restless. . . . He does not like to study, and by and by he comes to the place where he tells the truth when he says that he cannot study. His moral sense becomes perverted. . . . His moral standard is low in all respects. He will turn the most lofty sentiment in literature to vulgarity. . . . He is slouchy in his manner, his clothing, and his talk." There were other letters heaped upon the mass, and the judge went down into the records of his own court to bring forth the tottering, shaky specimens of cigarette-damned youth. As a final clarion call to the teachers to save Indiana from the terrible curse, some of Judge Stubb's closing sentences should be preserved and pasted into De Quincey's essay: "Something must be done to save the youth of our land. . . Some of us who are yet living have stood on the red line of battle at a time when it seemed to us that the whole world was filled with horror and despair, but now the wildflowers bloom in peace on the bloody field and above the crushed skeleton. Peace and prosperity now reign where once the bursting shells and rattling musketry carried death and destruction to friend and foe. But for moral degradation there is no reviving spring. Let the boys of our country become corrupted and their manliness destroyed, the hope of the nation poisoned at its fountain head, and the abomination of desolation spoken of by Daniel will be upon us."

SIR RICHARD OWEN.

In Sir Mountstuart Grant Duff's *Notes from a Diary 1886-8*, there is frequent mention of Sir Richard Owen. Once the famous anatomist told him what a happy use he had made of one of Milton's sonnets. He became a member of that highly select body "The Club" much earlier than most of the few who are chosen for admission because Johnson had expressed a wish that one member should be a physiologist. Hardly had he been elected when he was placed in a great difficulty. The opinion of the Club was asked as to whether a representation of Cromwell should be introduced in the new Houses of Parliament. Various views were expressed, when Lord Aberdeen, who was Chairman, said, "Well, we'll take a vote, and we'll begin with the youngest member." Owen extricated himself from an embarrassing position by saying, "Whatever we may do, we cannot raise for Cromwell a monument at all equal to one he has got already." The other members looked surprised, and he was asked to what he alluded, whereupon he quoted Milton's sonnet. The old man added that he was never so well repaid for learning a piece of poetry by heart. The moral is obvious, but we may be allowed to express a slight feeling of surprise that no one in a body, which is nothing if not literary, should have understood the allusion. On another occasion the diarist found Owen reading a volume of English letters, the frontispiece of which was a portrait of the Countess of Suffolk. Speaking of his memory, he said he found a difficulty sometimes in remembering ordinary names, but none with the pentasyllabic or hexasyllabic names of extinct monsters. Only that morning he had finished a paper for the Royal Society upon one of these—a creature of the crocodile kind, but without teeth—sent to him from Lord Howe's islands. Asked as to the personal appearance of Buckle, the author of the *History of Civilization*, Owen startled his questioner by answering, "Like a young Gibbon," an expression which, coming from the lips of the great zoologist, seemed to imply a resemblance to our quadrumanous relative. Owen, however, explained that he meant the historian. At another visit very near the end of Owen's life, he mentioned a curious instance of heredity in his own family. His grandson, then an undergraduate at Cavendish College, Cambridge, had developed so remarkable a turn for playing the organ that the authorities were able to dispense with the services of a regular organist. Professor Owen's mother was for several years organist at Ormskirk Church, and her father again was long organist at Lancaster. Their name was Parrin, and they came of ancestors who took refuge in England after the Revocation of the Edict of Nantes.

THOREAU, THE OPEN-AIR CULT AND TUBERCULOSIS.

Perhaps no American philosopher cultivated the open-air cult with greater zeal than Thoreau, who even went so far as to get into trouble by relapsing, as W. W. Godding remarks (*American Psychologic Journal*, 1883), into a state of nature on the shores of Walden Pond, yet Thoreau died at quite an early age from tuberculosis. Thoreau's early death, according to Elbert Hubbard, "was (Little Journeys, December, 1904) the direct result of his invariable and reckless lack of common prudence.

That which made him live in the literary way curtailed his years. The man was improperly and imperfectly nourished, physically. Men who live alone do not cook any more than they have to. Men and women both cook for emulation. Thoreau was such a pronounced individualist that he cared for no one but himself, and he cared for himself not at all. It is wife, children, and home that teach a man prudence and make him bank

against the storm. 'At Walden, no one bothered me but the State,' said Thoreau. If Thoreau had had a family and treated his household as he treated himself, that scorned thing, the State, would have stepped in and sent him to the workhouse and his children to the Home for the Friendless. If he had treated dumb animals as he treated himself, the Society for the Prevention of Cruelty to Animals would have interfered. The absence of social ties and of all responsibilities fixed in his peculiar temperament an indifference to hunger, heat, cold, wet, damp, and all bodily discomfort that classes the man with the flagellants. He tells of whole days when he ate nothing but berries and drank only cold water; at other times, of how he walked all day in a soaking rain, and went to bed at night, supperless, under a pine tree. Emerson records the fact that on long tramps Thoreau would carry only a chunk of plum-cake for food, because it was rich and contained condensed nutriment. A few years of plum-cake, cold mince pie, and continual wet feet will put the petard under even the stoutest constitution. During his shanty life Thoreau was imperfectly nourished, and for the victim of malassimilation, tuberculosis hunts and needs no spy-glass. In childhood Thoreau was frail and weak. Outdoor life gradually developed on his slight frame splendid strength to do and endure. He could outrun, outrow, outwalk any of his townsmen. In him developed the confidence of the athlete—the confidence of the athlete who dies young. Thoreau was an athlete, and he died as the athlete dieth. Irregular diet and continued exposure did their work—the vital powers became reduced, the man 'caught cold,' bronchitis followed, and the tuberculæ laughed."

The culture medium here portrayed is an excellent one for tubercle bacilli to infect, but the origin of the bacilli is, from the ordinary Lives of Thoreau, not so clear. One of the great philanthropic agencies of the day was the "underground railroad," which conveyed fugitive slaves from the United States to Canada. Many of these contracted tuberculosis on the way from the South, and infected their hosts at the various "stations" on the "railroad." Thoreau was an active agent, and his home was a "station." It is hardly surprising, therefore, that he should have contracted tuberculosis from the slaves he aided, since other than in the Latin countries very little attention was paid to infection by sputum, despite the fact that in Scotland and in the Irish school of physicians, influenced by it, consumption was as early as 1722 regarded as an infection. Many of the precautions urged now were carried out in Italy sixty years ago. The great development of tuberculosis among negroes since the war, under the unfavorable conditions of self-protection, indicates the dangers to which the agents of the underground railroad were exposed by their charges. The slight frame of Thoreau hints at the inheritance of the paratuberculosis defects pointed out by de Giovanni, who found that particular nervous states existed in the descendants of the tuberculous, whom he (*Bulletin Méd.*, 1887) divides into erethists, torpids, and energetics. There is usually a diminutive heart, whose right ventricle has comparatively exaggerated dimensions, while the arteries have lessened caliber. The victim of the torpid type is usually coarse-featured and coarse-skinned, with peculiarly unstable mentality; slowness of comprehension is combined with power of continuity of thought; at times mental apathy alternates with quickness of perception. Decided exaggeration of the lymphatic system with deficient functionation occurs, resulting in fitting a soil for germs. In other respects the torpid resembles the second type, the erethistic or nervously fussy type. This is generally characterized by the presence of a clear complexion, a fine skin, and features well cut and often beautiful. The lips are red and the teeth pearly white, though liable to early decay. The eyes are large and full, the pupil being widely dilated, and the white of the eye beautifully clear. The eyelashes are long, curved and silky, and the blue veins show distinctly through the clear, thin skin. The bones are light, the hands and feet well formed, the stature often tall, and the whole figure slightly and gracefully built. The erethists generally remain spare, and have a strong dislike to fatty food. They are vivacious and excitable, and the intellectual faculties are often highly developed. At an early age they show marvelous activity. The regularity with which such precocious tuberculous children die has given rise to the proverb anent exceptionally clever children that they are "too wise to live long." Wanting in stamina, they are incapable of prolonged exertion either of mind or body, and break down under conditions which would not prove injurious to the healthy. They are continually taking "cold," and are prone throughout life to affections of an inflammatory character. Multiple and frequent pregnancies occur. The children, deficient in vitality, are carried off in numbers during infancy by convulsions, brain fever, water on the brain, exhaustion, diarrhea, teething and other ailments, or succumb at the second dentition or at puberty. A small proportion reach maturity. Few live beyond thirty-five or forty years of age. However brilliant intellectually, they are equally emotional, impressionable and impulsive. There is a marked absence of mental stability. They are suspiciously capricious. The great secreting and eliminating glands frequently undergo perversions.

Both these types were peculiarly frequent in New England. The paternal ancestors of Thoreau came from the Island of Jersey; the maternal were of Puritan stock. The erethistic type appears in Thoreau's suspicional zoophilism, which led him, as his lately published journals show (*Atlantic Monthly*, January, 1905), to prefer the society of a woodchuck to his friends.

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held April 12, 1905.

The President, Harlow Brooks, M.D., in the Chair.

Demonstration of a Case of Hydatid Cysts of the Liver.—Dr. J. E. Welch demonstrated a case of hydatid cysts of the liver. The subject from whom the specimen was taken was a native of Switzerland, forty-nine years of age. It was not known how long he had been in this country. He had been admitted to Bellevue Hospital on March 6. The family history was negative except that his brother had tuberculosis. He had been in the habit of drinking about five or six glasses of whisky daily and as much beer, but was not a drunkard. His personal history showed that he had none of the ordinary diseases of childhood. He had had pneumonia about ten years before and since that time had had a cough. Eight years ago he had an attack of rheumatism, which was repeated the following year. For five months before admission he had been coughing constantly, and raising mucopurulent sputum, which was never blood tinged. Three days before admission he had a sudden sharp pain in the right axillary region, followed by chilly sensations, but no distinct chill. Physical examination showed a well-developed, fairly well-nourished man. The action of the heart was weak

There were no murmurs. The right chest showed hydropneumothorax. The urine had a specific gravity of 1.024 and was negative. The sputum contained many tubercle bacilli. The temperature ranged from 98° to 103° F. for the first two days; on the following three days, which included the day of death, it ranged from 96° to 101° F. The pulse ran from 96 to 140. At autopsy the right pleural cavity contained two liters of purulent fluid and air. The right lung was compressed to a mass about the size of the hand. The left lung was consolidated and contained many small tuberculous cavities. There was general congestion throughout the abdominal organs. The left lobe of the liver was represented by a narrow margin of shriveled tissue. Sections showed that the right lobe was congested and fatty. In the left lobe there was a cavity, eight cm. in diameter, having a thick fibrous wall, which contained a large echinococcus cyst. The cyst wall was folded upon itself on account of the confined space. There was no fluid present. No scolices were found. The diagnosis was made by the outer laminated and inner granular layers of the wall as seen under the microscope. The liver and a portion of the cyst wall were exhibited before the Society.

A Case of Eclampsia with Rupture of the Diaphragm and Stomach.—Dr. Welch also reported this case. No details of the clinical history were given. The patient was a woman twenty years of age. She was delivered at the hospital and two or three days after was taken with eclamptic seizure. She had several seizures, one after the other, in rapid succession, for two or three days, and finally died in a convulsion. At autopsy the body showed a slight diffuse jaundice. The pericardium had several small punctate hemorrhages. There were small hemorrhages in both lungs. The liver was slightly increased in size and yellow in color. All the other organs were congested. Sections of the liver showed yellow areas, some fused, but for the most part markings were irregular streaks of yellow. The central veins were somewhat dilated. There was general disintegration of the liver cells. In the cells were large deposits of fat, some in the shape of large globules. The kidney showed extensive parenchymatous change. There were two ruptures in the diaphragm on the right side, one around the left margin of the esophagus, which admitted the passage of three fingers, the other about two inches to the left of the esophagus. Here the muscle fibers were separated so far as to admit the passage of three fingers. The stomach was ruptured in three places along the lesser curvature, and the contents had been forced through the diaphragm. There were about 500 c.c. in the left pleural cavity and 200 c.c. about the spleen. The contents were sterile, contained blood, and gave an acid reaction. The rupture was evidently very recent, as there was no inflammatory reaction in the peritoneum or pleura. Sections of the liver and kidneys were shown.

Dr. Harlow Brooks, in the discussion, said that so far as he knew this was the first case reported in this country of rupture of the diaphragm from eclampsia. He had been led to believe that it was very rare.

Pronounced General Osteoporosis.—Dr. E. S. McSweeny reported a case of osteoporosis. The entire skeleton was exhibited. It was that of a fairly well-nourished woman, forty years of age, five feet seven inches tall. Its weight was about seven pounds. The bones had first attracted attention in the dissecting room two months after death, so that there was no record of their more recent state, nor could any history of the case be obtained, other than that the patient had died of pneumonia. Some of the vertebræ being the merest shells of compact bone tissue were almost completely destroyed in handling. As a whole, the skeleton showed very little change in gross outline, except a moderate cervicodorsal kyphosis. There were no fractures, ankyloses, or similar lesions. The individual bones without exception showed very considerable loss of substance, chiefly of the cancellous tissue. The compact tissue was defective here and there, evidently from an extension of the process. The skull vault was almost sieve-like; the scapulæ hardly thicker than heavy paper and extraordinarily translucent; while in the long bones the shafts were chiefly affected. On looking over the very meager literature bearing on such conditions, Dr. McSweeny had found but few cases reported. In these changes were mostly local and not so extensive as seen in the specimen shown. As a general process osteoporosis was evidently rare and usually ascribed to senility or osteomalacia. The skeleton exhibited showed none of the characteristic senile changes, and the age of the woman excluded such a possibility. Distortions of the bone were more characteristic of osteomalacia than of osteoporosis, whereas in the present instance the reverse was true. The case was interesting surgically in that so extensive a lesion could exist in a woman of this class without the occurrence of a single fracture and with so little deformity. She had probably had to make her own living and, judging from the fact that she had been committed to the workhouse, had led a rather hard life.

Dr. P. W. Nathan, in the discussion, said that it was difficult to say much about the case, since there was no history. The condition of the ribs and the spine and the condition of the neck of one femur reminded one of cases of osteomalacia. There had been cases of osteomalacia reported where the disease came on very suddenly and might involve the skeleton like this in a short time. Osteoporosis is not a disease as such; it is associated with many disorders of the bones. In this case he believed that the bones were probably soft in their original condition. Naturally after all the soft parts were removed, they appeared much more brittle than they were during life. In osteomalacia there is always osteoporosis if the new formed non-calcified osteal tissue is removed, as was done in the present instance. He considered this a case of osteomalacia of some kind. The femur particularly was interesting.

Dr. Harlow Brooks said that he was much interested in osteomalacia at present, as he had been studying the disease in the primates, where it was very frequently found. He had never seen anything which approximated the changes in these bones. He had not seen a condition of the skull such as was found here, even in the fragile bones of the monkey. The condition of the thorax looked exactly like osteomalacia.

Dr. Nathan said that he thought the disease as found in monkeys was not exactly analogous to the osteomalacia found in man. It was more analogous to rickets.

Dr. Brooks stated that osteomalacia and rickets in the primates are two distinct and easily differentiated diseases.

The Addition of Marble or Other Calcium Compounds to Nutrient Broth: A Reliable and Convenient Method for Growing the Pneumococcus.—Dr. Charles Boldaun demonstrated cultures of the pneumococcus growing in marble broth. During the course of his work with the pneumococcus he had felt the need for a fluid medium like plain broth in which there would be no body fluids. Plain broth was almost worthless, for growth seldom lasted for more than one or two generations. He had at first tried to neutralize the broth to phenolphthalein, but had found that did not work. The addition of glucose to the broth did cause luxuriant growth of the pneumococcus, but the production of acid was so great that the cultures died off quickly. Attempts were then made to neutralize the acid formed by the addition of calcium carbonate. Experiments were made with glucose broth with calcium carbonate and with plain broth with calcium carbonate. The glucose broth proved to be unreliable, but the plain broth with calcium carbonate gave a good growth every day. In testing the acid in the various media it was found that cultures in plain broth with calcium carbonate usually remained neutral to penolphthalein. He had at first thought that the calcium carbonate had neutralized the acids and that this was the reason for the luxuriant growth. It was, however, found that the cultures in the medium containing glucose died off very quickly and that the presence of calcium carbonate did not increase the viability. In plain broth cultures with calcium carbonate alone, the cultures in one case were still alive at the end of thirty days. When plain broth was inoculated there was often not only no increase but a positive decrease of organisms, whereas when calcium carbonate was present there was growth from the start. This fact could not be reconciled with the assumption that the calcium carbonate acts only by neutralizing the acids formed. Tests had therefore been made with other calcium salts, chloride and sulphate. These indicated that it was the calcium element, in part, at least, which made the pneumococcus grow in this broth. Cultures of the pneumococcus grown in this broth lost little or none of their virulence. In preparing the marble broth the marble was broken into small pieces, then washed out in test tubes. The tubes were filled in the usual way and sterilized. The cultures remained viable fully as long as ascitic broth cultures. The growth was not quite so profuse as in ascitic broth, but was a marked growth. In the cases in which marble broth can be employed, its use obviates the tedious collection of ascitic fluid and the careful Pasteurization which ascitic broth requires.

Dr. F. C. Wood, in the discussion, said that he had been much interested in Dr. Boldaun's remarks on the use of calcium carbonate. It had been employed by Dr. Hiss for a year and a half in keeping his cultures alive for a long time. Dr. Hiss had found it important to see that the pneumococcus flasks were shaken up every day. This brought the acid into contact with the calcium carbonate.

Dr. Boldaun said that the point was not the neutralization of the acid, because when glucose was present the culture died out as fast as without the calcium carbonate. The important point was that the pneumococcus needed the calcium salt in some form or other.

A Method for Microscopic Identification.—Dr. Leo Buerger presented a method for the microscopic identification of colonies of the pneumococcus when grown on the surface of meat infusion serum agar or, preferably, meat infusion glucose serum agar, containing 1.5 to 2 per cent. peptone and 2.5 per cent. agar plus one-third of its volume of a high proteid ascitic fluid. The surface colonies of the pneumococcus show a circular, disc-like, flattened growth with a regular contour. When viewed from above, the surface appears glassy, with often a slightly depressed center. When looked at from the side or by transmitted light they appear as distinct milky rings inclosing a transparent center. The ring colonies may vary considerably in their size, but they can be detected in colonies which are not over 1 mm. in diameter. Occasionally the characteristic appearance is not observed until forty-eight hours have elapsed. This appearance, so far as the speaker was aware, was diagnostic of the pneumococcus. It must be differentiated from two other types of colonies, first, from those with a prominent periphery occasionally met with in the case of streptococci; secondly, from those colonies which show rings only by transmitted artificial light. The former, if carefully examined, will be seen to possess a distinct nucleus which is never seen in the characteristic pneumococcus forms. The latter is not to be mistaken if it is studied by reflected light. The center of these streptococcus colonies is raised above the periphery and when held up against an artificial light appears to have a bluish peripheral ring.

Mycotic Aneurisms.—Dr. E. Libman presented three cases of mycotic aneurisms. The first case was sick about a year previous to admission with chills, fever and sweating. This had lasted for about two weeks, and the symptoms had not recurred until about a month before admission to the hospital. After entering the hospital he had a feeling of weight in the epigastrium after eating and pains radiating to the back and between the shoulders. The patient lost forty pounds in a few weeks. Temperature on admission was 99.6° F. Physical examination showed nothing except an indistinct small mass felt just to left and below the umbilicus, with an enlargement of the heart and a systolic murmur at the apex transmitted to the left and also over the arch of the aorta and the lower third of the sternum. While in the hospital the temperature rose to 103° F. Leucocytes were 25,000, hemoglobin, 33 per cent. Exploratory laparotomy revealed a small aneurismal sac lying in the mesentery near the root. At postmortem there was a marked hypertrophy and dilation of the left ventricle with atheroma of the mitral valve which showed recent vegetations, and two aneurismal pouches on the edge of the flap. At the hilum of the spleen an aneurism of the splenic artery was found measuring about 6 cm. in diameter, just below which there was a sacculation of about 60 c.c. In the mesentery there were two well developed aneurisms, one small area of ulceration and two beginning aneurisms. The ulcerated area in the vessels and the well developed aneurisms showed a distinct sharp break in the intima and a tendency to localization at the bifurcation of the vessels. The lesions were all situated in the branches of the superior mesenteric artery. Streptococci were found in the lesions.

Case II had a history of six weeks' illness, with tonsilitis at the beginning. There was cough with mucous expectoration. Three weeks before admission the patient noticed a swelling in the left groin, which pulsated and was painful. On admission a loud, blowing systolic murmur was made out at

the apex of the heart which could be heard in the axilla and posteriorly. The second pulmonic sound was accentuated. In the left femoral region there was a small oval, elastic swelling. This was painful to the touch, and had expansile pulsation. A loud systolic diastolic humming murmur with systolic accentuation could be heard over the mass. A diagnosis was made of arteriovenous and the patient was operated upon on the day of admission by Dr. Wiener. The external iliac artery was tied in two places and cut between the ligatures with the intention of tying the femoral artery below the sac. Resection of the lower end of the sac was attempted, but it was found necessary to tie the femoral vein and artery. At autopsy the mitral valve was found thickened, and the aortic flaps insufficient. On the under surface of one of the aortic flaps there were very large vegetations. On the center of this flap and on the margins of the other flaps were masses of fine vegetations. There was marked atheroma of the aortic arch. The kidneys showed chronic interstitial nephritis and there was a small aneurism on one of the lesser branches of the renal artery. Intestinal vessels showed no changes. The femoral artery showed marked endarteritis and there was an aneurism at the point where the profunda was given off. The sac contained thrombotic masses, most of which were not decolorized. The remains of the vessel wall were present in the sac. The femoral vein had a small defect in its wall externally and anteriorly which led into the sac. Bacteriological examination showed *Staphylococcus aureus* in the aneurismal sacs of the femoral and renal arteries, while streptococci and *Staphylococcus aureus* were obtained from the heart's blood.

Case III was admitted to the service of Dr. Rudisch with a history of rheumatism in the ankles and knee joints at the ages of nine and fourteen years. The present illness dated back three months. The symptoms first noticed were diarrhea, cramp-like pains in the abdomen, and pain in the ankles and wrists. The patient was weak and had a poor appetite. For four weeks his feet had been swollen whenever he was out of bed, and he had had a cough for four or five days. He had slight fever and sweated a good deal at night. Physical examination showed slight cyanosis with clubbing of the fingers. The apex beat of the heart was palpable in the fourth space 1 cm. outside of the nipple. A short systolic thrill was present at the apex and a short systolic murmur which was transmitted to the anterior axillary line and the pulmonic area. The first heart sound was very sharp and the second pulmonic sound accentuated. The leucocytes were 12,400, hemoglobin, 50 per cent. No changes were noticed about the joints. The temperature, which was 102° F. on admission, ranged from 99° to 101° F. The urine showed a trace of albumin and a few hyaline and granular casts, also a few red and white blood corpuscles. There were a few petechial spots on the conjuctiva, palm of the left hand, and on the cheeks. A diagnosis was made of mitral stenosis and acute endocarditis. The differential blood count showed 76.5 per cent polynuclears, 22 per cent. lymphocytes, and 1.5 per cent. eosinophile. Treatment was made by injections of collargol. A month after admission an elongated, bulging mass, 1.5 inches long, parallel to the femoral artery and just outside it, was noticed at the junction of the upper and middle third right thigh. The mass did not pulsate and did not disappear when the artery was occluded. Two days later expansile pulsation and a bruit were made out. A diagnosis was made of a mycotic aneurism. Five days later the mass had increased in size, was distinctly cystic, and appeared to be attached to the femur. Two days later an acute parotitis developed on the left side. Three days later there was an attack of right hemiplegia with absolute aphasia. During the day, however, there was a partial return of speech. Two days later a marked motor aphasia appeared and the diagnosis was made of probable rupture of one of the branches of the left Sylvian artery. An operation was performed by Dr. Lilienthal and an incision was made over the elastic swelling, which was found to consist of a softening laminated blood clot. The lateral aspect of the femur was eroded for a depth of three-eighths of an inch, for about two inches. The walls of the defect were quite rough. Two weeks later there was a hemorrhage from the aneurismal sac which was controlled by packing, but twelve days after this it was found necessary to tie the femoral artery, the bleeding having been found to come from a small rupture in the wall of the artery. Shortly after this there was a rise of temperature with development of a right sided pneumonia, and the patient died on the same day. During the course of the disease four blood cultures were made, which showed the presence of a small number of attenuated streptococci possessed of moderate hemolytic power. At the time of the operation on the thigh, cultures from the clot were made and streptococci found. Postmortem examination showed pneumonic areas in both lower lobes of the lungs. The heart showed hypertrophy of the left ventricle and dilation and hypertrophy of the right ventricle. The mitral valve showed a moderate stenosis. There were bright yellowish green vegetations on the flaps and the surface of the auricle. There were small, yellow infarcted areas in the heart wall, but no emboli were found in the branches of the coronary artery. The spleen, which was enlarged, was deformed by recent and old infarcts of the striking yellow color repeatedly found in splenic and renal infarcts in cases of acute endocarditis, due to attenuated diplococci and streptococci. The kidney showed recent and old infarcts. On the branches of the superior mesenteric artery there were several aneurisms, two about the size of a walnut, the other two about the size of a bean. The liver was very large, congested and fatty. At the hilus there was a large aneurism developed from the right branch of the hepatic artery. Near the surface of the liver were numerous small, irregular yellowish areas. Part of the right femur was removed. It showed marked erosion. The exact origin of the aneurism could not be traced, as the aneurism had been opened up during life and the sac was found almost entirely destroyed by suppuration. Bacteriological examination showed the presence of the same attenuated streptococci that had been present during life in all the organs of the body.

Attention was drawn to the following points. In the second case there was an arteriovenous aneurism of the femoral artery, apparently secondary to a tonsilitis. In the third case the rapidity with which the femur was eroded was certainly very striking. In all three of the cases there was present a chronic interstitial nephritis. It was likely that this predisposed to a general infection and made both the

valves and the vessels more liable to attack by the bacteria.[1]

Dr. James Ewing, in the discussion, said that he had been greatly impressed by the extent of the aneurisms in these cases. When Dr. Libman had called attention to the fact that the patient in the second case had had an attack of acute tonsilitis six weeks before death, he had received the impression that Dr. Libman intended to connect the tonsilitis with the development of the aneurisms. The examination showed that the heart valves and the aorta exhibited old lesions favorable to the development of aneurisms, so that it would seem difficult to demonstrate that these aneurisms developed as a sort of sequela to the tonsilitis.

Dr. Libman said that prior to the attack of tonsilitis this patient might have had fever. Of this, however, there was no evidence. But he thought it was not at all improbable that there was a connection between the aneurism and the tonsilitis. It is a clinical fact that tonsilitis predisposes to systematic infection with the production of acute endocarditis, acute nephritis and other lesions. It would not take long for thrombotic masses or vegetations to form on valves already the seat of disease and the lodgment of such emboli from such sources in vessels should readily produce mycotic aneurisms. It was remarkable how rapidly such aneurisms could be formed, and how readily they could rupture or invade the surrounding tissues.

Some Observations on the Subway Air.—Dr. E. E. Smith presented some observations on the air in the Subway, which he made in the month of December, at the request of the Health Commissioner. They were few in number, but were systematic and were believed to show some general conditions. The air was taken from the cars of the Subway during operation, and, for comparison, from the Subway stations and from cars of the elevated road, and from the outside atmosphere at a distance of five feet from the level of the street. The temperature and humidity, the amount of oxygen and carbon dioxide, and the number of micro-organisms in the air were studied. The results did not afford any basis for adverse criticisms.

The temperature and humidity did not indicate conditions to cause discomfort. The amount of oxygen of the air was found to be normal. An indication as to whether air is vitiated is found in the amount of carbon dioxide present. Pure air is put at 3 to 4 parts in 10,000. Authorities agree that 7 parts in 10,000 is the upper limit of safety. In this respect the air in the Subway cars is worse than the air in the Elevated cars. Bearing in mind the temporary occupancy of the cars the carbon dioxide did not show an alarming percentage. The air in the empty or partially filled cars was within the safety limits. In regard to the number of micro-organisms found under present conditions, there was one striking fact, namely, the large proportion of molds present. After considering the possible causes, Dr. Smith believed that two might very probably exist: (1) That the atmospheric conditions, the absence of light and the moisture of the walls, owing to their being recently built, were favorable to the development of molds; (2) that the production of currents of air by the movement of the trains kept the molds in suspension in the air. The constant moving of the air tended to prevent their settling out. The question of the influence of the presence of molds on health was one on which our present knowledge is too meager to permit of definite conclusions.

Dr. James Ewing, in the discussion, said that he was much interested in these figures, which, as he understood them, indicated a very much larger bacterial and mold content in the Subway air than in that of the street. He had not understood exactly how these tests were made on the street, but it seemed at any rate that it would be a dangerous thing to go into the Subway if there were so many more micro-organisms in the Subway than there were in the street. Some years ago he had made some tests on the bacterial condition of the air of the streets for Dr. Woodbury. They were intended to determine how many bacteria would fall on Petri dishes exposed in various places. There was an enormous difference in the number of bacteria in the air of different streets and in different states of weather. It seemed to him that unless these experiments were very carefully controlled as to temperature, air curents, etc., they were unfair as a comparison between the air of the street and that of the Subway.

Dr. Smith said that Dr. Ewing's remark especially applied to observations made with Petri dishes and not to the same extent to air examined by passing through the aërobioscope where the surface was not exposed in that way. The air had been taken at five feet above the surface of the street, and it was taken in a spot where it was guarded from wind. On one or two occasions there was snow on the ground, so that there could have been but very little dust. The temperature in the street was from 25° to 35° F. Dr. Smith did not think that the figures given were in any way alarming. They were no greater than were found in crowded rooms in our own houses. Personally he believed it quite possible that the growth of the molds was very largely due to the damp condition of the Subway when it was first opened. He would not be at all surprised if later observations should show that the growth of the molds had become very much less.

Report on Some Observations on Fatty Extracts From Organs.—Dr. E. K. Dunham reported some observations on fatty extracts from organs. He had been working on the extracts, from kidneys especially, for a year or two, his attention having been called to the subject by a question which came into his mind as to whether the fatty changes which are so familiar were really due altogether to the presence of neutral fat. He had speedily come to the conclusion that what was usually regarded as fat was really not only neutral fats, but contained, in addition to this, a very considerable amount of other fat-like substances, among them lecithin and protagon. Quantitative analyses of these substances had been made with some degree of success, and it had been found that in fatty extracts from the kidney the amount of lecithin ranged from about 30 to 67 per cent. of the extract; showing that there might be as much or more lecithin or phosphorized fat as neutral fat in these organs. His reasons for using the kidney were, in the first place,

because the kidney was easily freed from obvious fat; secondly, because it hardly seemed probable that the kidney could be regarded as in any sense a normal fat depot. This was certainly not true of the liver. The results of examination of the liver varied somewhat from those of the kidney. One or two other organs had been examined in a less thorough way. The fact that these phosphorized fats were so uniformly present in the cells and were really so abundant, making up something like 6 to 8 per cent., in one case 10 per cent., of the total solids of the organ, suggested that they were very important cell constituents, and furthermore suggested that possibly some of the fat found in the different forms of degeneration might be in part lecithin or phosphorized fat, in part, a neutral fat derived from the fatty acids they contained, since the fatty acids might be split off from these phosphorized fats. It was interesting in this connection to recall some observations made by Albrecht, published in the Transactions of the German Pathological Society, in which he calls attention to the fact that there are certain minute structures in cells which are double refracting. These are double refracting substances. Albrecht called attention to the fact that these fine granules ("liposomes") occur in the heart in a series of rows lying between the longitudinal striations of the muscle fibers, and also to the fact that the fatty granules first appear in this situation in fatty changes in the heart. He is inclined to think that substances like protagons may become modified in such a way as to give rise to these fat droplets. There was one very extraordinary physical quality of these phosphorized fats, and that was their power of taking up water and producing myelin forms so that a mere trace of lecithin put on a slide and moistened would make a hundredfold its bulk of myelin figures. It seemed to absorb water and swell up with interesting and curious motions, growing so fast that one could watch its development. It had been suggested that these phosphorized fats and lecithin-like bodies or lecithins might be a very important constituent in cytoplasm in causing the other constituents to assume and maintain the form of an emulsion in which the bodies in solution are separated into droplets by a film of myelin substance very sensitive to variations in the amount of moisture. Perhaps the changes which are known as parenchymatous or fatty degenerative changes, might have to do with modifications in this emulsion in which these myelin films may form essential parts. Possibly in the minor degrees of these changes we may have more imbibition of water through osmotic pressure. In the more chronic fatty changes it is possible that we have a chemical change in the myelin substance. It was pretty certain that a complicated molecule like these lecithins, present in the cell in such abundance, must be of deep significance. So far as microchemical staining reactions go, the lecithins will take up those we are accustomed to use for neutral fats. It is more possible to make a distinction by means of polarized light. Many of these substances are double refracting, but it is exceedingly difficult to make very accurate observations respecting double refraction on minute fatty granules.

A Note on a Peculiar Action of a Streptococcus on Blood Plates.—It has been repeatedly noted by Dr. E. Libman in studying the growth of streptococci on plates of blood-agar that the streptococci vary as to their influence on the surrounding medium. Some will cause a disappearance of the blood in a larger or smaller area about the colony and some will not have any effect of this kind. Some authors are of the opinion that the hemolytic effect, so-called, varies in accordance with the virulence of the organism. This we have not found to hold. The streptococcus on the plates which Dr. Libman showed was isolated by Dr. Bauman from the blood of a case of phlebitis and periphlebitis of the leg. On the blood-agar plates it was noticed that after twenty-four hours the organism was surrounded by a clear area. Surrounding this clear area the blood on the plate was darker in color than on the rest of the plate. After forty-eight hours a second clear ring appeared outside of this area of darkened blood. In one observation the process extended so that there were three clear concentric rings about the streptococcus colony. It was very difficult to explain how the organism could produce a result like this.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held March 13, 1905.

The President, Thos. E. Satterthwaite, M.D., in the Chair.

The Constitutional Treatment of Bright's Disease.—Dr. W. H. Porter read a paper on this subject. (To appear in a subsequent issue of the MEDICAL NEWS.)

Recent Advances.—Dr. R. W. Wilcox said he entirely agreed with Dr. Porter as to the fact, now clearly established, that in chronic interstitial nephritis the condition is not limited to the kidneys, but is widespread; implicating the arteries especially and extending to every tissue of the body. One of the points of importance which had recently been brought out was the impermeability of the kidney to sodium chloride. This found expression in the amount of anasarca present, and by regulating the amount of sodium chloride ingested, good results could sometimes be obtained. By the daily weighing of the patient the quantity of sodium chloride it was necessary to take out of the food could be ascertained. Another point was that the diminution of the fluid ingested had often been found to be accompanied by an increased amount of dropsy. Dr. Wilcox gave a note of warning against the use of so-called diuretics. Even the drugs that were supposed to be least irritating might be followed by serious injury. In chronic interstitial nephritis (the arterial type) he said it was possible to make a diagnosis by means of the sphygmograph before there was any evidence presented by the urine, and long before the development of any changes in the eye.

The Advantages of Erythrol Tetranitrate.—Dr. Porter had spoken of the utility of nitroglycerin in this affection. He himself believed that much better results could be obtained with erythrol tetranitrate, which is official in the British Pharmacopœia. By means of this drug the characteristic effects of the nitrites were produced more slowly and gradually, and lasted for a much longer time.

Lumbar Puncture and High Intestinal Irrigation.—In the persistent headache not infrequently met with, and also in preventing coma and convulsions, good results were now often secured by the use of lumbar puncture. This measure was purely symptomatic, however, and had no curative agency. If he were to mention any one thing that was of special value it would be the systematic use of high intestinal irrigation, as practised by Kemp. By means of it he had seen comatose patients snatched from the very jaws of death, and afterwards restored to a moderate degree of usefulness.

Lavage of the Renal Pelvis in the Treatment of Bright's Disease.—This was the title of the second paper, by Dr. Winfield Ayres (published in the MEDICAL NEWS, July 1, 1905, p. 7).

The Treatment of Pyelitis.—Dr. H. A. Kelly, of Baltimore, read the last paper of the evening, on this subject. He said that pyelitis might be of all grades of severity, and he desired to call attention to the great importance of appropriate treatment in the milder forms with a view to the prevention of the very grave consequences liable to result from the neglect of these. The advanced grades, such as pyelonephrosis and pyelonephritis, were everywhere recognized as surgical conditions, but if the attention of the profession could be directed to the early stages of pyelitis, it would be found that these cases were amenable to simple treatment. Nature's methods of cure were always suggestive, and what nature suggested here was irrigation. One plan of treatment was the expectant; keeping the patient in bed and giving plenty of water. Urotropin was about the best drug that could be used in these cases. Another method was to employ irrigation by means of ureteral catheters, and very small catheters would usually answer for this purpose. Strictures of the ureter were sometimes met with. In one instance that he had seen the stricture was in the vesical mucosa, and this he had been able to completely do away with by snipping with scissors. When the stricture was more deeply seated, catheters of various sizes were required, and sometimes metallic instruments were called for. Stone in the kidney was sometimes met with. Another class of cases was that associated with a low grade of hydro-nephrosis. Dr. Kelly expressed the opinion that a good many appendices and a good many ovaries and tubes had been removed from patients in whom this was the real source of trouble. He narrated a case in which there had been persistent localized pain for a long time, and when he slowly injected fluid into the kidney on the side affected the patient was able by her sensations to locate at once the seat of the pain. This case promptly yielded to treatment. In one case of pyelitis affecting both sides he found it necessary to amputate both ureters and make an anastomosis with the bladder. The point that he desired to make was that while the severe grades of pyelitis called for radical surgical procedures, the milder ones might be successfully treated by catheterization and irrigation, with urotropin internally.

Dr. Ayres' Statements Corroborated.—Dr. F. M. Johnson, of Boston, said that from an experience of a considerable number of cases he could confirm the statements made by Dr. Ayres. These were private cases which had been referred to him after treatment of all kinds, with very little benefit. He had added the lavage, at the same time maintaining other treatment, and marked improvement had often resulted. It was astonishing, he thought, how little lavage, even of the bladder, was made use of by the profession. Lavage of the kidney was no more dangerous than that of the bladder if it were performed skillfully and under proper precautions. Our knowledge was constantly being increased by contributions in one direction or another, and lavage of the renal pelvis seemed to him to be a measure worthy of careful consideration.

The Test of Time Required.—Dr. G. M. Edebohls said that in the present state of the treatment of Bright's disease any addition to our resources would be most welcome. At this time, however, it was absolutely impossible to arrive at any positive conclusions as to the value of Dr. Ayres' procedure. Only nine or ten months had elapsed since he had made it known, and it was essential that it should be tested by the observations of several years. He could not agree with Dr. Ayres that a diagnosis of incipient Bright's disease might be made on the presence of a little albumin and a few granular and hyaline casts in the urine. All these signs were sometimes to be found with a movable kidney, and might entirely disappear after fixation of the organ.

Pain in Hydronephrosis.—He agreed with Dr. Kelly in regard to the pain met with in hydronephrosis, and felt sure that ovaries and tubes, and even the uterus itself, had sometimes been taken out when the real trouble was in the kidney. It might be that it was movable kidney in some instances which caused the slight hydronephrosis spoken of by Dr. Kelly.

Ureteral Catheterization a Difficult Procedure.—He did not think it would be right to resort indiscriminately to catheterization of the ureters, as this required special skill. There were fewer men able to do this, he believed, than to perform a major operation on the kidney. With these limitations he desired to endorse the papers of the evening.

The Curative Effect of Lavage Hard to Understand.—Dr. Willy Meyer said that Dr. Kelly had an advantage over the general surgeon in the fact that all his patients were women, as ureteral catheterization was a much simpler matter in the female than in the male. As to Dr. Ayres' treatment of Bright's disease, he thought it difficult to understand how lavage of the renal pelvis twice a week could exert any positive influence on the entire parenchyma of the kidney, considering the comparatively large size of the organ.

The Treatment Does Not Seem Philosophical.—Dr. F. Bierhoff said that he had to confess that the more he had seen of ureteral catheterization the more had he become convinced that the best treatment for pyelitis is rest in bed. Only in the severe cases did he think this procedure should be resorted to. As to the treatment of Bright's disease by lavage, this did not seem to him at all philosophical. The fluid injected was confined entirely to the pelvis and calices, while in this affection we had a process which had its origin in the remote tissues of the kidney; and he failed to see how the Malpighian bodies could be affected in the slightest degree by such treatment. In order to take the place of any accepted method of treatment a proposed method must accomplish at least as much, if not more than the other; this had not been demonstrated here. Dr. Ayres had stated that the albumin and casts diminished, but this result could be secured by simple rest in bed and in various other ways. He did not think, therefore, that he (Dr. Ayres) was justified in making any claim, since the same results could be obtained by much simpler methods. The only surgical treatment of Bright's disease which had as yet proved of real value was Dr. Edebohl's renal decapsulation. If this disease ordinarily originated from an extension of inflammation from the renal pelvis, lavage might seem to be indicated, but the whole trend of authoritative opinion was just the reverse of this, recognizing that the process originated in the remote tissues of the kidney.

The New Theory Untenable.—Dr. A. Lapowski said that Dr. Ayres had invented a new theory, and it was not tenable. He had based the supposed efficacy of lavage on the benefit derived from washing out the renal pelvis. But it was not possible to thus wash away gonorrheal infection. The gonococcus would stick, no matter how thoroughly the lavage was carried out, and it could be removed only by means of a curette. He also thought Dr. Ayres' method attended

with considerable danger, as the parts were not in the same condition as in the normal kidney.

The Term Bright's Disease Should be Abandoned.—Dr. A. A. Berg thought the time had come when the term Bright's disease should be given up. The cases should be designated as chronic nephritis. It was very difficult, he said, to understand how lavage of the renal pelvis could have any effect on such a condition. If we really had an inflammation ascending from the bladder, accompanied by obstruction, the condition might no doubt be benefited by the use of lavage, but this was not the usual history in chronic nephritis.

Dr. Ayres, in closing the discussion, said that in his cases it was a fact that, notwithstanding various other measures employed to prevent the occurrence of casts and albumin in the urine, they continued to develop; and that under the use of lavage they progressively diminished. He had been very careful to state that lavage was applicable only in selected cases, and he had claimed for it only such results as, within the limitations he had specified, actual experience had shown to be fairly attributable to its effects. In interstitial nephritis no benefit was derived from lavage, except at the very beginning of the process. He was sorry that Dr. Johnson had not given more details of his cases, as he had had the same experience in Bright's disease that he himself had met.

TENNESSEE STATE MEDICAL ASSOCIATION.

Seventy-second Annual Session, held at Nashville, April 11, 12 and 13, 1905.

The Association met at Watkins' Hall, under the presidency of Dr. Paul F. Eve, of Nashville.

Prayer was offered by Rev. W. M. Anderson. Addresses of welcome were delivered on behalf of the city by Mayor A. S. Williams, and on behalf of the medical profession of Nashville by Dr. Geo. H. Price, the response to which was made by Dr. H. Berlin, of Chattanooga.

Melancholia.—Dr. S. T. Rucker, of Memphis, read a paper on this subject. He defined the disease, and then referred to the etiology, symptoms, varieties, pathology, diagnosis, prognosis, and treatment. Heredity was encountered in about 50 per cent. of the cases. Ill health, mental strain, worry over financial affairs, domestic troubles, and disappointment in love were also factors largely responsible for most cases of melancholia. Auto-infection undoubtedly played a considerable rôle in some cases. Pregnancy, especially in primiparæ, was an aggravating cause, and generally began about the third or fourth month. The puerperal state did not so often produce melancholia as pregnancy and lactation. Severe forms of agitated melancholia were occasionally associated with chronic alcoholism. The sobering-up after a prolonged spree or debauch would precipitate an acute attack of melancholia, not infrequently ending in suicide. The onset of melancholia was almost always gradual. At first it might be only a feeling, which took no definite shape, and there might be no delusions. Every thought and everything in the environment had a sorrowful color. When questioned, the patient would simply say he felt depressed, or he had the blues. The morbid feeling constituted the disorder. The symptoms varied from a simple state of dejection to a state of profound depression, in which the patient was either paralyzed by the dreadful nature of his concepts, or was thrown into a state of agitated suffering, associated with marked precordial distress and peculiar pains in the back or top of the head. The author mentioned three varieties of melancholia, the acute, subacute, and chronic. There was no known pathological anatomy for melancholia. It was considered a functional disease of the brain. Melancholia could hardly be mistaken for acute mania, as in melancholia there was a slowing of the thought process; while in acute mania there was an accelerated flow of ideas, and the mania was unusually cheerful and talkative. The prognosis in melancholia was very favorable. Fully 90 per cent. recovered. Thorough investigation, speedy separation from relatives and friends, and an early commitment to an institution for treatment should be the rule in this class of patients.

Dr. M. Campbell, of Knoxville, said that melancholia agitata and simple melancholia were symptoms of but one and the same disease. Melancholia itself was not, strictly speaking, a mental disease, but a symptom of a pathological state that underlay the symptom of depression that was most prominent, whether it be an organic or functional disease, but most generally it was functional. A large percentage of the cases of melancholia that were sent to hospitals for the insane did not recover. He did not think half of them got well. As to the treatment, he suggested a change of scene, getting away from the conditions that produced the disease, building up the patient physically, giving hypnotics to produce sleep, warm baths, etc.

Dr. W. J. Breeding, of Taylor's, related the history of a woman, forty-two years of age, mother of eight children. In the family history there was insanity in an aunt. He was called to see her in a former pregnancy, when she was very hysterical, and was troubled with nausea and vomiting. He saw her in the sixth week of pregnancy, when she was in a very depressed condition. He made a diagnosis of hysteria. The woman recalled her experience in a former pregnancy, and said she could not live through this one, believing she would have a repetition of nausea and vomiting. There was no pathological condition, so far as could be determined. She had numerous delusions up to the seventh month of pregnancy, when a miscarriage occurred, the fetus being badly deformed. It was thought she would now get well, but in a couple of weeks she lapsed into a condition of melancholia, eked out a miserable existence for two or three months, and then committed suicide by hanging.

Dr. C. P. McNabb, of Knoxville, mentioned two cases, in neither of which would the family consent to sending the patient to a hospital. One patient had three attacks of melancholia, with three partial recoveries. The other was now in her third attack.

Dr. A. F. Paschall, of Crossland, thought that in the case of young men advertising literature played an important rôle in the cause of melancholia.

Dr. S. S. Crockett, of Nashville, said there was a popular impression that there was an insanity that developed in puerperal women that differed from other forms of the disease. There never was a greater mistake. Pregnancy and lactation should be regarded as one factor that might produce insanity in a woman who was otherwise predisposed to it.

Dr. Louis Leroy, of Nashville, agreed with Dr. Crockett, that there was no special type of insanity peculiar to the pregnant woman. The condition had been recognized as an etiological factor, possibly

as the exciting cause of the disease, to such an extent that even though incorrect from the standpoint of pathology, clinically the term puerperal insanity was recognized both professionally and by the laity. The probability was that the causes were few in number: First, that the shock to the nervous system resulting from the profound changes occurring in pregnancy might bring on an attack which was impending, or accentuate the nervous disturbance, otherwise held under control. On the other hand, many cases were the result of auto-intoxication.

Dr. S. T. Rucker, in closing, said that melancholia recurred in some instances; but when the patients were carefully treated, recurrence would seldom take place.

Diagnosis of Kidney Diseases.—Dr. Louis Leroy, of Nashville, read a paper with this title, and, among others things, said that in renal diseases possibly more than in some other classes of ailments accurate discrimination in diagnosis was important with reference to the prognosis as well as treatment. It was a matter of some interest to a patient as to just what his life expectancy was, and how long a period he might expect to devote to settling estates or arranging business matters. The physician should exercise care and judgment in his diagnosis, as a failure to distinguish between the parenchymatous or interstitial nephritis, or to at once make a snap diagnosis of nephritis from a trace of albumin without further investigation of general clinical conditions and the exclusion of some other lesion microscopically, or a repeated examination, in the absence of casts, microscopically, to determine some cyclic or functional albuminuria, might render him with some justice a subject of ridicule, for which years of careful and conscientious work could scarcely atone. While malformation of the kidneys were of great rarity, their importance in surgical cases should cause the possibility to be constantly borne in mind. The absence of one kidney or fusion of both into one mass should be considered, and the presence of an organ on both sides determined, if possible, while debating the admissibility of operative measures. It was not always possible, and frequently quite difficult, to determine the presence of the kidney when in normal position, either by percussion or palpation, especially in patients with thick abdominal walls, or large, well-developed spinal muscles. In such cases the presence of the organ might be determined by the X-rays, or both ureteral orifices might be determined by a cystoscopic examination, in which case the presence of two kidneys might be considered as assured, the possibility of a single kidney having two pelves and ureters being so extremely slight as to be negligible. In case of movable kidney, however, it was usually possible to recognize the condition by palpation, sometimes assisted by percussion, and one might sometimes be surprised to find no clinical symptoms associated. With some cases, the kidney readily returned to its normal position, where it remained for some time, and it might be necessary to make several examinations at different times before finding it when displaced. In appendicitis the location of the point of tenderness, the usually higher temperature, absence of blood in the urine, tenseness of the muscles of the abdomen and flank, and the increase of polymorphonuclear leucocytes in the blood should direct attention from the kidney, especially if the mass could be palpated. Movable kidney in all its bearings was considered at length. Neuralgias were usually found in patients of a more or less neurotic temperament, and would not be found to be associated with hematuria. Ovarian inflammation might be puzzling, but one would usually be able to elicit some exciting cause, and local tenderness should be easily recognized by vaginal examination. Hematuria was absent and some endometritis was frequently associated. Diaphragmatic pleurisy would usually be influenced somewhat by respiration, even though the diaphragm be held rigid. There would be absence of abdominal breathing, and cough was usually present. The respirations were usually shallow and hurried, and early in the attack auscultation would frequently elicit the friction sounds. The essayist described the points of differentiation of kidney diseases from gastric ulcer, ataxia, chronic valvular diseases of the heart, and then referred at length to acute parenchymatous nephritis and acute interstitial nephritis. Pyelonephritis was usually secondary to some other infection below, but especially in typhoid or tuberculous infections might originate through the blood.

Perinephritic Abscess.—Dr. W. A. Bryan, of Nashville, discussed this subject, and the differentiation of this form of abscess from other abdominal conditions. He reported the following case: Mr. F., locomotive fireman, aged twenty-eight years, had no evidence of disease since childhood. In August, 1904, he got a superficial burn on his left olecranon, which became infected, but healed kindly. After a few days an abscess developed near the burn. This was opened and healed. A few weeks later three or four other abscesses formed around the site of the original abscess, were opened, or ruptured, and healed. In October he began to have pains in the lumbar region on the right side, and soon afterwards quit work and took to his bed. Pain in the right side was described as a "catch," and in his back there was constant aching. He became distinctly septic. Liver dulness was elevated one inch in the right nipple line; right side one and one-half inches larger than the left. Enlargement of the right loin was very perceptible, and fluctuation was present; pus on aspiration, and urine normal. December 15, 1904, the speaker operated, removing twenty-four ounces of pus. Patient improved, but had pain again from the beginning after the operation in his left side. It was aspirated, pus was found, and two weeks from the first operation a second one was performed, removing eight ounces of pus from the left side, after which patient made an uninterrupted recovery, and has since gained forty pounds. The pus gave a pure culture of *Staphylococcus aureus*. There was no connection between the two abscesses. He learned from the patient at the second operation that another surgeon had aspirated both sides and found pus before he saw patient.

Treatment of Hypertrophied Tonsils.—Dr. J. F. Hill, of Memphis, entered his protest against the promiscuous and wholesale excision of children's tonsils. There were three kinds of diseased tonsils: (1) A tonsil which was constantly swollen, red and easily irritated; this tonsil was of a specific scrofulous, or tuberculous nature, and the only logical method of dealing with it was by excision. (2) A tonsil which was diseased in the interior, which formed ocasionally into an acute abscess. (3) A tonsil with ulcers on the surface, which might be either indolent or active, and were easily managed by a two per cent. solution of nitrate of silver. As to treatment, tonsil No. 1 was treated by complete ex-

cision. Tonsil No. 2, which was diseased internally, had openings leading from the surface to the interior, and at the bottom of these openings there was a quantity of fungous tissue, with the formation of acute abscesses. The openings to the tonsils, as the crater was to the volcano, allowed the escape of diseased mucus from the interior of the tonsil. When these openings were closed from cold, or otherwise, the mucus was retained and decomposition set up; hence an abscess. Tonsil No. 3, which had ulcers on the surface, could be relieved with 2 per cent. solution of nitrate of silver, but tonsil No. 2 gave considerably more trouble. His method of treating tonsils of this character was to pass a small curette through these openings into the bottom of the tonsil and remove all the diseased or granular tissue, then carry a 10 per cent. solution of nitrate of silver into the tonsil. This should be repeated in from three to six days, and continued until the tonsils were cured, which usually required six treatments. By this method the tonsils were cured and left to perform their natural functions. He laid down two general rules: (1) Cure all tonsils which could be cured, and leave them intact. (2) Excise all tonsils which could not be cured.

Treatment of Hypertrophied Tonsils.—Dr. J. T. Herron, of Jackson, in a paper on this subject, quoted from some of the best authorities, to show the importance of removing hypertrophied tonsils by some operation, and not allow them to remain, thus weakening the mental and physical strength of boys and girls. He detailed a number of cases upon which he had operated with gratifying results. Advice properly given would do much to dispel from the minds of the laity the old idea that hypertrophied tonsils must not be removed.

Dr. G. C. Savage, of Nashville, said it was a great mistake to allow children to go on from year to year with enlarged faucial tonsils, especially if they were subject to repeated attacks of inflammation. There was no harm from clipping a tonsil unless the child should happen to bleed to death when the operation was done. This rarely occurred. A tenotome, shaped after the manner of the tonsillotome, was just as easy to use on the pharyngeal tonsil as the tonsillotome on the faucial tonsil.

Dr. T. J. Happel, of Trenton, preferred Tiemann's tonsillotome for removing tonsils. He had tried the scissors and other instruments, but said the practitioner should select that instrument which was best adapted to his use, then the work could be done more successfully.

Medical Ethics.—Dr. T. J. Happel, of Trenton, read a paper on this subject. He said it was to be regretted that most graduates left medical colleges with a vague sort of idea that there used to be in the dim past a set of rules governing the relations of medical men to one another, to their patients, and to the public at large, but that since nothing had ever been said to them by their professors upon this subject, those rules had long since passed into innocuous desuetude. In many instances they soon became imbued with the idea set forth by a certain lecturer of the importance of "getting there," and that they laid down for their own guidance "get there" in any way one could, provided he did not violate the eleventh commandment. They followed their own golden rule as written and interpreted in these days of greed for gain—do unto the other fellow as you would expect him to do unto you if he could, and do it first.

Origin and Treatment of Malignant Growths.—This was the title of the President's address, delivered by Dr. Paul F. Eve, of Nashville. He mentioned two varieties, one of the epithelial type of cells known as carcinoma; the other of the endothelial variety, or connective tissue cells, known as sarcoma. Both of these in many respects presented clinical features very much alike. He referred to the theory that cancer is due to parasitic origin, but said he was very much more favorably impressed by the other theory, which bases the origin of cancers upon cell proliferation. Assuming that this disease was due to cell proliferation, if one could in any way check or change these cells, he had the promise of an ultimate success and recovery. About two years ago he operated upon a lady for scirrhous mamma, with involvement of the neighboring glands. A very complete operation was made, and every vestige of the disease removed, so far as could be discovered. Her recovery seemed complete in every respect, and he flattered himself that there would be no recurrence. Four months after the operation she returned with a reappearance in the scar tissue. A second operation was performed, consisting of curetting the diseased structures. The patient was subjected to treatment with the X-ray for four weeks. At first improvement was noticed, but at the end of the third week the wound looked very unhealthy, and at the end of another week the patient returned to him, appealing, as all those unfortunate cases do, for some means to save her life. The appearance of the ulceration was foul and fungous, and every indication pointed to general infection and a speedy death. He began to treat this wound with balsam of Peru, after first irrigating with bichloride of mercury, 1-3,000. After the first few days the unpleasant odor ceased, and he was surprised to notice a decided change and granulations of a healing nature springing up in the wound. This treatment continued for five weeks, with an occasional touching up of the granulations with the solid stick of nitrate of silver. At the end of this time the wound was entirely healed, and the patient looked the picture of health. He had the pleasure of seeing this patient a short time ago. There was not the slightest evidence of any recurrence, and the woman was in excellent health. Since this case he had had quite a number of other cases, which had been treated in a similar manner. Improvement had been marked in every instance, and the ulcerations from the foul and fungous condition had assumed healthy granulations, healing occurring slowly, but effectually. He cited two more cases.

Gastric Dilatation Without Stenosis.—Dr. Fenton B. Turck, of Chicago, discussed the pathology of this subject. He cited the class of cases usually observed, and advanced the statement that many severe diseases may go on indefinitely without symptoms and without serious consequences, but as soon as there was gastric atony and dilatation, the medical adviser was called in for the relief of pressing symptoms. In childhood the dilatation was usually acute, due oftentimes to indiscretions in diet, but the stomach proved its own best relief by ejecting the cause of the trouble, giving itself the only remedy required—rest. In these cases the symptoms were mostly confined to vomiting, and rarely proved troublesome, yielding readily to treatment by rest. In adults the severest lesions might have been present for indefinite periods of time—gastroptosis from various causes; gastritis, either acute or chronic, including atrophy, and yet the symptoms be wholly absent. But when gastric atony with dilatation supervened, there were at once symptoms of a most positive character; and many diseases that progressed to a

fatal ending without recognition were on post-mortem examination discovered to be gastric atony with dilatation, the fundus of the stomach often resting on the pelvic apparatus. He drew a picture of the mechanical movements of the stomach and of the physiology of its action, the non-activity of the cardia in the process of digestion, excepting for the chemical action that took place there, and the expulsive movements of the pyloric portion in rhythmic waves. At this point he outlined a number of experiments to show that it was not due to any stimulation of the stomach contents that caused the muscularis of the stomach to begin activity. In the laboratory he had introduced into the stomach of dogs hydrochloric acid, the starches, peptones, albumoses, and the like, none of which had the slightest effect in causing muscular contractions of the stomach. He had, after all chemical and physiological means of stimulation had failed, introduced water in varying quantities, and air—immediately upon which the stomach action began—deciding, according to his view, that stomach muscle movement was wholly due to distention. Taking up the question of the actual conditions present in stomach fatigue, Dr. Turck cited the findings of Helmholtz and others, who had determined the purely chemical nature of the state, and of Mosso, who, upon injecting the blood of a fatigued animal into the circulation of one not under fatigue, had brought about a precisely similar state. These facts had led unavoidably to the conclusion that some changes had taken place in the blood itself; that there had been formed in the process of metabolism certain products which, for want of a better name, must be known as toxins, and that these toxins were capable of vast reproduction, if not interfered with, or unless antipoised. Dr. Turck had made exhaustive experiments along the same line in the laboratory, using dogs, rabbits, guinea-pigs, and horses. He had been able to inject the toxins of fatigue into the circulation from one animal into another, and had been able to accomplish fatigue even to the point of death. The profundity of the infection depended upon the completeness of the fatigue in the animal previously prepared and the amount of the toxins injected. But he had decided, and his experiments were bearing fruit, that if metabolism created products which were toxins, and that the stomach muscles which had created these toxins were capable of renewing their function after a period of rest, then it was inevitable that these toxins had their antibodies in the circulation; that when the state of fatigue had commanded the muscle to rest, that is, to cease creating these toxins, then it became a matter of time when the antibodies in the circulation would be in the majority, and by their presence restore the muscle to its former state. He deduced from these experiments, as well as from the nature and course of fatigue in the stomach, that rest was the means at hand for the cure of the condition. In dietetics no fast and hard rule could be laid down, the prime requisite being to give the greatest possible amount of rest, the shortest possible period of muscular activity, and the most serviceable foods to maintain the strength of the patient. He preferred two meals daily at the outset of treatment, one in the morning and one in the evening. Theoretically, a liquid diet was preferable, but practically he employed solid food in a finely divided state, properly prepared, with a sufficient amount of liquid to aid the stomach in the maceration of the mass, and to the end that it might be easily propelled into the intestines. If 3,000 calories were required of a mixed diet under normal conditions, it would be well to cut this down to 1,000, or even less, at the outset. For example, 100 grams breast of chicken, finely divided; 100 grams mashed potatoes, 100 grams toasted bread, 30 grams of butter, 300 c.c. hot, rich milk, which was first coagulated with rennet, in order that it might not be coagulated in the stomach, then shaken back to liquid and heated. Meat, macreated in water, then pressed for its extracts, crushed crackers, hard boiled eggs, and a bit of bran or ballast was another favorite form of diet for a change. If there was persistent anorexia the patient would lie on the right side for two hours following the meal. In connection with the diet, certain mechanical methods were employed, most of which he had found to be fruitful of harm rather than good in these cases. Lavage, galvanic and faradic electricity, exercise, and the more or less systematic bathings and drugs were some of the means which Dr. Turck failed to appreciate. The high frequency current with Oudin resonator he had found sometimes of advantage as an adjuvant.

Food Adulteration in Tennessee.—Mr. Lucius Brown, chemist, of Nashville, in a paper on this subject, said that milk was peculiarly liable to sophistication on account of its perishable nature and the readiness with which it could be adulterated. This took the form of watering, thereby reducing the quality, and the addition of preservatives to conceal or prevent decay. There was no form of food adulteration which was meaner than this. Milk was the standard food of young children, and was largely used for invalids, and the addition to it of such materials, which had a directly injurious effect on the digestion, and usually only took down the danger signal without removing the danger, should be relentlessly and severely punished. An examination of pure food legislation showed that twenty-two States had a regularly organized food inspection department. It was significant that Kentucky had just increased its appropriation for this purpose from $7,500 to $10,500. For the proper enforcement of pure food laws a qualified analytical chemist was an absolute necessity. Not less necessary was a wise and active pure food commissioner. There need be, on the part of the retailer, no fear of a hardship being worked on him by a proper enforcement of food legislation. He was always given an opportunity to put himself right, if he desired to do so, under any food laws. But in order to reassure him most States allow the retailer to be exempt from conviction if he produced a written guarantee from the wholesaler or his agent resident within the State.

Early Diagnosis and Early Treatment of Otitis Media.—Dr. N. C. Steele, of Chattanooga, said that careful observers knew there was a large number of adults who were permanently deaf in one or both ears. Of every one thousand seriously deaf ears, perhaps in 999 the disease was otitis media, and every aurist knew that chronic otitis media was generally incurable. He pointed out the general management and treatment of these cases, and closed by saying that the physician who looked carefully and intelligently after the patient's general health, as well as the local treatment, would have the greatest success in otitis media, just as he would in other local diseases.

Tuberculosis Cutis.—Dr. J. M. King, of Nashville, discussed this subject. He pointed out how the

initial skin lesion was formed, and discussed the differentiation of lupus from rosacea, eczema, and blastomycosis, which he said was rarely necessary. Radiotherapy, Finsen light, and violet rays were at present considered the most acceptable method of treatment, and should always be used if the patient was in reach of it. The X-rays and Finsen light were both satisfactory, but the ideal treatment was the combined use of X-rays and Finsen light.

Gastro-Intestinal Diseases of Children in Summer.—Dr. Zeb. L. Shipley, of Cookeville, divided the acute diarrheas of infancy on the basis of their etiology into two main classes, namely, those due to nervous origin, and those due to infection. Simple diarrhea was of nervous origin, manifested by an increased peristalsis. This increased peristalsis might be caused by various conditions acting through the central nervous system, or by the mechanical action of undigested food. Among the most important factors acting through the central nervous system were sudden changes in temperature, prolonged exposure to heat or cold, fright and fatigue. Food might fail of digestion from being unsuitable, or from the digestive organs being functionally weak. In either case the food became a foreign body. In this form of diarrhea the intestinal mucous membrane showed no pathological lesion, unless it be a slight hyperemia. The stools were increased in number and fluidity, and usually contained particles of undigested food. The chief factor in the treatment of this form of diarrhea was the removal of the cause. If the alimentary canal contained undigested food, this could best be eliminated by giving fractional doses of calomel and sodium bicarbonate, often repeated, until one or two grains had been given, or castor oil given in teaspoonful doses acted admirably. The cause having been removed, the diarrhea usually ceased. But should it continue, the treatment should be directed to the control of the excessive peristalsis. The author next devoted considerable attention to infective diarrhea, and said in the prophylactic treatment of it the infant should have the best possible hygienic surroundings, be given plenty of fresh air, and bathed frequently. Care should be taken not to overfeed the infant, as less food was needed in warm weather than in cool, and owing to the depression produced by the heat the child was less likely to digest its food. The infant should be lightly clothed, and kept as quiet as possible.

How Shall We Feed and Treat the Baby?—Dr. Herman Hawkins, of Jackson, in a paper with this title, laid down three cardinal rules: (1) A food should be given the baby which could be assimilated and given at regular intervals. (2) One should obtain the best possible hygiene of person and surroundings. (3) As little medicine as possible should be given. Each rule was discussed at considerable length, and several cases were reported.

Amyloid Degeneration.—Dr. C. P. McNabb, of Knoxville, defined this disease, and then discussed its etiology, pathological anatomy, symptoms, diagnosis, differential diagnosis and treatment. Treatment consisted of removal of the cause. If syphilis or chronic malarial cachexia was present, the patient should receive proper medication. If there was a chronic suppuration, the surgeon should be called early, and pus evacuated. The physician should be very watchful in cases of hip joint disease, old pyosalpinx, and ileorectal abscesses.

The More Serious Complications of Grippe.—Dr. E. A. Cobleigh, of Chattanooga, said that one of the primal results of influenza which was impressed upon him early was not simply the usual debility which accompanied most of the cases, and seemed out of all reasonable proportion to the appreciable conditions presented, but its indefinite persistence and extreme degree in quite a good many cases. These patients, wholly without regard to age or previous vigor, were too feeble for any movement or exercise beyond the minimum of vitality required to stay alive. This one element of debility—passive existence alone—was profound, and the sole cause for uneasiness. Instead of recovering within ten days or a fortnight, most of these sufferers lingered for weeks, sometimes even for months, and not a few dwindled on for a year or two, to die of sheer exhaustion at last. Cases were cited in point. The next condition, often occurring by itself, was marked by extreme nervousness. A third condition, not very frequent, but seen often enough to impress the clinician, was marked by mental involvement, occasionally amounting to prolonged delirium, to stupor little short of coma, to hallucinations during or even after convelescence from the real attack, and rarely to mania or continuing insanity. One of the most impressive and rare complications of grippe which he recalled ever having seen consisted in extreme clonic spasmodic seizures, particularly involving the heart, the diaphragm, and the muscles of respiration, with perfect mentation during it all, but giving rise to the most pitiable agony of fear of impending death. The writer discussed several other complications of influenza, and closed by saying that his object was to sound a note of danger, and to awaken physicians to the frequency of complications, and insisting on their prompt recognition.

Clinical Significance of Ascites.—Dr. Raymond Wallace, of Chattanooga, discussed this subject, and reported two instructive cases. One case illustrated unusual difficulty of making an accurate diagnosis. The unusually pronounced alcholic history in this case, with excessive peripheral arteriosclerosis, taken with the gastric symptoms and the presence of ascites, naturally led to a diagnosis of atrophic cirrhosis; and the absolute absence of any cirrhotic changes in the liver was a point of interest. The disappearance of the miliary carcinosis of the peritoneum after scrubbing and exposure to the air presented a phase analogous to the operative cure of miliary tubercle of the peritoneum.

Acute Septic Osteitis.—Dr. Jere A. Crook, of Jackson, stated that his experience in the treatment of this disease comprised only a few cases, and the greater number of them did not come under his treatment until they had become chronic. He presented a specimen of a tubular sequestrum that he removed from the femur of a ten-year-old boy. This was a case of chronic osteomyelitis that had been discharging freely for several months. Upon cutting down upon the femur a large cloaca was found, and a freely movable sequestrum. The opening was enlarged with a chisel, the sequestrum removed, and almost the entire cavity of the shaft was curetted. It was irrigated and packed with gauze and allowed to granulate from the bottom. Another case was one that he saw in connection with his father. This was a severe case of chronic osteomyelitis of the femur in a twelve-year-old boy. The disease had existed for a year, and the necrosis had progressed so far that the shaft of the bone was entirely consumed for about two inches. The ends of the remaining bone in this case were rounded with bone forceps,

all loose pieces removed, the two freshened ends put in apposition, drainage inserted, and the limb encased in splints. The result was unusually good. The bone united, the wound healed entirely, and the patient had a useful leg with only about three inches of shortening. Here amputation seemed indicated, but conservative treatment saved the limb. He had only amputated twice for esteomylitis, and then after making every effort to save the limb. Amputation should be the dernier resort, only to be done when necessary to save life. Other similar cases were reported.

Prophylaxis of Tuberculosis.—At the evening session of the second day this subject was discussed largely for the benefit of the laity, and speeches were made by Dr. John A. Witherspoon, Rev. Collins Denny, Captain A. J. Harris, and Mr. G. H. Baskette, representing the lay press.

Gall-Stones in the Common Duct.—Dr. W. D. Haggard, of Nashville, read a paper on this subject. He said that gall-stones in the common duct had been found once in every five cases operated by Robson, and once in every seven cases of the Mayos. It was estimated that 67 per cent. occurred in the duodenal end, 15 per cent. in the hepatic end, and 18 per cent. in the middle of the choledochus. They varied in size usually from a split pea to a nutmeg, although exceptional instances of much larger stones had been recorded. They were usually solitary, although more than one was frequently found. Freeman, of Denver, removed thirty-seven. They usually caused death in from six to twelve months, from cholemia, if the obstruction was complete and unrelieved. He had seen death ensue in six weeks, from cholemia and infection. He spoke of the colics being unsucessful in the majority of cases, and even when stones had been expelled it usually meant that others were retained. He exhibited eight stones removed from the common duct, after the patient had passed forty-five by the bowel during a period of five years, but had had no jaundice except once, for a period of two days. The duct was dilated so much that the bile escaped alongside of the stones. Stones were about as liable to ulcerate into adjacent viscera as to pass into the intestines. The ball-valve stone of Fenger, with its alternate stoppage and escape of bile, with varying jaundice, gray, then brown stools, was described. The pain, rigor, followed by a rapid rise of fever, sweating, sudden drop in temperature to normal, the appearance of jaundice, lasting a few days, and tenderness on pressure under the ribs, were described as a characteristic sequence in common duct stones, which might be repeated every few days or weeks. Suppurative cholangitis, acute and chronic pancreatitis, were detailed as complications. The absence of jaundice in 35 per cent. of Kehr's cases was dwelt upon, and the occurrence of primary cancer of the gall-bladder or ducts in 5 per cent. of the Mayos' cases, was mentioned. Absence of enlargement of the gall-bladder, with stone in the common duct, was explained in consonance with Courvoisier's law, and enlargement of the gall-bladder from other obstructions of the duct was instanced among many other differential points between calculus and non-calculus obstruction. Operation was not urged in acute obstruction by stone, but recommended in all cases that had been in existence for several weeks or longer, unless there were ecchymotic spots from long-standing cholemia. A quiescent interval between ague-like attacks, and in the absence of jaundice, was recommended for operation, if such an interval could be attained. Many specimens illustrating the various sizes, shapes, complications, and special symptoms of duct stones were exhibited. Choledochotomy and cholecystotomy were shown by large drawings. The Robson incision was recommended, and with a large cushion under the thorax the ducts could be brought almost to the surface by traction on the gall-bladder, and in a straight line; with the finger in the foramen of Winslow the stones could be palpated and extracted. The finger inserted into the duct, if possible, is said to be the best. The duct should be drained by tubage or gauze tied with catgut to the duct. Drains should be surrounded with gutta percha tissue. Cholecystectomy was advocated if one was absolutely certain of the patency of the common duct, if the gall-bladder was (*a*) contracted, suppurating, thick-walled and useless; (*b*) in gangrene; (*c*) neoplasms; (*d*) fistula into other viscera, and (*e*) in obstruction to the cystic duct. Robson's mortality in choledochotomy was 5 per cent. in the last 21 cases; 6.5 per cent. in 137 of Kehr's cases; 7 per cent. in 137 of the Mayos' cases, with an additional 4 per cent. who survived the operation, but died some weeks after. The Mayos did 30 consecutive cases without a death.

Circumcision.—Dr. E. A. Timmons, of Columbia, read a paper on this subject, in which he discussed its technic, method of anesthesia, after-treatment, and reported several cases.

Appendicitis.—Dr. John A. Gaines, of Nashville, read a paper on this subject, in which he cited several anomalous cases of this disease.

Etiology and Pathology of Appendicitis.—Dr. Walter Lenehan, of Nashville, contributed a paper with this title, which was based on the examination of twelve cases, which were reported in detail, after which the author discussed the etiology, prediposing causes, and immediate causes. He had found the following organisms in his cases: *Bacillus coli communis, Streptococcus pyogenes aureus, Staphylococcus pyogenes aureus, Bacillus influenzæ, Bacillus typhosus,* Klebs-Loeffler bacillus, *Bacillus tuberculosis,* and *Diplococcus pneumoniæ.* Some non-pathogenic organisms, notably the gas bacillus and a few yeast fungi, were also found, but were invariably associated with one or more of the pathogenic organisms. The organism most frequently found was the colon bacillus. The author drew the conclusion that any micro-organisms capable of producing inflammatory changes in any part of the body might also produce the same changes in the appendix.

Laryngeal Diphtheria.—Dr. O. H. Wilson, of Nashville, stated that the objects of his paper on this subject were, first, to emphasize the importance of early mechanical relief when mechanical obstruction threatened life, and one should not delay until depression was marked. He should remember that rapidity of progress was the characteristic feature of laryngeal diphtheria. One did not know what would happen before his next visit. Second, that while in no other operation did skill show to better advantage, intubation was not a difficult procedure, but could be learned easily by practice. An early operation, though possibly awkward, was better than waiting to give a moribund case to an imported consultant. Moral: Don't wait; intubate.

Tabes Dorsalis.—Dr. G. P. Edwards, of Nashville, discussed this subject, saying that the disease predominated in males ten to one. A neuropathic heredity was an important predisposing factor. The disease might appear in childhood from hereditary

syphilis, but in the acquired form it occurred between twenty-five and fifty years of age, the greater proportion occurring about the age of forty years. The symptomatology of tabes embraced almost every function in the body, the clinical features of which could not be enumerated within the scope of a short paper; but the author mentioned the chief symptoms, and the more important clinical features. The treatment should be directed, first, to the removal of any syphilitic processes present, or suspected; to the improvement of the general health, to stimulate the function of the cells impaired but not lost, to encourage restoration of coordination in the muscular system, and correct any incidental disorders which might retard or complicate the desired result. The author believed that any stage or condition of tabes might be improved or benefited by properly directed treatment. The development of the degenerative changes could be arrested completely in nearly every pre-ataxic case, and that much of the lost function could be restored. He believed that these results might also be obtained in a majority of the ataxic cases, and that this majority was reduced somewhat in proportion to the duration and intensity of the ataxia and the abuse of the specific remedies employed. The author's clinical observation, aggregating fourteen cases in his private work, had been uniformly satisfactory. In these fourteen cases, embracing a variety of conditions and degrees of advancement, all had responded to treatment in a most satisfactory manner. In every case the disease had been arrested and continued so to the present time. In nine cases marked improvement in coordination, gait and general health had persisted. In five cases the knee-jerk had been restored to normal; all painful sensory symptoms had disappeared; dribbling of urine had ceased, and little evidence of the diseases remained. In two cases the pupillary reflex to light had returned to normal. In six cases the Rhomberg sign was barely noticeable with both feet close together and the eyes closed. In two cases the patients could stand upon one foot with the eyes closed. The author had demonstrated to his own satisfaction, at least, that the X-ray, when of sufficient penetration to obliterate the shadow of bony structures, would stimulate cell activity in the diseased cord, facilitate the restoration of the lost function in cells not completely destroyed, and relieve the crises and other lightning pains. May not one hope for advancement in the therapy of this disease as well as in tuberculosis, cancer, and many other conditions as witness in the advanced therapeutics of to-day?

Alcoholic Insanity.—Dr. I. A. McSwain, of Paris, offered the following suggestions on this subject: (1) The children of drunken and debauched parents ought, for obvious reasons, to be taken away from them and placed in decent homes, or removed to industrial institutions provided by the State. This would check their hereditary tendencies to drunkenness, and therefore reduce the number being raised up to become a burden to the State in the way of paupers, criminals and lunatics. (2) Young people, who early in life contract the pernicious habit of drinking should also be removed from the temptation of their environments, and placed in institutions in which they should be taught some useful employment, and restrained from vicious habits. (3) The drinking man, as soon as he began his spree, before he was crazed by it, should be taken into custody, not as a mere nuisance, but as a dangerous man, or one likely to become so, because of insanity in the incipient stage. (4) The confirmed drunkard, the chronic alcoholic subject, should on no account be allowed to exercise his personal liberty in the pursuit of delusions which result from prolonged excesses.

The following papers were also read: "Some Recently Collected Statistics on the Increasing Frequency of Abortion; Some Causes for the Same," by Dr. J. L. Andrews, of Memphis; "Keratosis Follicularis," by Dr. G. P. Edwards, of Nashville; "Bone Surgery," by Dr. R. A. Barr, of Nashville; "The Physician as an Advertising Medium," by Dr. F. J. Runyon, of Clarkesville.

Officers.—The following officers were elected: President, Dr. Cooper Holtzclaw, Chattanooga; Vice-Presidents, Dr. S. W. Woodyard, Greeneville; Dr. Alfred Moore, Memphis; Dr. A. F. Richards, Sparta; Secretary, Dr. George H. Price, Nashville; Treasurer, Dr. W. C. Bilbro, Murfreesboro; Delegates to American Medical Association, Dr. W. J. Miller, Johnson City; Alternate, Dr. G. O. Bicknell, Madisonville; Dr. W. D. Haggard, Nashville; Alternate, Dr. Louis Leroy, Nashville.

Memphis was selected as the place for holding the next annual meeting; time, second Tuesday in April, 1906.

BOOK REVIEWS.

Studies in the Psychology of Sex. Sexual Selection in Man. By Havelock Ellis. F. A. Davis Company, Philadelphia.

Havelock Ellis continues his studies in the origin and development of the ruling sense of organic nature. In this volume he discusses the influences of touch, smell, hearing and vision. Touch he shows is the most intimate and vital of the primary sexual characters.

No other English author has contributed so luminously to the great subject as our author, proving at the same time scientific and interesting. The great tendency to pander to the prurient is carefully suppressed, and the present volume, like his previous ones, is eminently sound and satisfactory.

On the subject of the relation of music to sexual attraction, selection, etc., the author is not in his usual judicial mood. Whether he lacks a musical training, and thus is outside of the gamut, is not apparent, but he is strangely misinformed and, we believe, lacks psychological insight regarding the powerful impulse to sexual thought that music is capable of exciting in a large number of people in all strata of society.

Treatise on Diseases of the Skin for the use of advanced students and practitioners. By Henry W. Stelwagon, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College and Woman's Medical College, Philadelphia; Dermatologist to the Howard and Philadelphia Hospitals, etc. Third edition with 220 illustrations in the text, and 26 full-page lithographic and half-tone plates. W. B. Saunders & Company, Philadelphia, New York and London.

This treatise was so very well reviewed by us when it first appeared, that we can only repeat our good opinion of its efficiency from the general practitioner's standpoint. In this edition the X-ray and high frequency current are given due notice, and the Finsen light treatment has been enlarged upon. The illustrations are as good as would seem possible in a work of this price.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 87. NEW YORK, SATURDAY, SEPTEMBER 9, 1905. NO. 11.

ORIGINAL ARTICLES.

THE RECOGNITION AND TREATMENT OF PANCREATIC INFLAMMATION.[1]

BY CARL BECK, M.D.

OF NEW YORK;

PROFESSOR OF SURGERY IN THE NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

No surgical field has been so much neglected as that of pancreatic diseases, and up to the present only a sporadic interest is shown in it.

This deplorable fact reflects the whole history of the pancreas, which was probably known to Hippocrates, but certainly not understood by our great ancestor, as is evident from his essay Περὶ ἀδένων. Hippocrates assuming that all glands of the body consisted of κρέας (flesh), it is not astonishing that this gland was given the term Πάνκρέας (all flesh). Eudemus, in the fourth century, advanced the theory that the pancreas discharged a saliva-like fluid, which served the purpose of digestion, but Herophilus and Galen denied this assumption, claiming that the pancreas simply served as a kind of support for the stomach and the large blood-vessels. For centuries thenceforward no interest was taken in this gland; but in 1642 Georg Wirsung [not Wirsung], the German demonstrator at the anatomical institute of Padua, in Italy, recognized the duct of the pancreas which still bears his name. More than a hundred years later Santorini detected the second duct.

The discovery of the ferments of the pancreatic gland by Claude Bernard in 1855 revived the scientific interest in this important organ, and the conjoined investigations of physiologists like Schiff, Bidder, Pawlow, Heidenhain, of pathologists like Cruveilhier, Rokitansky, Virchow, Recklinghausen, Klebs, Orth, Ziegler, Langerhans and Dieckhoff, and of clinicians like Friedreich, Frerichs, von Mering and Minkowski gave us an insight in its functions and their disturbances. Especially the discovery of the latter authors, that diabetes followed the extirpation of the pancreas in lower animals (1889), and furthermore the brilliant development of abdominal surgery, led to a better understanding of the physiological, anatomical and clinical features of the organ. The classical contributions of Gussenbauer, who was the first to operate on the pancreas, of Körte, Oser, Hahn, Senn, Robson, Moynihan, Flexner, Halsted, Mayo and Woolsey have also helped to establish the physiology as well as the surgery of the organ upon a new basis.

To appreciate the diseases of the pancreas the anatomy as well as the topography must be thoroughly known. In order to recapitulate the important anatomical points it should be remembered that the pancreas is an elongated gland, situated behind the stomach on a level with the twelfth dorsal or the first lumbar vertebra, where it crosses the aortic foramen of the diaphragm. Its length is five to seven inches, and its weight about two to two and one-half ounces.

The organ is divided into the head, the body and the tail. The hammer-shaped head is situated in the concavity of the duodenal loop on the right of the spinal column, and is deeper located than the other parts of the gland. At its posterior surface the ductus choledochus communis passes down in a groove—sometimes in a canal. Anteriorly it comes into contact with the flexura coli hepatica, and posteriorly is strikes the vena cava ascendens.

The body is separated from the left crus of the diaphragm by the left suprarenal capsule and from the right by the vena cava ascendens. The posterior surface rests on the aorta descendens and the lymph-vessels accompanying it, and the inferior surface rests on the duodenojejunal flexure. It is furthermore situated between the branching off of the truncus coeliacus and the arteria mesentica superior. From the arteria coeliaca the splenic, hepatic, and gastroduodenal arteries, and the ramus pancreatico-duodenalis superior branch off, while the superior mesenteric artery sends off the arteria pancreatico-duodenalis inferior. All these arteries send branches to the adjacent organs.

Below the body is found the solar plexus and the lymph-vessels arising from the cisterna chyli. The tail is connected with the hilum of the spleen by the pancreatico-splenic ligament. Posteriorly it is bounded by the left kidney and anteriorly by the flexura coli lienalis. The insertion of the transverse mesocolon is found below the inferior pancreatic margin.

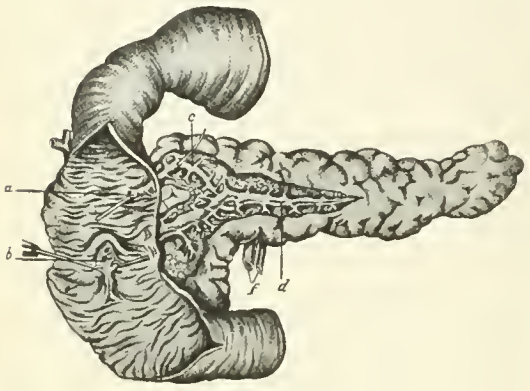
Some also distinguish a neck of the pancreas indicated by a slight inversion at the left of the head.

As mentioned above, the pancreas possesses a large and a small duct, both of which open separately into the duodenum. The large duct, called the Wirsüngian, passes straight from the tail to the head, where it alters its direction by turning downward and backward, uniting with the ductus choledochus communis, and thus forming the ampulla of Vater. An inch above the Santorinian duct opens into the duodenum after it continues forward where the Wirsüngian canal makes its turn. The wall of the Wirsüngian canal is thin and smooth; its larger diameter amounts to three millimeters. Its structure is like that of the paro-

[1] Paper read before the Annual Meeting of The American Therapeutic Society, Philadelphia, May 5, 1905.

tid gland, but its texture is looser and softer. Areolar tissue, dipping down in its interstices, so that it is divided into lobes, surrounds it. These lobes are again divided into lobules, forming a constellation of alveoli, which connect with the branches of the duct. Columnnar epithelium lines the minute ducts, while the alveoli are tubular and lined with columnar cells.

Fig. 1.



Pancreatic Ducts.

a Ostium duct. Santorini; *b* Papilla Vateri; *c* Duct, Santorini; *d* Duct, Wirsüngianus; *f* Sup. mesenteric vessels.

The distribution of the branches can be well studied now by the Roentgen rays (injection method). The intraalveolar tissues are filled with groups of small polygonal cells, with a round nucleus and a refractive cell body, known as the "islands of Langerhans."

The secretion of the pancreas is clear and slightly viscid. The taste is salty. Its specific gravity is 1,030 and the reaction alkaline. It contains three ferments, viz.: It emulsifies fats and splits them into fatty acids and glycerin; it changes the albuminates into peptones and influences the carbohydrates like the secretion of the salivary glands; it changes starch into dextrin, maltose and grape-sugar.

Our knowledge of the symptomatology of pancreatic diseases is still in the infantile stage. Great difficulties in an exact diagnosis are offered by the deep situation of the gland and its intimate contact with the neighboring organs, viz., the stomach, duodenum, liver and biliary tracts. Thus it is sometimes impossible to learn whether the pancreas itself or one of the neighboring organs is primarily affected. Physiology, however, frequently comes to our rescue. The specific physiological functions of the organ, described above, are disturbed as soon as the pancreas becomes diseased. Thus we may be able to make a diagnosis from the cessation of the functions, viz., the non-division of fat into fatty acids and glycerin (fat-diarrhea) and the discontinuation of the regulation of the sugar-consumption (diabetes). If, while biliary disturbances are absent, much fat is present in the feces, pancreatic disease may be suspected. The presence of sugar in the urine corroborates the diagnosis, if there are other symptoms pointing to pancreatic disease. The absence of sugar alone proves nothing against it.

The other signs of pancreatic disease are not reliable. Of course, pain is a valuable symptom, and if present in the pancreatic region may point to acute and chronic inflammation as well as to neoplasm, cyst and lithiasis. But sometimes the pain is found in the epigastrium and at other times towards the back only. Sometimes there are colicky attacks, followed by more or less grave collapse, such conditions often being mistaken for "cramps of the stomach" or colicky attacks of the biliary or intestinal sphere. Thus the character of the pain in these disorders is not so specific that it could be utilized for diagnostic purposes. Only after excluding the disorders mentioned can we regard the pain in this region as emanating from a pancreatic affection.

24. Small intestine.
25. Bladder.

The same may be said of the cachexia following pancreatic disease, since this important symptom is also found in the various affections of the stomach and the duodenum, as well as with neoplasms of liver and gall-bladder. That the stomach and intestines are more or less disturbed in pancreatic disease hardly needs to be emphasized.

But they resemble the various diseases peculiar to these organs so much that differentiation cannot be established on that basis. A more reliable distinction can be made if jaundice is present, since this symptom is nearly always observed in disease of the pancreatic head, provided it is of an inflammatory character or caused by abscess, neoplasm or fibrous degeneration. This is most natural because the common duct becomes compressed. In such cases the gall-bladder will be extremely enlarged without being tender, while the duct is obstructed by the presence of biliary calculi and becomes small and tender on touch. In other words, in chronic jaundice, complicated with considerable enlargement of the gall-bladder and not showing colicky attacks in the biliary sphere, a diseased pancreatic head should be suspected. A pancreatic calculus can be readily detected by the Roentgen method, but it is difficult to differentiate it from a biliary or renal concretion.

Palpation can be relied upon in thin individuals when the organ is enlarged by inflammatory processes or abscess-formation. In such cases it generally overlaps the small curvature of the stomach. The examination is best done while the patient is anesthetized and after the stomach and bowels have been well evacuated. But if the conditions are not very favorable, the intumescence may be taken for a tumor at the posterior surface of the stomach or in the omental bursa or the glands of omentum or mesentery. Cysts of the mesocolon or even inflamed retroperitoneal glands may be also mistaken for a diseased pancreas. By the artificial dilatation of the stomach by air or water, the organs to which the intumescence belongs can, at times, be defined. Percussion is of value only when the tumor is very large. As general causes of chronic pancreatitis syphilis, mercurial poisoning, arteriosclerosis and injuries are to be considered.

In summing up it becomes evident that there is not one sign which is absolutely pathognomonic for pancreatitis. Only by carefully considering the history, the mode of the onset and the various combinations of the different symptoms, a diagnosis can be made in a number of cases.

We distinguish three forms of pancreatitis, viz., the acute, subacute and chronic form. The classification of Fitz, who has done so much in elucidating the pathology of the pancreas, in hemorrhagic, suppurative and gangrenous pancreatitis is tempting, but not opportune, for the reason that one of these forms passes into another. In other words, it would rather indicate a variation degree or stage than a difference in kind.

The predominant symptoms of acute pancreatitis are: Sudden pain in a previously healthy individual at the upper region of the abdomen, followed by collapse and vomiting. Constipation is always present. Soon after the first symptoms the abdomen becomes distended. The urine contains sugar and sometimes albumen. Slight jaundice is frequently observed. If the patient survives the first stage, his face assumes the Hippocratic expression. The temperature is of the irregular septic character, that is now subnormal, then excessively high, while the pulse rate is extremely high, with poor quality. The tenderness and rigidity of the recti muscles makes it difficult to palpate the pancreatic intumescence without the aid of anesthesia.

In differentiating the possibility of intestinal obstruction, perforative appendicitis, perforative duodenal or gastric ulcer, ulcerative or suppurative cholecystitis and inflammation of the bile ducts must be eliminated.

The preference of acute pancreatitis is for healthy men of thirty to forty years.

It is reported by Osler and Manges that cures were effected in patients whose inflamed pancreatic glands were exposed by laparotomy and left untouched. We might safely say that in the great majority of cases the course is grave from the beginning. Those patients who survive the severe shock in such cases still succumb to necrosis of the gland or to abscess-formation, provided no effort is made to drain off the hemorrhagic effusions generally found in abundance at this stage. If it is realized that in acute pancreatitis a high degree of hyperemia is always present, which leads to hemorrhage in the tissues, the importance of early discharge of these fluids, so favorable for bacterial development, is self-evident.

In these cases, in which the process virtually starts as a hemorrhage (pancreatic apoplexy), the inflammation being the consequence of the bloody infiltration of the tissues, early surgical interference is so much more promising.

In all cases of acute pancreatitis the autopsy *in vivo* as well as *in mortuo* revealed the fat necrosis either in the gland itself or in some of the adjoining tissues. Whether this unfortunate phenomenon is the consequence or the cause of the hemorrhagic inflammation is still *sub judice*.

In the subacute form the symptoms are virtually the same but of a milder degree, the collapse especially being less sudden and less severe and sometimes entirely absent. The superior abdominal region swells less rapidly, and the nausea is less marked. The meteorism being less extensive, palpation gives better chances, so that the swollen pancreas may be well defined. The constipation is followed by diarrheic stools of a fetid odor, containing pus or blood. The pulse is not as excessively high as in the acute form and varies between 80 and 110. The morning temperature is sometimes normal, whereas in the evening the thermometer registers from 103° to 105° F. The pain localizes itself in the epigastrium. The grave symptoms may gradually disappear, while the increasing cachexia and the presence of albuminuria tell of the continuous pathological changes. Then an abscess often forms, in which case a tumor develops, projecting into the upper region of the abdomen. Sometimes it burrows into the loin or below the dia-

phragm, where it establishes itself as a subphrenic abscess. It is in just such cases that surgery promises good results. Especially, if gangrenous portions of the pancreas become imbedded in circumscribed foci, peritoneal adhesions enveloping them, free exposure and draining may be directly life-saving.

In chronic pancreatitis the inflammatory process generally starts in the ducts, bacteria invading them from the duodenum or the common duct (ascending inflammation). Sometimes the inflammation is caused by constitutional disturbances like syphilis or abuse of alcohol (hematogenous inflammation). Inflammatory induration of the pancreas is also produced by the partial or complete obstruction of the ducts by concretions, or cicatricial stricture or by tumors. Other important etiological factors are injuries of the abdomen, directed against the pancreas.

Autopsies, made in cases of syphilis, arteriosclerosis, alcoholism, interstitial hepatitis, and also in cases of diabetes, reveal a more or less extensive fibrous degeneration in the pancreas. In syphilis the signs of periarteritis are found, the adventitia being infiltrated with lymphoid cells and the capillary network disappearing around the acini.

The symptoms of chronic pancreatitis are: Gradual and painless onset, gastric disturbances, constipation or diarrhea and pain in the epigastrium, jaundice and cachexia. Albuminuria is always present and glycosuria seldom absent. The temperature is generally normal in the morning and rises to 101° to 102° F. in the evening. The pulse is usually normal, and if jaundice be present, abnormally low. At a late stage the blood-degeneration finds its expression in hemorrhages from nose and intestine. Blood may be vomited and the integument shows petechiæ. The presence of all these signs, however, does not make the diagnosis *a priori*, since they may all be observed in other chronic diseases of the gastro-intestinal tract or in cholelithiasis, carcinoma of the liver or cholecystitis.

Sometimes the thickened pancreas can be palpated. But then carcinoma will be thought of first, the contradiction, however, being furnished by the continuous or temporary decrease of the tumor in favorable cases.

The course of chronic pancreatitis is slow. In the majority of cases fibrous degeneration may gradually destroy the functions of the organ. Sometimes there are secondary changes in the adjoining tissues, like compression of the duodenum and the common duct or thrombosis of the portal vein. Such secondary conditions are especially accessible to surgical interference.

No doubt many cases of pancreatitis, not only of the chronic, but also of the acute type, could be saved by surgical interference.. Why, up to the present, this has been done only to a limited extent explains itself fully by the great difficulty of diagnosis, which makes the surgeon hesitate to risk an operation in a region, the accessibility of which is, as described above, impaired by its topographic peculiarities. He will also fear the vascularity of the organ which makes hemostasis extremely difficult. Clinical experience further shows that interference with the pancreatic parenchyma not only inhibits nutrition of the area involved, but also irritates the adjoining organs, a condition which is frequently followed by fat-necrosis. Another aggravating circumstance is the fact that the patient is generally in a state of greater or less collapse.

If, however, it is realized that acute pancreatitis is virtually an infectious process not unlike acute appendicitis, the difference being that the virulence in the inflamed pancreas is still greater, its ferments being an additional factor for the greater intensity of the toxic nature of the affection, we understand that only under extraordinary circumstances medical, or expectant treatment, rather, is successful. It is natural, therefore, that surgery has tried to approach the focus of infection with a view of discharging and draining off the infectious virulent exudates at an early stage, instead of waiting until the process concentrates itself, so to say, into an abscess. Of course, if the patient survives the acute stage, it would be most desirable to operate on a well-defined circumscribed abscess-focus, and, in fact, if we could hold the patient over till this stage is reached, such treatment would be the one *par excellence*. But how many do survive? As long as the clinical experience is so sad in this respect it seems to me that, in spite of all the difficulties presented, the surgeon should, instead of hoping for improbable developments, not hesitate to do what he used to do in all other infectious processes which his scalpel has a chance to reach.

In fact, Nimier, Robson, Lund, and especially von Mikulicz, are strongly in favor of early operation for acute pancreatitis, Nimier incising the pancreas and packing it, whereas Robson is for an incision below the umbilicus and counter-incision below the rib arch. Lund and von Mikulicz divide the gastro-hepatic ligament and drain the omental bursa extensively, and eventually expose the diaphragm after rib resection.

Referring again to the uncertainty of the symptoms, which may just as well be pathognomic for other abdominal disturbances, one factor deserves the greatest attention, viz., that these other disturbances demand laparotomy likewise. Practically, therefore, the surgeon need not fear that after having opened the abdomen he will be embarrassed by the presentation of pathological conditions which may not require surgical interference. In practice the surgeon will consequently open the abdomen whenever there are symptoms of the nature described, which would point to the possibility of the presence of pancreatic inflammation. If the intra abdominal inspection reveals the presence of fat-necrosis, pancreatic inflammation and exudation should be assumed, and if palpation verifies it the exudate must be discharged and the area drained.

The *modus operandi*, which is virtually identical with that in cholecystotomy, would therefore be the following: An incision is made alongside the outer margin of the rectus muscle. If a tumor was felt in the median line, the incision may reach from the xiphoid process to the umbilicus. If the rib arch proves to be in the way, Marwedel's method of resecting the costal arch may be advisable. The further procedures must bear an exploratory character.

At first the ducts are inspected and palpated, in order to ascertain whether there be a calculus in the Wirsüngian or the common duct, or in the papilla Vateri. In this event, extraction of the calculus must be followed by duct-drainage. If such steps are contemplated, large gauze pads must be ready to mop up the secretions as they escape. If there is a pancreatic exudation it must be discharged. During these manipulations the abdomen is frequently irrigated with hot sterile water. I regard the use of these simple means as very important in intra-abdominal operations, because, in the first place, they stop surface-hemorrhage, permitting the surgeon to see more clearly. At the same time they remove exudations and blood-clots in an easy, mechanical manner and eliminate, therefore, a favorable soil for bacterial development. The repeated hot-water irrigations, to a certain extent, also possess bactericidal properties. It is true they cannot kill bacteria directly, because they are not hot enough, but they affect bacteria in such a manner that their resistance is lowered. After the field is thoroughly cleaned, packing with three per cent. iodoform gauze is done. If the patient is in grave collapse, ether should not be given, and local anesthesia administered instead.

In the subacute, or chronic form the patient can always be given the benefit of a full general anesthesia.

If the pancreatitis is caused by pressure from cholelithiasis or cholecystitis, or both, it will often be relieved indirectly by cholecystotomy. The compression ceasing then, the hyperemic condition of the pancreas naturally disappears. If the pancreatitis be caused by retrograde infection from the gall-bladder or the common duct, the pancreatitis may also subside after cholecystotomy. If not, the pancreatic duct must also be drained.

My own experience with acute pancreatitis has not been very encouraging. Among three cases I have lost two. In none of them could an accurate diagnosis be made before the abdomen was opened. In one of the fatal cases the pancreatic focus was of a pyemic nature and developed after puerperal infection. The second developed on the basis of chronic cholecystitis, which caused infection of the pancreas. The third case was due to a severe injury sustained by a woman of thirty years, who was thrown against the projection of a strong table while wearing a heavy corset, the latter apparently having aggravated the violence. Although the patient was in considerable collapse, the hemorrhagic exudation could be well drained off, and recovery was speedy.

In a fourth case the diagnosis cholelithiasis was made by an excellent diagnostician, who requested me to open the gall-bladder. He apparently had good reasons for his assumption, because the patient, a woman of fifty-five years, had numerous colicky attacks in the region of the gall-bladder and was jaundiced repeatedly in the course of the last seven years. Lately the general condition became impaired, the loss of flesh also being marked. The urine contained no albumen, but traces of sugar. The epigastrium, as well as the region of the gall-bladder, was tender and the liver slightly enlarged. After the abdomen was opened at the outer margin of the right rectus muscle, a small, fibrous gall-bladder was found of the shape which I described in the *Deutsche Medicinalzeitung*, May 7, 1898, as "Hour-Glass Gall-bladder." It contained no liquid whatever. But there were a number of adhesions between gall-bladder, liver, omentum, duodenum and colon, covering a hard, nodular mass, which was recognized as the head of the pancreas. After dissecting the adhesions and isolating the pancreatic head as much as possible, I closed the abdomen without interfering with the gall-bladder at all. The patient made an uninterrupted recovery and has had no colicky attacks since. It seems to me that the patient suffered from cholelithiasis for a number of years, small calculi having probably been present, which, while causing cholecystitis and circumscribed peritonitis, were expelled during the numerous and violent paroxysms, leaving a much degenerated gall-bladder. In the meanwhile the peritonitic irritations had produced the adhesions which extended to the pancreatic head and obstructed the duct more or less, thereby causing retention of the pancreatic secretions.

I reserve to myself the privilege of describing these cases more fully in a future communication. All in all, I have no doubt that pancreatitis is of much more frequent occurrence than is generally assumed, and if the conjoined efforts of the family physician and the surgeon will be in the direction of more frequently suspecting pancreatitis in apparenty obscure abdominal ailments, our statistics will soon present an altogether different appearance.

Treatment of Pertussis.—In the treatment of whooping-cough, R. Rahner (*Munch. med. Woch.*, June 20, 1905) speaks well of the action of antitussin, an ointment consisting of difluordiphenyl and fats, which is applied locally to the neck and chest. After five days the intensity and the frequency of the attacks will be much diminished. Besides being an antispasmodic, the drug is also an excellent expectorant, and more serious complications, such as bronchopneumonia, are most certainly avoided. Since it is absolutely harmless, it may be used for nurslings. Bad results were never seen, and failures occurred only in the case of infants suffering from rachitis or broncho-pneumonia.

THE CARE OF THE INFANT.[1]

BY HENRY P. DE FOREST, PH.B., M.S., M.D.,
OF NEW YORK;
LECTURER ON OBSTETRICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, LECTURER AND DEMONSTRATOR IN OBSTETRICS, LONG ISLAND COLLEGE HOSPITAL, ASSISTANT PATHOLOGIST, METHODIST EPISCOPAL HOSPITAL.

I HOPE you do not expect me to set before you this afternoon a mental feast of original ideas about the care of infants, nor to give you an exhaustive list of all that has been written upon this subject in Germany, Morocco, England and Siberia since the infancy of Cain and Abel down through the ages to the present time. For those who desire such a bibliography I refer you to the Library of the Medical Society of the County of Kings.

I fear indeed that little that I shall present to you in the forthcoming paper will be original, for the early care of infant is a subject that has received attention since the birthday of mankind. All that any one individual can do in this line is to accept at the outset the teachings of some one who has trodden the path before him, and then from time to time record the results of his own personal observation and experience. In my own case I had the singular good fortune to have as "mentor, guide and friend" a man whose exceptional mental gifts had been cultivated by the benefits of collegiate training and the medical course of the New York College of Physicians and Surgeons. His Alma Mater then sent him abroad for two years' work in the best maternity hospitals of the world, and upon his return installed him as the resident obstetrician in an institution, then in its infancy, but now a child of lusty growth, the Sloane Maternity Hospital. In the ideal environment of the Sloane, Dr. Ervin Alden Tucker lived for five years, seeing thousands of cases, regulating every minute detail in the management of mother and child, and teaching those fortunate internes who, like myself, came under his authority with that accurate knowledge, lucidity of statement, practical application of many theories, and innate enthusiasm that later during the few brief years of private practice quickly caused him to be recognized as one of the leading obstetricians in this or any other country. I was indeed fortunate to have had the benefit of this man's influence and instruction. So far as possible I still follow the directions he laid down. These directions I propose to embody in the present paper, together with such results of personal experience as time has brought me.

As a foreword let me interpolate the answer that I have formulated to the oft-repeated question of the expectant mother to the physician engaged to attend her at her approaching confinement. "What articles shall I have in readiness for the proper care of myself and of the baby?"

This question would doubtless be answered differently by every physician who has been in practice for five years. To try and secure a composite photograph of the views of different individuals I proposed this question to my class of students at the Long Island College Hospital, with the request that a written list be handed me by each student, made out after a conference, not with the text-book alone, but also with his medical preceptor. Sixty lists were handed me, containing, as a rule, a well-considered list of articles. These lists were then tabulated, duplicates were eliminated, and the resulting list was discussed with the supervisors of nurses of six of the leading hospitals in the city and with a large number of trained nurses. The idea was to secure a list of articles that should be within the reach of all save the very poor, and not to include non-essentials. The net result is as follows:

ARTICLES TO BE IN READINESS FOR AN APPROACHING CONFINEMENT.

For Use of the Mother.

Towels, freshly laundered	6
Sheets, freshly laundered	3
Rubber Sheet	1
Labor pad, made of newspapers and clean muslin or "Quilted Mattress Protector"	1
Lochial guards, preferably of gauze and paper wool, or of cotton waste, or of cotton gauze, sterilized	36
Binder, abdominal, 18 inches wide and circumference of hips	3
Binder, breast, made from pattern	2
Safety pins, "Clinton," Large No. 3	24
" " " Medium No. 2	48
" " " Small No. 1	36
Wash bowls, earthen or agate	2
Water pitcher, earthen or agate	1
Slop jar	1
Absorbent gauze for wash cloths, etc. (yards)	10
Fountain syringe, one gallon	1
Glass douche tip, for syringe	1
Glass drinking tube	1
Douche pan, white enamel or agate ware	1
Hand brushes	2
Antiseptic tablets, 7½ grains, bichloride, blue	100
Lysol, fluid ounces	8
Vaseline in a tube	1
Chloroform, Squibbs, fluid ounces	4

For Use of the Baby.[1]

Flannel bands, 6 inches wide, 30 inches long	4
Diapers	24
Woolen blanket, soft, old, and about a yard square	1
Flannel petticoats	3
Slips	4
Knitted flannel shirts	2
Bath tub, white, at least two feet long on bottom	1
Bath thermometer	1
Bath aprons, flannel and rubber	1
Hot water bag	1
Absorbent cotton (pounds)	1

1 At time of labor room should be cleared of all needless articles and ornaments. Protect carpet with layer of newspapers with sheet tacked over them. Clear bureau, mantel and table tops, protect with papers and cover with clean towels ready for instruments, etc. Have plenty of hot and cold water and ice in readiness. Have these supplies at hand, in good order, and easily accessible.

1 Read before the Associated Physicians of Long Island, Manhattan State Hospital, Central Islip, L. I.

Olive oil (sweet oil), fluid ounces	4
Castile soap	1
Baby basket to hold dressing materials, etc.	1
Baby powder (lycopodium, 3; zinc stearate, 2; Boric acid, 1;) ounces	4
Powder for cord (salicylic acid, 1; zinc oxide, 1;), ounces	1
Boric acid (pounds)	1
Salt shaker for boric acid	1
"Lightning" jar, ½ pint, for boric acid solution	1
Scissors, pin cushion, needles and thread.	

This list is printed upon the Standard Library Bureau card (6 in. x 6 in.) for medical work. On the front of the card a space is left for the name, address and telephone number of physician, patient and nurse. On the back page, after it has been folded vertically, is the special direction:

"Urine: Send half a pint of morning urine to doctor's office every two weeks after the sixth month."

This card I have now used for three years, and have heard many comments on it from the householder's point of view. I have found it, if not ideal, certainly of material use to both physician, nurse and patient. I trust the discussion here will render the list still more valuable by proposed amendments.

Let me now present for your consideration a brief personal statement of my mode of procedure in the conditions that may arise in the care of infants during the first month of life, and which primarily come under the rule of the obstetrician. Only the more common ailments will be considered; the rarer forms of infantile anomalies and pathology will be eliminated more or less completely.

Obstetric Accidents which may happen to children during or soon after birth.

In anticipation of the possible occurrence of such accidents certain preparations should always be made as soon as labor is fairly begun. A bath-tub, partially filled with hot water should always be in readiness and an abundant supply of hot water should be continuously provided. Upon a sterile towel on a table near the bedside should be arranged two pairs of artery forceps, scissors and tape for the cord, a curved needle threaded with a yard of heavy silk, tongue forceps or a small double tenaculum for seizing the baby's tongue if necessary, a plate upon which are spread a dozen thin pledgets of absorbent cotton dampened with boric acid solution, to use for the child's mouth and eyes, a gauze compress for insufflation, and a bottle of 2 per cent. nitrate of silver solution with a dropping tube for the instillation of the eyes. All the supplies appertain to the child, any one of which may be needed at an instant's notice. Have them ready beforehand.

Cleansing of the Mouth as soon as the head is born may be regarded as the first step in the actual medical care of the infant, for with the establishment of pulmonary respiration the separate existence of the new-born actually begins. The mouth should be cleansed as soon as it emerges over the perineum. The small, thin borated flakes of dampened cotton are to be used, wrapped around the tip of the little finger, and the mouth thoroughly wiped out. Proper attention to this detail may prevent asphyxia or a later foreign-body pneumonia from inhalation of blood or meconium. Several such pledgets of cotton are required and the child not infrequently makes efforts to breathe while this is being done.

Cord around the Neck. Most of our books and teachers lay great stress upon the importance of removing the cord from around the neck as soon as the child's head is born. Formerly I believed in and practised this myself, but I must say that, with greater experience, I have come to attach less and less importance to this procedure. When the child's head is born it is best to remove the cord at once if it can be quickly and easily done, as when the cord is long and loosely encircles the neck. If the least difficulty be experienced in removing the cord it is best to pay no further attention to it but proceed at once to the completion of the delivery. Less time is thus lost and time at this stage of labor is of vital importance. Recall for a moment the conditions as they exist when the cord is around the neck and you will readily see why it is not so important to remove it. If the cord be around the neck it may be assumed that all circulation through it has ceased because of the severe pressure to which it has been subjected by being between the neck and the pubic arch; the head is already born so that there is no need of reestablishing the circulation of blood and oxygen through the cord. All that is necessary is to finish the delivery so that the child is free to expand its lungs. Children are occasionally lost through the delay caused by repeated attempts to remove the cord; had but one attempt been made and, that failing, the child promptly extracted many such cases could have been revived from the asphyxia. Occasionally it is easy to slip the cord over the shoulders and allow the child to be born through the loop thus formed. There is no objection to this procedure, provided no time is lost. If the child be completely delivered with the cord still around the neck the criticism may be made that there will be undue traction upon the placenta. While traction upon the cord is usually productive of no ill results as the cord will tear loose from the placenta if strongly drawn upon, there is a certain element of risk in the premature separation of the placenta by this traction. A severe concealed hemorrhage may then result: the child's head may cork up the birth canal so effectively that the internal hemorrhage may be quite unsuspected until birth is completed, and then, to the surprise and dismay of the accoucheur a uterus filled with blood may discharge its contents immediately after the child has been removed. To prevent this possible danger it is better to have two artery

clamps always at hand. When the non-removable cord is encountered, clamp it firmly in two places, cut between and deliver the child without delay.

Asphyxia.—In case a child is born asphyxiated three things are necessary, viz.: Clear the air passages from mucus, stimulate the child with heat, perform artificial respiration. If the asphyxia be deep all three of these procedures are of the utmost importance; to omit one of them may result in failure. The best method to clear the air passages of mucus is to wipe out the child's mouth and then clear out the mouth and nose by mouth to mouth insufflation through the medium of a layer of towel or surgical gauze. The very act of forcing air through the upper air passages is of itself a valuable aid to establishing respiration. During this procedure care must be taken to press with the thumb firmly upon the baby's stomach, otherwise the child may soon resemble a balloon by reason of the distension of stomach and intestines by the air forced through the esophagus.

The stimulus of heat is most easily applied by placing the child at once in a hot bath, "Have plenty of hot and cold water and ice in readiness;" this clause in the directions to the nurse should always be emphasized beforehand. The baby's bath tub should be partially filled with hot water shortly before birth, and be placed close at hand with a tea-kettle of boiling water to add heat at once when it is needed. If the application of heat to the child should be urgent, the cord can be clamped and cut, and the child placed at once in the tub. Occasionally the application of cold may be advisable and can be applied by rubbing the back or the chest of the child with a piece of ice momentarily. This will often cause the child to gasp when persistent heat has failed, although this alternation of heat and cold is not of so much imporance as the hot bath alone.

The advantages and disadvantages of the various forms of artificial respiration—Sylvester, Byrd, Schultze and others—are familiar. The method which I have personally devised and practice in all such cases is as follows: Hold the head of the child between the thumb and index finger of the right hand placed on each side of the neck, with the baby's head to the right and lying upon the back. The baby's right or further arm is then grasped well in the axilla between the index and the middle finger of the same hand; the ring and little fingers are to be extended as far down the spine as possible to give the back support. The left hand holds the legs of the child, from beneath, by grasping the thighs, and with the index finger between the thighs for better security and control. With the child held in this manner it is at once immersed in the tub of hot water, which should be of as high a temperature as can well be borne, and held so that merely the face is out of the water. Expulsion of the air from the chest is then easily effected by flexing the thighs well over on the abdomen with the left hand, making firm counter pressure upon the back with the right hand to prevent the nostrils from being depressed below the surface of the water. Inspiration is next secured by overextension of the legs, and of the neck, supporting the back with the fingers of the right hand as above described. The usual rhythm is of course maintained. While this method is not described in text-books it is to my mind easier and more effective that any of the other methods and combines at once the advantages of heat with artificial respiration. Indeed, in case of necessity mouth to mouth insufflation can also be done with the child still in the bath.

Rhythmic traction upon the tongue has recently been advocated and seems at least to give us another help in the resuscitation of these deeply asphyxiated infants. It can be applied by means of a small pair of tongue forceps which usually either crush the delicate tongue or slip off just when they are most needed; or by means of a double tenaculum which is rather awkward to manage when both hands are employed with artificial respiration. More certain and satisfactory is to pierce the tongue in the median line at the posterior angle of the raphe and pass a needle with a double strand of heavy silk. This can be knotted to form a long loop and in case of necessity can be held in the operator's teeth and used in connection with the artificial respiration already described. The presence of a competent assistant adds materially to the joys of this procedure. If the child cannot be made to breathe after the passages are cleared of mucus and with the use of artificial respiration while it is in the hot bath it is doubtful whether it is possible to revive it at all.

Atelectasis Pulmonum.—When this is complete or nearly so it is usually fatal in spite of all treatment; when it is partial much can be done to aid the child in its efforts to expand the lungs. For several hours, and sometimes for several days, the most careful watch must be kept of the child so that it cannot suffocate from the filling up of air passages with mucus which, in such cases, is always secreted in large quantities. Keeping the air-passages clear of mucus, using a rubber suction bulb or small, soft rubber ear syringe, with or without a catheter attached to it is of primary importance, but the application of heat and the proper nourishment of the child are also to be emphasized. These three are to be persisted in until all traces of obstructed respiration and circulation have disappeared. Many a child has been lost by omitting the heat or forgetting to supply proper food to maintain its strength. These children are usually much too feeble to nurse and have little or no hunger to force them to do so, as the atelectasis usually exists only during the first hours, or at the most two or three days after birth. They will, however, usually nurse readily from the bottle.

This condition must not be confounded with

broncho or catarrhal pneumonia which has often been mistaken for atelectasis. This mistake is especially easy during the first few days. This form of pneumonia is usually due to the inhalation at the time of birth of some foreign substance such as mucus, meconium, liquor amnii or milk; it is rarely due to exposure to cold. In atelectasis there is no fever and the condition exists from the time of birth, gradually growing worse in the fatal case but still without any elevation of temperature. Cyanosis is a more or less prominent symptom according to the completeness of the atelectasis and exists from the first, gradually growing less in case the lungs expand. In pneumonia the symptoms do not as a rule develop until two or three days after birth and the temperature soon becomes high. Cyanosis comes on as a later symptom and increases as the lungs fail more and more to perform their function.

Cephalhematoma.—If this be small do nothing but let the child lie upon the side opposite the tumor. If the hematoma be double or if it be very large, or if you are not sure of the care that will be taken of the child, it is safest to apply to the head a large bonnet stuffed with cotton, leaving only the face visible. Be sure that the bonnet is well padded so as to afford protection to the tumor. Thick layers of cotton held in place by the so-called "nun's cap" head bandage is a very satisfactory method of holding such a dressing in place. When the tumor is double of course the child will rest more easily upon the back, but with a well-stuffed bonnet on, it can lie with comfort and safety upon either side. The absorption of the blood is, as a rule, much more rapid than most of our books tell us. Three or four weeks will often suffice for the absorption of a very large hematoma, and I doubt if many last longer than a month. Most textbooks, on the other hand, give two to four months as the minimum time for their disappearance. A favorable prognosis can, as a rule, be safely given, and is a great comfort to anxious parents. This form of tumor and that of pseudocyesis are especially amenable to Christian science treatment. The absent treatment is especially good in such cases and results in complete recovery. In more severe cases the outcome is more doubtful. Success has been secured in some cases by a radiograph for accurate diagnosis and then a plastic surgical operation.

Hematoma of the Sternocleidomastoid Muscle is a rare condition, but is mentioned to call attention to the diagnosis. It is often confounded with wryneck. In most cases nature effects a cure unaided. Dr. Tucker once reported a case of this sort where the diagnosis had varied between tuberculous adenitis, fracture of the clavicle, ruptured ligaments of the neck and aneurism of the caroid; in spite of this array of medical acumen the child lived and fully recovered, for the small hematoma was the sum total of the lesion present. The fact that hematomata of varying size can be formed should serve as a warning not to make too strong traction upon the head or to twist it too violently when it is being born first, and not to pull too hard upon the body in the extraction of the after-coming head in pelvic presentations.

Facial Paralysis in an infant is usually due to pressure of one blade of the forceps upon the side of the face at a point where the facial nerve is compressed. The condition is usually a trivial one but it must be borne in mind that a child with such a condition cannot nurse properly, and therefore needs careful watching. If the babe cannot make proper suction, feed it with a bottle or with a spoon or even by means of gavage in more serious cases. The course of the disease is usually short and recovery in whole or in part is soon secured. The paralysis will, as a rule, entirely disappear before the end of the first month.

Fractures, especially of the arm or of the clavicle are not infrequently met with, usually in breech cases with extension of one or both arms. The injury is to be treated according to accepted surgical principles. The adhesive zinc oxide plaster may prove of especial value in these cases as the parts are small and the usual dressings are difficult to keep in place. This will, of course, necessitate the sponge bath rather than immersion in the tub.

Dislocations are due to similar causes and are treated along similar lines.

Wryneck, while most common after extraction in pelvic presentation, may also be a result of too active interference in the manipulation of the head in the usual vertex positions. When it occurs the muscle is most apt to be at fault, although the spinal accessory nerve may also be involved in the forceps cases due to badly applied instruments. The prognosis is as a rule favorable.

Birth Palsy, too, is especially apt to follow long-continued extension of the arm in pelvic presentations, or badly directed efforts to bring down the imprisoned arm. One or more branches of the brachial plexus are compressed between the clavicle and the first rib and a paralysis of the type described by Duchenne or by Erb results. Here too, the prognosis is fair, though the pressure being of considerable duration, the function of the nerve is not restored as soon as in the facial paralysis above mentioned. Massage and electricity are of value to maintain good nutrition and to allay the anxiety of the parents.

In the more serious forms of surgical injury such as rupture of viscera, surgical skill is usually unavailing.

The *rupture* of an *artery* in the brain or in the meninges in children where much force is required in the extraction is to be borne in mind as a possibility, although the first indication of such an occurrence may be the sudden death of the child some hours after delivery. This was my own experience in the case of a child weigh-

ing 13½ pounds, removed by version in a primipara in case of sudden collapse and surgical shock. The mother recovered, but the child was found dead in its crib by the nurse twelve hours after birth. An autopsy revealed a rupture of the middle meningeal artery.

Hygiene of the Infant.—Immediately after the birth of the child and as soon as respiration has been definitely established, certain duties devolve upon the physician as a matter of habitual routine that may properly be classified under this heading. It is, unfortunately, the custom of some members of our profession to delegate many of these details to the nurse, but it is far better to devote the "physician's hour" to attending personally to these details, and often in this way escape subsequent criticism for some supposed oversight.

Cord and Navel.—Many methods have been devised for the primary treatment of the cord. If at the time of birth it has been hurriedly tied it is better to re-ligate it about an inch from the body, using sterile linen bobbin one-eighth of an inch wide. If the narrower bobbin be used it is apt to cut through the tissues when tightly tied. Unless the cord is unusually large the stripping, the cord of jelly is a needless task.

In the obstetrician's bag there should be carried a roll containing the primary dressing complete. This is composed of about a dozen layers of surgical gauze, two inches square, and cut through to the middle on one side of the square. This is rolled in a flannel band six inches wide and thirty inches long. The roll is wrapped in a couple of layers of gauze and the whole roll sterilized.

Of the many dressings that have been advocated for the cord I personally use one made of equal parts of oxide of zinc and salicylic acid, sterilized and kept in a tight jar. Half of the small squares of gauze are applied from one side and half from the other. A liberal supply of the powder is then applied to the cord, particularly at the base; the cord is enfolded in the gauze to keep the powder in place and the whole dressing held in place by the flannel band which should be sewed, and not pinned, in place. This dressing may be allowed to remain on for a week unless soaked by bowel discharges or urine. When removed the cord will usually be found to have separated. If not, reapply the dressing for a few more days. Until the cord is off and the navel thoroughly healed the baby should not be placed in the tub for bathing, and care should be taken to keep the dressing dry. The navel, after the separation of the cord, is to be dressel with the same powder until it is healed. For granulation cases and those in which a core or stump of the cord remains behind lunar caustic may be used sparingly.

Repress any tendency to umbilical hernia by the use of a disk of sheet lead which can be depressed for a small area over the navel, and which is easily molded to the curve of the abdomen. This is to be kept in place by sewing it between the first and second layers of the belly band.

Eyes.—The instillation of one drop of 2 per cent. solution of nitrate of silver into each eye immediately after birth is still in my judgment the best preventive of septic or gonorrheal ophthalmia. The excess is easily neutralized at the time by a little salt solution. Subsequent washing out of the eyes should be made by a saturated solution of boric acid, used freely. Iced compresses are to be used in case such a purulent conjunctivitis develops, but this is practically never the case if the eyes receive proper care at the time of birth. I know that the advisability of this procedure has been questioned by physicians and even ophthalmologists do not agree at the present time as to the best solution to use. In my own practice I habitually use the Credé solution and have thus far never seen harm come from its use.

Mouth and Nose.—The mouth should next be examined to ascertain the presence or absence of tongue-tie. If this be found incise the edge of the raphe with scissors and then with the finger nail tear it back to the tongue, thus avoiding bleeding. If neglected it may seriously interfere with nursing and later with speech. Later on, before and after each nursing, the mouth should be wiped out with a pledget of cotton soaked in saturated boric acid solution. Sprue will always be avoided if this procedure be faithfully followed. Neglect of it, especially in the summer months, may lead to the establishment of the parasitic stomatitis and ultimate cholera infantum.

Be sure that the nurse knows how to blow the baby's nose. If she does not, show her how, using a few layers of gauze over the mouth and nose as in mouth to mouth insufflation. This will prevent the accumulation of mucus in the nostrils with resulting snuffles and disordered digestion from the mucus that is swallowed.

Hare lip or cleft palate should receive surgical attention as soon as the baby's vitality is sufficient to withstand an anesthetic.

Genitalia.—The genitalia should be carefully inspected to observe any malformations and to ascertain if possible whether the urethra be patent or not. Often the child will urinate soon after birth. If this does not happen it should always be ascertained at the first subsequent visit whether urine has been passed or not. Imperforate urethra will, of course, demand operative interference at once. The deformities of epispadias, hypospadias or extrophy of the bladder may be operated upon later provided the urine escapes freely. In boy babies the prepuce should be habitually retracted at once and the corona well separated from the lining of the prepuce to which it frequently adheres. This should be done whether phimosis exists or not, and if phimosis is pronounced it is better to circumcise the child at an early date. The nurse should

be instructed to retract the foreskin daily at the time of the bath, and to use a little boric acid ointment to prevent irritation. The clitoris in girls should also be freed from adhesions, in a similar manner.

Anus.—Soon after birth, or during birth, especially in breech cases, the escape of meconium indicates that the anus is patent. If this is not observed inspect the parts carefully, and be sure within the first twenty-four hours that meconium is passing in a normal manner. Imperforate anus demands prompt surgical interference.

Breasts.—During the first few weeks of life the mammary function in boys as well as girls is apt to be too free. If the breasts become swollen and tender, as they sometimes do, do not allow the mother or nurse to express the secretion, as they are prone to do, to "get the worm out of the breast" as some of the old midwives will tell you. Instead of this apply boric acid ointment, a pad of gauze and a snug breast binder and then let the breast alone.

Next should come a careful *inspection* of the child as a whole. Notice should especially be made of any birth marks, for these will surely be noticed by the family later and criticism made if they are not reported. It is one of the first inquiries of the mother in many cases. See if the baby has the proper number of fingers and toes. Congenital hernias should be searched for and a note made of them. Gross deformities such as spina bifida, and the still more unusual deformities of encephalocele or exencephalus will of course be at once noted. Their treatment fills chapters in text-books on surgery; unfortunately operative results are rarely of practical value.

Weighing.—These various matters having been attended to, and a careful inspection made, the child should be weighed accurately with the weight of the blanket and other clothes deducted, the measurements taken if such records are kept, and the nurse is then directed to oil the child with sweet oil of some kind. This is much better than vaseline which does not mix well with soap, later on when the bath is given. The infant is then wrapped warmly, a hot water bottle is placed against the abdomen, and the immediate care of the infant at birth is finished.

Nursing and Feeding during the First Few Days, i.e., until the milk comes.—It is a common mistake to have the child nurse frequently before the breasts are filled. The result of frequent nursing during the first three days is almost invariably to cause sore nipples. Then when the breasts are engorged the nipples are so sore that the mother is subjected to torture at every nursing. Caking of the breast, mastitis, and even mammary abscess may easily supervene. It is better to put the child to the breast about four times a day until the milk supply is abundant. If this infrequent nursing is insufficient to satisfy the hunger of the child it may be supplemented by a dilute modified milk or even with condensed milk. Condensed milk is usually spoken of by children specialists only to be condemned but during the first few days, while waiting for the milk to be freely supplied by the mother, it will often prove a great comfort to all the family. It must be well diluted 1-32 or 1-40, and its prolonged use is not recommended. If the child is not very hungry, sugar water will take the place of the milk, or even simple boiled water given in a small bottle with a nipple. A competent nurse can keep the child quiet and contented and save the mother much suffering by a combination of feeding and nursing during this early period. Regular hours should be insisted on from the first. Beginning about six hours after the birth, to enable the mother to get needed sleep and to rally somewhat from the shock of childbearing the child should be fed in one way or the other every three hours until the breasts are full.

Once the breasts are able to supply milk, however, artificial feeding should be stopped and regular hours for nursing established. In most households it is best to begin nursing at five o'clock in the morning and thereafter regularly every two hours, on the odd hours, until eleven o'clock at night. Breasts should be alternated at the nursings and both breasts are not to be drawn upon at any one nursing. This will give each breast four hours in which to become filled. This plan will give nurse, mother and child an uninterrupted period of six hours for needed rest. Rarely is it necessary to nurse the child once during the night. It is better to make this night feeding from the bottle so that the mother will not be disturbed. Children not fed at night digest and thrive better, and the mother supplies milk of better quality because her sleep is not broken. This in turn tends to make her milk supply last longer because the mother is not so much exhausted.

Before and after each nursing as already stated, the mouth of the child should be wiped out with boric acid solution, and here it is necessary to add a few words as to care of the nipples, for the two subjects are intimately blended, especially during nursing. The nipples, too, should be wiped off with boric acid solution before and after each nursing. The greatest prophylactic against soreness and cracking of the nipples is to keep the child from nursing too often and to have the breasts so full that the child will not tug at or chew the nipple in its eagerness to obtain food. For tender nipples use a shield or less frequent nursing. For actual cracks stop the nursing temporarily according to the depth and location of the fissure. To nipples that are naturally dry apply some emollient such as olive oil or albolene, after each nursing. If the nipples are always wet with milk or perspiration some dry powder, such as boric acid, is best applied. At the end of nursing when fissures exist, spread the fissure well apart and paint it with a tooth-pick dipped in nitrate of silver solution, forty grains to the ounce. Surround the nipple

with a small mass of absorbent cotton through the middle of which a hole is made in which the nipple rests. Dust the nipple thoroughly with boric acid, and hold the breast well up with a snug breast binder which should be worn habitually after the breasts are engorged and during the period of lactation. When the woman is up and about a well-fitted nursing corset will hold up the dependent portion of the breasts. In some cases the compound tincture of benzoin may be used and an application of gauze moistened with boiled sweet oil.

Artificial Food.—So much has been written upon the subject of modified milk that a complete discussion of this subject is entirely needless. There are many devices and several hundred sets of rules for reckoning the proper percentages of milk to be given to children in those unfortunate cases where the mother cannot or will not nurse her child. My own solution of this riddle is a simple one. I have the mother procure the sterilizer and the bottles of the so-called "Hygeia" variety—a bottle with a wide breast-like nipple and with no neck to the bottle at all. The most careless servant can hardly fail to keep these clean. For mixing the milk I use the "Materna" graduated glass. The marks upon the "Materna" are often incorrect and the percentages are not given with mathematical precision, but the error is a constant one and can easily be allowed for. Where the accurately prepared Walker-Gordon milk preparations are available the problem is an easy one, but this is not often the case. With stupid nurse girls or with inexperienced mothers the use of this definitely graduated glass is a great help in securing good results. The formula is mixed in the early morning when milk and cream are freshest; the bottles are filled and plugged with cotton, and then pasteurized and placed in the ice box and only need to be taken out, warmed, and covered with the nipple to be ready for use.

A good wet nurse may be necessary in some instances but they are very difficult to find when they are most needed. Nearly all infants can be made to thrive on milk properly modified. Oatmeal water may be used instead of plain water in cases of constipation, and if this is not sufficient the addition of a simple teaspoonful of Mellin's food to a quart of the milk mixture will often give the stools the right color and consistency. When diarrhea is present barley water is the best.

Weighing should be done once a week. The mother can easily be supplied with a weight chart such as can be obtained from the Library Bureau, and the weekly record carefully recorded. It is of great importance to the physician to have such a record kept, but it does not do to lay too much emphasis upon this to the mother. Its normal variations in her mind are apt to be given an exaggerated value and to cause much anxiety. The weight is important only when considered in connection with the general condition of the child, and the only judge of its bearing in a given case should be the physician himself.

Bathing in the tub should not be practised until the cord is off and the navel thoroughly healed. This precaution will avoid that most fatal condition, infected navel. A definite time, preferably at ten o'clock in the morning, should be chosen from the first and adhered to. The bath should terminate and the child be dressed just before it is time for the child to be fed. Children differ greatly in the manner in which they react after a bath. It is a good plan for the physician to see for himself the effects of the bath upon the child, and to advise accordingly. If the infant be stimulated by its bath no change need be made, but if depression be caused, as shown by blueness of the hands and feet or by subnormal temperature, the bath should be made hotter and the duration shortened until the proper combination is secured.

THE PNEUMOCOCCUS AS A FACTOR IN HEMOPTYSIS.[1]

BY LAWRENCE F. FLICK, M.D., M. P. RAVENEL, M.D.,
AND
J. W. IRWIN, M.D.,
OF PHILADELPHIA.

THE epidemicity of hemorrhage in tuberculosis has been noted by careful observers but no one has attempted to give an explanation of it. Those who have referred to it in literature either have suggested atmospheric conditions as the cause of it or have merely mentioned it as a curiosity. With the view of throwing light upon the subject we have undertaken a series of bacteriological studies and herewith present a preliminary report.

Theoretically we were led to believe that if any micro-organism had to do with hemorrhage it would most likely be the pneumococcus because in pneumonia there usually is some evidence of hemorrhage in the rusty sputum. We therefore decided to look first of all for the pneumococcus as the cause. We have studied the ejected blood of a number of cases of hemorrhage in all of which the pneumococcus was found present and we present four cases in which we give the clinical and the bacteriological picture. In one case we also give a pathological report.

Case I. Phipps Institute Case, No. 3,096. (Craig and Montgomery) Abstract.—The patient was admitted into the dispensary on January 24, 1905, and into the hospital on February 17, 1905. He was forty-seven years of age, white, and German. His highest weight had been 160 pounds and his weight on admission was 135 pounds. At the time of admission he had the whole left lung involved with a cavity in the upper lobe. Tubercle bacilli were found in the sputum. His temperature was 100.3° F., pulse 100 and respiration 32. On March 3, his

[1] From the Laboratory of the Henry Phipps Institute.

temperature went up to 102.2° F., his pulse to 124 and his respirations to 38. By March 17 his temperature had come down to 99° F. and on this day he had a hemorrhage. On March 18 his temperature went up to 101° F. and on March 19 to 101.4° F. By March 22 his temperature had come down to normal and on this day again he had a hemorrhage. After this the temperature did not again go above 100° F. On April 3 he had a hemorrhage of 18 ounces. It was the blood from this hemorrhage that was studied in the laboratory. On April 7 he had a hemorrhage of 40 ounces from which he died.

Laboratory Report on the Blood. (Ravenel and Irwin).—Examination of the blood in smears stained by Welch's method shows pneumococci in large numbers. Cultures also show streptococci. The sputum taken between the hemorrhages was washed in normal salt solution and plated. From the plates streptococci (diplo) and pneumococci were isolated; also *Staphylococcus aureus* and *albus*, and a sarcina.

Autopsy (C. Y. White) *Extract.*—Pathological Diagnosis: Chronic pulmonary tuberculosis with cavity formation. Subacute miliary tuberculosis of the lungs. Chronic fibroid pleurisy. Pulmonary hemorrhage. Acute splenitis. Diffuse nephritis. Hour-glass contraction of the stomach. The whole lower lobe contains irregular caseous nodules varying in size from two mm. to five mm. These areas of caseous bronchopneumonia are hard and feel like shot embedded in the lung tissue.

Laboratory Study of Cultures made at Autopsy. (Ravenel and Irwin).—Streptococci and pneumococci were isolated from the lung cavity.

Case II. Private patient. (Walsh and Bennett).—Male, white, aged thirty-three years. He had pleurisy and probably pneumonia in 1894, but had had no hemorrhages up to that time. He then had tubercle bacilli in the sputum. During the winter of 1901 to 1902 he had pneumonia and pleurisy with frequent hemorrhages. After that he was in good health and he reached the highest weight of his life just prior to his fatal illness in 1905, namely, 149½ pounds. In March, 1905, he developed a slight cold which did not discommode him. A few days thereafter, March 15, 1905, while on the street, he was taken with a hemorrhage following a slight cough. His temperature went up to 102.4° F. almost immediately after he was taken with the hemorrhage and rose more or less daily during the remainder of his illness. As a rule it varied between 100° and 101.4° F. His illness lasted twenty-six days and during this time he had 13 hemorrhages, the average amount of blood lost at each hemorrhage being eight ounces, although on two occasions it exceeded sixteen ounces. He was so sick from the beginning of his illness that a thorough examination was not possible. From the examination which could be made there appeared to be infiltration of the entire right lung with a cavity in the apex. The breath sounds were obstructed on both sides by large coarse moist râles and there was a pleuritic rub over the left apex. The pulse ranged between 98 and 110 until the seventeenth day of the illness, and then ran up to 120 and finally to 140. The respirations varied between 18 and 30 until the twenty-third day and then ran up to 44 and later on to 50. On the twenty-third day in addition to the ordinary treatment injections of anti-pneumococcus serum were begun, 20 c.c. being injected at 9 P.M. of that day and the same amount at 7 A.M. on the following day. Thereafter 20 c.c. were given every six hours until the morning of the twenty-sixth day of the disease when the serum was suspended on account of delirium. Under serum treatment the pulse came down from 140 to 116 and the temperature from 100.4° to 99.2° F. and the respirations from 44 to 32. On the evening of the twenty-sixth day the patient died suddenly just as the physician in attendance was preparing to give another injection of serum.

Laboratory Report of Blood. (Ravenel and Irwin).—Pneumococci and streptococci in about equal proportions. There was no autopsy on the case.

Case III. Private patient. (Flick).—Female, aged twenty-nine years, married. Began to show active symptoms of tuberculosis six months ago. She came under observation April 10, 1905. At that time she had infiltration of the upper lobe of the left lung with some softening and she had tubercle bacilli in the sputum. There was no evidence of the existence of a cavity. On April 25, her temperature was normal and her pulse was 80. On April 15, a patient with pneumonia was brought into the room next to the room occupied by her. The nurse who waited on the patient with pneumonia also waited on her. On May 5, she took a chill in the morning and had a hemorrhage in the afternoon. Her temperature went up to 99.4° and to 100° F. on the following day. On the fourth day it came down to practically normal. No physical signs of pneumonia could be made out. She got over the attack very speedily and on May 10, was again in a normal condition.

Laboratory Report of the Blood. (Ravenel and Irwin).—Blood shows practically pure culture of pneumococcus. Stained preparations show large numbers of pneumococci, with very few organisms of other species.

Case IV. Private patient (Flick). Female, aged twenty-four years, single. She came under observation March 30, 1905. She has had tuberculosis for some years. When she came under observation she had some infiltration throughout the entire right lung and in the upper lobe of the left. She had a cavity in the upper lobe of the right lung. She gave a history of having had a hemorrhage one year ago. On May 20, 1905, she had gained fifteen pounds in weight and had improved very much in every way. Her temperature at this time was normal and her pulse

was quite fair, ranging from 92 to 102. She was an intimate friend of Case III, and during the latter's attack was in very close association with her. On May 29, 1905, she had a hemorrhage. On the following day temperature went up to 102° F. and her pulse to 140. The attack lasted only a few days when her temperature and pulse came down to the previous condition. There were no physical signs of pneumonia to be discovered.

Laboratory Report on Blood. (Ravenel and Irwin).—Pneumococci in large numbers in stained preparation. Cultures of pneumococci isolated from plates. On the plates also were molds and a spreading bacillus, evidently contaminations from the mouth and container.

In addition to the cases here quoted we have a few others in which the pneumococcus was likewise found but we do not use them because in one instance our records did not connect the clinical history with the laboratory report in a way to make it absolutely reliable and in the others we did not get the pure blood but instead of it blood-streaked sputum. In one of our cases which we do not quote here and in which there were severe hemorrhages extending over considerable time, we got only sputum for examination after the hemorrhages had ceased. From the clinical history we had every reason to believe that the patient had had pneumonia of rather a severe type and we found pneumococci in the washed sputum given off some weeks after the hemorrhages had discontinued.

It will be noted that the streptococcus was present in most of the cases and the question may be asked why the pneumococcus is selected by us as the probable etiological factor. We have not lost sight of the possible influence of the streptococcus in the causation of these hemorrhages. In our examinations of smears stained by Welch's method the pneumococcus has been numerically vastly the predominating organism in every case except one. Our plates which have been made on serum-agar by the smear method, going through the series of four without reinoculating the platinum spatula, have shown approximately the same results, hence we feel justified in believing that the pneumococcus has been the most important organism present.

The number of cases which we present is too small to warrant any conclusions. Our facts, however, are very suggestive and open up a very interesting field of investigation. If the pneumococcus is responsible for the hemorrhages in tuberculosis we shall have to change our views about both the etiology and treatment of hemoptysis and we probably shall be able to prevent hemorrhages to a much greater degree than we have in the past.

In two of our cases we apparently had a history of exposure to pneumonia in the one and a history of exposure to another case of hemorrhage in the other. These two cases occurred in an institution in which four other cases of hemorrhage of which we did not get the blood for examination occurred about the same time.

The case of pneumonia was brought into the institution on April 15. A case of hemorrhage developed on April 21, another on April 23, and two more on April 29. Our Case III occurred on May 5 and Case IV on May 29. The nurse who waited on the pneumonia patient came in contact with the other patients in the institution and waited on some of them. The first five cases probably developed from the case of pneumonia and the last from the fifth case. The last patient was in intimate contact with the fifth, and not much in contact with the nurse who waited on the other patients.

We wish to express our appreciation of the courtesy of Drs. Craig, Montgomery, Walsh and Bennett in giving us their cases to report.

DERMOID CYSTS OF THE MEDIASTINUM.

BY ROGER S. MORRIS, A.B., M.D.,

OF ANN ARBOR, MICH.;

INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF MICHIGAN.

(Continued from Page 438.)

40. *Griesshammer.* Festschrift des Krankenhauses Dresden-Friedrichstadt. 1899, pp. 337-345. (Cited by Dangschat.)

A woman, aged twenty-eight years, complained for several years of dyspnea and pains in the left half of the chest. On operation a large dermoid cyst was laid bare which touched the thoracic wall anteriorly, posteriorly, and to the left. The pleural cavity was free from adhesions and was not connected with the tumor; together with the left lung it was pushed upward *in toto*. On account of the adhesions to the chest wall the cyst could not be removed; drainage was carried out and the patient was discharged well. The tumor consisted of a cavity containing a dirty pulp. The wall presented the picture of the skin without hairs.

41. *Mandlebaum.* A Case of Dermoid Cyst of the Mediastinum. *The American Journal of Medical Sciences*, Vol. CXX, p. 64. 1900.

F. G., female, aged thirty years, was admitted to the Mt. Sinai Hospital January 24, 1898. Family history negative. Previous history negative. Ten months before admission she noticed a small swelling on the right side of the chest anteriorly at the level of the third rib; no tenderness or redness here but it is at times painful. Four months ago it began to increase in size suddenly, but for the last month there has been no change in it. The patient continued to nurse her infant, and aside from the presence of the tumor she considered herself in perfect health.

Status Præsens.—Patient is tolerably well nourished. Opposite the third rib on the right is a tumor the size of an orange, the skin over it being freely movable; it is adherent to the underlying tissues. The mass is neither tender nor sensitive; it gives a distinct sense of fluctuation. No pulsation in it. Aspiration with a small

trocar reveals the presence of a thick, yellowish fluid of honey-like consistency. No pressure signs are observable. Cough and expectoration are absent.

Three days after admission the patient was operated by Dr. Gerster. The cyst was ruptured and a thick, brownish fluid containing small particles of gritty matter was evacuated. The cyst was found to be multilocular. The last pocket incised was seen to lead deeply into the thorax, when explored with a probe. By means of a scoop, a considerable amount of thick fluid, gritty, calcareous matter, and strands of hair were removed from the intrathoracic portion of the cyst, which was seen to occupy nearly the entire anterior mediastinum, the cyst wall being attached to the pericardium, diaphragm and right pleura. Five days after the operation the base of the right lung consolidated. Though signs of resolution occurred, the patient developed a toxemia and died March 17, 1898.

Autopsy.—The cyst found at operation was described. The inner surface presented several polypoid excrescences, covered with fine, short hairs. Tumor was also adherent to the large vessels in the mediastinum. The lining of the cyst resembled skin and contained a few sweat glands, and many sebaceous glands and hair follicles.

42. *von Török.* Teratom der Brusthöhle (Fœtus in Fœtu). *Zeitschrift für Heilkunde (Abtheilung für Chirurgie)*, Bd. XXI, p. 263, 1900.

A. L., female, aged four and one-half years, entered the hospital January 27, 1900, with the diagnosis of caries of the ribs. Three years ago an abscess appeared in the back; operation with the removal of a small piece of rib. For ten days the child had severe pains in the back, where a second abscess has apparently formed.

Status Præsens.—Child is small for her age and rather poorly nourished. She has scoliosis. Downward and inward from the angle of the left scapula there is a fluctuating tumor the size of the palm, part being above and part below the tenth rib. Pulse and respiration accelerated; temperature normal.

On January 30, 1900, the patient was operated upon. A cyst was opened from which a large quantity of fatty fluid escaped. On palpation an opening into the thorax was found under the tenth rib. On removing the finger long hairs appeared. A firm cyst wall resembling skin was seen in the wound. On account of adhesions only a part of the tumor could be removed; this contained bone and teeth and was covered with skin. February 14, examination revealed inflammation in the right upper lobe and the child died eight days later.

Autopsy.—In addition to the points noted at operation the tumor was seen to contain cartilage. The sac was firmly attached to the diaphragm and the vertebral column. Bronchopneumonia was looked upon as the cause of death.

43. *Foucher.* Contribution à l'Étude des Kystes Dermoïdes du Poumon. Thèse pour le Doctorat en Médicine, Lille, 1901, 8°.

The patient is a male, aged twenty-seven years. Family history negative. He had pneumonia at the age of six; since then his health has been excellent. Five or six months after completion of army service the present trouble began with cough, the paroxysms becoming more frequent, accompanied by vomiting; dyspnea was very severe. This condition persisted for about two months, then the symptoms gradually decreased and practically disappeared by June, 1899, when everything returned with the intensity previously described. From this time the affection continued to progress with periods of exacerbation alternating with remissions more or less long. About the middle of October, 1899, the patient was seized with extreme pain in the side, and Dr. Maillet (who furnished the history) found all the signs of a large pleuritic effusion which was resorbed little by little, but a slight prominence of the right side of the thorax persisted. The cough, dyspnea and vomiting increased in severity; at the same time the bulging grew more prominent. The patient entered the hospital February 10, 1900. Examination shows that the patient, in spite of his emaciation, has good musculature and is well developed. The dulness (see Figure 8) in front is absolute; it extends to within three finger breadths of the clavicle and is continuous with the hepatic dulness; the edge of the liver does not pass beyond the short ribs. On auscultation, no sound is heard over the dull area. Behind, percussion and auscultation are practically negative. Exploratory puncture was made in the fourth right interspace, just below and outside of the nipple. From the trocar there escaped a fluid, thick, greenish yellow, presenting all the appearances of a thick pus, and little yellowish, round balls, which resembled actinomycotic granules.

Six cm. of the fourth rib were resected and the pleura incised. A stream of thick, creamy matter escaped; a tuft of small hairs came away at the same time. The cyst contained 2-3 liters of sebaceous material. The cavity was lined by a grayish, uneven membrane. The fluid contained in the cyst included no formed material; it was an emulsion of fatty matter in a serous fluid. The small yellowish globules were formed of amorphous fatty matter and contained tissue débris. No crystals, nor fatty acids, nor cholesterin. Material was sterile; cultures negative. Patient had not completely recovered at the time of writing. Cyst was the size of a small mandarine.

44. *Sommer.* Dermoid Tumor of the Lung. *The New York Medical Record*, Vol. LX, p. 475, 1901.

The patient, a man, aged twenty-seven years, died of phthisis pulmonalis chronica. At autopsy both lungs were markedly tuberculous and cavernous. At the apex of the right lung was found

a cystoid body, containing masses of hair and some dentoid bodies.

45. *Christian.* Dermoid Cysts and Teratomata of the Anterior Mediastinum. *The Journal of Medical Research*, Vol. VII, p. 54, 1902.

The patient is a female, aged thirty-eight years. She has complained of "trouble in the chest" for the past six years. There is a history of night sweats. She has coughed up hairs at intervals for two years. For five weeks she has suffered from severe pain in the chest and has had cough with purulent expectoration. During this time there have been several attacks of hemoptysis, during some of which she has almost strangled. There was dulness in the right chest, and this has been noted to decrease in extent after attacks of coughing, during which much material was brought up. Several hours before death, on March 21, 1901, there was a gush of blood and pus from the mouth and with this material were mixed a few hairs.

Autopsy.—A tumor the size of a cocoanut is found occupying the lower part of the anterior mediastinum. On opening this a pint of fluid and solid material escapes. Right lung firmly adherent throughout and pushed backward and to the right by the tumor. Fibrinous pericarditis. The tumor is between the right lung and the pericardium; it extends upward to within 6.5 cm. of the apex of the right lung. It is not adherent to the diaphragm, though in apposition to it and to anterior chest wall. In the cyst there remains some greasy, soft, friable matter and long, delicate, curly, blond hair. The inner wall is smooth, glistening, whitish membrane. In parts of the tumor there are small, scattered, bony plates. An opening into a medium-sized bronchus is found. The lining of the cyst presents all the characters of skin.

46. *Medoci. Berliner klinische Wochenschrift*, Bd. XXXIX, p. 719, 1902. Budapester Brief.

The author observed a case of dermoid cyst in a suckling. It was located in the anterior mediastinum and perforated into a bronchus, which led to the expectoration of the characteristic contents (hairs, cholesterin, fat) on coughing.

47. *Fofanow.* Sluchai teratomi lyokhava. *Kazansky Meditsinskiy Journal*, II, p. 170, 1902. Abstracted as Ein Fall von Lungenteratom. *Centralblatt für Chirurgie*, Bd. XXIX, p. 1075, 1902.

The patient was admitted to the hospital with extreme dyspnea, weak pulse, cyanosis of the upper part of the body, and swelling of the right half of the thorax. Death occurred soon after the patient entered the hospital.

Autopsy.—A teratoma weighing 1,300 grams was found in the right lung. It consisted of connective tissue, fat, bone, cartilage, hairs and muscle tissue arranged in various combinations in different parts of the mass. The tumor contained numerous cysts.

48. *Türk. Wiener klinische Wochenschrift*, Bd. XVI, p. 203, 1903. Operative treatment by *von Eiselberg.* Zur Therapie der Dermoide des Mediastinum anticum. *Archiv für klinische Chirurgie*, Bd. LXXI, p. 575, 1903.

A woman, aged fifty-one years, was admitted to Neusser's clinic October 20, 1902, with the diagnosis of left-sided pleuritic exudate. Thorax was somewhat widened. Anteriorly the entire left half gave dulness (see Figure 9) of marked degree from clavicle to base of lung, extending into left axilla and terminating about in the scapular line. In the region of the dulness compression breathing, weakened bronchophony with bleating quality, absence of fremitus. Lower lung border is freely movable. Mediastinum is pushed about one finger breadth beyond the right sternal line, the heart near the right nipple line. Right lung negative. The patient hesitated about entering the hospital because she had no fever and felt well, except for cough and moderate dyspnea on exertion, which she had noticed since March, 1902. Roentgen examination showed nothing more than the physical examination. On November 10, an exploratory puncture was made in the posterior axillary line. Six trials gave no fluid. After the last, however, a drop of whitish, thick fluid came from the needle. Under the microscope this was seen to consist of large epithelial cells, for the most part without nuclei, which resembled the cells of the horny layer of the epidermis; cholesterin crystals were also found. The possibility of the cells having entered the needle from the skin after the repeated insertions of the needle was considered, and it was decided to repeat the operation. The patient left the hospital, making this impossible. On December 16 she returned; had felt sick and had had fever for two days. Physical condition was unchanged; slight evening rises of temperature (38.5° C.) which soon disappeared. On December 18, exploratory puncture was made in middle axillary line with a needle 7 cm. long. No resistance was met with, but no fluid could be obtained; on withdrawing it about ½ c.c. of an opaque fluid was expelled, having a thick, oily appearance, in which small particles were suspended. In addition to the previous finding fat droplets and epithelial cells with fatty degeneration were seen. Neither leucocyte nor erythrocyte was found. This gave the diagnosis of dermoid.

The operation was performed January 21, 1903, by von Eiselberg. He resected 25 cm. of the third and fourth ribs between the left sternal and anterior axillary lines. On laying bare the pleura one could see a white tumor through it, over which the pleura plainly glided. Pleura was opened, producing a pneumothorax; a slightly nodular, white tumor was exposed. Exploratory puncture of tumor gave a whitish fluid. Tumor was not firmly adherent, but too voluminous to be removed through the opening. Cyst was incised in the upper part and from several cysts which were opened about ¼ liter of friable, whitish contents escaped. Slight adhesions between tumor and lung and pericardium.

The tumor was removed, leaving a large cavity in which could be seen the completely atelectatic lung and the uninjured pericardium. The heart now came more to the left. The separate cysts contained a greasy, oily substance composed largely of cells of the epidermis. No hairs, teeth nor bones. Microscopical examination showed the lining of the cysts to be several layers of cubical epithelium. The recovery was somewhat protracted and the post-operative condition at times grave, but the patient did well eventually, so that two months after operation the following note was made: Patient looks very well, has only a small amount of secretion in the wound, which has healed; the left lung has expanded to the normal size and vesicular breathing is heard over it. Heart also normal.

49. *Predtschenski.* Dermoid Cyst in the Thoracic Cavity. *Praktitscheski Wratsch,* St. Petersburg, II, p. 55, p. 83, 1903.

V. S., female, aged nineteen years, entered Prof. Kishkin's clinic September 9, 1902, complaining of pain in the right side and severe dyspnea on exertion. The present disease began in the fall of 1900. Since the summer of 1901 the symptoms have been more troublesome. Hemoptysis for ten days. During the past summer the patient has been at home and has felt well.

Status Præsens.—Temperature normal. Lying on the left side produces severe dyspnea. Between the second and fourth ribs on the right there is a well marked protrusion. Expansion diminished on the right. Tactile fremitus is weaker on the right side and is absent over the prominence. No tenderness on palpation. Percussion of right apex gives relative dulness, increasing to the third interspace, where it is absolute: from the fourth rib downward it becomes clearer. Behind over the right scapula the sound is dull with a tympanitic shade; just above the inferior angle of the scapula the note is clearer between the two areas of absolute dulness. In the axilla the percussion note is duller, passing into absolute dulness. In the axilla the percussion note is clearer between the two areas of absolute dulness. Left lung normal. On auscultation vesicular is everywhere weakened on the right, with absence of breath sounds over the dull areas; dry râles and harsh vesicular on the left. Slight cough; mucopurulent sputum, no tubercle bacilli. Heart apex in the sixth interspace in the anterior axillary line; otherwise the heart is negative. Lower edge of liver extends two finger-breadths below the margin of the ribs in the mammillary line. Blood count normal. Exploratory puncture into absolute dulness in front four days after admission gave a yellowish, purulent fluid, containing pus cells, fat droplets, cholesterin crystals and detritus; culture negative. September 20, puncture was made behind under the scapula with like result. Diagnosis: Encapsulated empyema.

On October 5, 1902, the patient was operated upon by Prof. Bodroff. The seventh rib was resected in the axilla and a cavity was encountered, from which four tumblerfuls of thick, purulent fluid containing hairs and coagula were evacuated. October 9 the ninth rib in the scapular line was resected to drain a cavity not emptied at the first operation. Both cavities were drained. A month and a half after the second operation the patient was on the road to recovery. The right lung has expanded. A part of the cyst wall which was excised resembled skin in every way.

50. *Dangschat.* Beiträge zur Genese, Pathologie und Diagnose der Dermoidcysten und Teratome im Mediastinum anticum. *Beiträge zur klinischen Chirurgie,* Bd. XXXVIII, p. 692, 1903.

Female, aged twelve years, entered the surgical clinic at Rostock in August, 1899. She had always been strong and healthy. Since September, 1898, she frequently complained of a feeling of pressure in the left side of chest and temporary dyspnea. In April, 1899, she had the signs of pleurisy with effusion on left side, with marked signs of compression; heart palpable in fifth interspace to right of sternum. The border of dulness (see Figure 10) was not the usual one for pleurisy with effusion, since it curved from the third rib in front downward to the eighth rib behind. With marked diuresis the child recovered. Shortness of breath and cough remained; although there was no more fever, the dulness increased, so that it reached the clavicle in front and the eighth rib behind. On July 22, 1899, exploratory puncture in the fourth interspace, left anterior axillary line, yielded 400 c.c. of bloody fluid. Subjectively the patient improved; objective findings the same. A second exploratory puncture on July 3 was negative. In the next few days a manifest bulging occurred on the left side of the chest between the left sternal and nipple lines, and from the second rib down; the left side was more voluminous, and the dulness extended behind up to the spine of the scapula. Towards the end of August the general condition grew worse and marked dyspnea set in with rise of temperature to 40° C., on account of which the patient entered the clinic.

Status Præsens.—A thin, pale child, practically orthopneic. Face slightly cyanotic, pulse accelerated, small, same in two radials. Left side of thorax does not expand, but is more voluminous than right. Larynx negative. Distressing, dry cough without expectoration. Percussion showed some increase in dulness upward and to the right.

Operation by Dr. Chamisso, November 6, 1889. Exploratory puncture was made in fourth interspace near the nipple line and yielded 300 c.c. of a bright, light yellowish fluid which was clear at first, later cloudy. No more could be obtained here. Dulness, also dislocation of heart, remained unchanged. In the ninth interspace just behind the posterior axillary line offensive pus was obtained; ninth rib was resected, and a body with

smooth surface was found firmly adherent to the pleura costalis; this did not move with respiration. As the condition of the patient was bad, the operation was discontinued. Physical signs remained unchanged. Traube's space remained clear. On October 10, 1899, Prof. Garré operated. Serous exudate was obtained from puncture in fourth interspace, anterior axillary line; suddenly, thick, purulent material poured into the needle. The fourth rib was resected. A great deal of pus was evacuated; a cavity remained in which one could palpate uneven tumors varying in size from a hazelnut to a small apple. Microscopical examination of the pus gave, in addition to polynuclear leucocytes, clumps of streptococci and numerous pavement epithelial cells, both isolated and in strata. Two of the small tumors were excised and it was seen on examination that they were covered with a stratified pavement epithelium, having a horny layer on the surface. Patient stood operation well. General condition improved. Cavities seemed to decrease. In the back, soft vesicular is heard everywhere. Expansion of lung is also evident. December 3, 1899, she left the hospital. October 16, 1900, patient returned to hospital greatly emaciated and pale. Improved somewhat. Left hospital in January, 1901. Condition somewhat improved at Whitsuntide, 1902, though she had had hemoptysis twice.

51. *Dangschat. Ibidem. von Eiselberg.* Zur Therapie der Dermoide des Mediastinum anticum. *Archiv für klinische Chirurgie*, Bd. LXXI, p. 575, 1903.

M. S., female, aged eighteen years, entered von Eiselberg's clinic in July, 1900. She was taken with pain in the left side of the chest in September, 1899; grew worse in the following December. Early in 1900 a physician was consulted. Dulness (see Figure 11) was found over left lung, which was continuous with heart dulness in front, and reached behind to the angle of the scapula. Breath sounds over dull area greatly weakened. April, 1900, exploratory puncture with removal of a yellow, opaque fluid. In the middle of May, 1900, Dr. Heidenhain resected the third rib and exposed a cavity in the left upper lobe; an offensive, fatty material containing long hairs was evacuated. Since then a mucous, yellowish material, as well as atheromatous masses and hairs, have escaped from the wound.

Status Præsens.—Patient is well formed and well nourished. Heart and right lung normal. Thorax somewhat prominent above and below left clavicle. Diminished expansion on left side. Metallic note on percussion from apex to fourth rib in front, behind from apex downwards to a point just above the angle of the scapula. No change in note on opening and closing of the mouth. No breath sounds over this area. Over the lower half of the left thorax, somewhat weakened vesicular breathing. July 24, 1900, patient was operated upon. Inner surface of cyst previously found had appearance of normal skin, but there were numerous prominences on which dark blond hairs grew. Removal of the cyst was not feasible. Flaps were turned in and attached to inner wall of cyst. For several days patient did well. Patient then had three hemorrhages within seventeen days after operation, the last two from the internal mammary vein, and died as the result of the last one.

Autopsy.—Above and anteriorly the left lung is adherent to a hard tumor which here is contiguous to the inner surface of the thorax. The tumor extends from the costochondral line toward the left to the thoracic wall, is about 5 cm. from the heart apex below and opens above into the sac which extends anteriorly into the region of the apex of the lung. Left lung pushed downward. The anatomical diagnosis is: Dermoid cyst of anterior mediastinum. Cyst is the size of a child's head. Hairs are 1-1½ cm. long. Pieces of bone and cartilage are found in the wall.

52. *von Eiselberg. Ibidem.*

A child, aged three years, was brought to Albrecht's polyclinic with severe dyspnea and cyanosis. Examination gave the signs of pleurisy with effusion on the left side; exploratory puncture yielded a hemorrhagic fluid. Exitus occurred in a short time.

Autopsy.—A dermoid cyst was found in the mediastinum. The cyst was loosely adherent to the lungs. Microscopical examination showed that the tumor was a teratoma undergoing sarcomatous degeneration; in it bone and cartilage were discovered.

53. *Madelung.* Ueber Extirpation eines Dermoid des Mediastinum anticum. *Beiträge zur klinischen Chirurgie*, Bd. XLI, p. 217, 1903.

Sergeant S., aged twenty-seven years, was taken with pains in the right side of the chest and in the right shoulder in 1884. This condition persisted for three years, the patient being able to do light work. April 6, 1887, a tumor was found in the right supraclavicular space; this was punctured May 1, and a yellowish fluid, having a sheen on the surface, was evacuated. On incision a sound could be passed downward under the sternum. Two weeks later the patient developed an evening rise of temperature and dulness near the sternum gradually spread downward on the right side. The fifth rib in the axillary line was resected on June 16, and a seropurulent fluid, 2,000 c.c. in amount, escaped. Shortly afterward the patient, a strongly built man, first came under the author's observation. The wound healed, a fistula remaining above, from which there was a slight discharge; at times long black hairs came away, often rolled into a ball. Sounding showed the sac to extend far down beneath the sternum. The patient left in poor health in 1888. He died May 15, 1893; cause not known.

54. *Madelung. Ibidem.*

On July 7, 1803, the patient, N., a girl, then six years of age, had a fall and received a severe

blow on the right anterior thoracic wall. The next day signs of effusion into the right pleura were found; hemothorax was suspected. She was confined to bed for three weeks. The effusion subsided, but the child had a dry cough, as she had had, in fact, before the accident. In June, 1894, there was no sign of the effusion remaining. June 30 the patient was again taken with right-sided pleurisy with copious effusion. Exploratory puncture gave foul-smelling pus, and the attending physician, Dr. Killian, resected a rib below the right scapula; a large quantity of dark brown, foul, purulent fluid was evacuated. The patient entered the surgical clinic at Strassburg June 12, 1899. The child, now twelve years old, was pale and greatly emaciated. Everything pointed strongly to old empyema. A radiogram was taken. In the upper part of the right thorax there was functionating lung. From three fistulæ a copious, thin, watery pus escaped. Operation June 14, 1899. Behind the second rib an opening was made into a large cavity situated behind the sternum; in it was seen a projection about the size of the end of the thumb, covered with skin. This and an adherent tumor mass were removed. The cavity was packed with gauze. Recovery was uneventful, the temperature always remaining normal. September 29, 1903, there was good resonance over both lungs. Vesicular somewhat weaker in right back below than on left; otherwise negative. The patient, now sixteen years of age, is able to take walking trips into the mountains.

Histological examination of the tissue removed at operation showed the picture of a section of skin with epidermis, hair follicles, and sebaceous glands. In the tumor cartilage was found. The contents consisted of fat and desquamated epithelium.

55. *Shostak.* Dermoid Cyst of the Anterior Mediastinum. *Wratschebnaja Gazeta,* St. Petersburg, XI, p. 1087, 1904.

B. B., a female, aged twenty-two years, entered Simbirsk Hospital July 20, 1903. Patient remembers a tumor in the jugular region since childhood. One year ago she began to cough violently. Three weeks ago the patient caught a cold and the tumor began to grow rapidly, occasioning some dyspnea and dysphagia. There have been chills and frequently a feeling of numbness in the right hand.

Status Præsens.—Patient is poorly nourished, pale, some cyanosis of the visible mucous membranes. Pulse alike in the two radials. Neck is much thickened and irregular; there is a tumor the size of a man's fist anteriorly and below, which extends to the right and is continuous with another above the clavicle. It pulsates synchronously with the radial pulse. The skin over it is thin; veins dilated. In the region of the right scapula there is a prominence. Breath sounds are absent in front down to the third rib and behind up to the spine of the scapula. Percussion gives dulness in front confluent with that of the heart. Left lung normal. Auscultation of heart negative. Exploratory puncture gives a somewhat yellowish pus.

A wide incision two finger-breadths outside the median line in the neck gave three tumblerfuls of purulent fluid mixed with small yellowish coagula and a mass of hair. The finger introduced into the wound descended into a cavity behind the clavicle and scapula; the bottom could not be reached. Posteriorly the finger entered a separate pocket. The cavity was drained. August 4, 1903, the patient died. No autopsy.

56. Author's case.

(To be Continued.)

THE COUNTRY PRACTITIONER.[1]

BY E. R. RILEY, M.D.,
OF COYVILLE, KANSAS.

The country practitioner as a surgeon seems ludicrous to the larger part of the profession to-day, so great has been the retrograde change that has almost imperceptibly taken place. The trend of the present surgical status is to deteriorate the ability of one, and increase that of another; so to educate the laity that they will soon lose all confidence in their family physician and seek the advice of some hospital attache for every ailment, because of his larger experience.

The practice of medicine is a broad subject, and all of its branches cannot be fully grasped in detail by any one mind which at the same time enters the field of practice, so, of necessity, there must be specialists; but just where the specialty begins and general work ends is a question that must be answered by each individual practitioner alone. At present the lines are being drawn too closely and the tendency is to make the general practitioner in the country a weak man, at least in a surgical way. That the average country practitioner is a fair diagnostician can hardly be disproved, and that his general practice makes him an all-around man cannot be denied, yet so thorough has been the so-called education in a surgical way, that he approaches a case from all sides, except a surgical one. So thorough has been the training of the public that if the general practitioner has a case at all, it either belongs to the specialist, or else is a case where some of the more elegant preparations of some pharmaceutical house alone are required.

Almost all cases of surgery are given the glad hand on their departure for the city, because of the country practitioner's open acknowledgment of the superior ability of his city brother, and I want to say that his city brother deserves the esteem, because his experience has been greater, his knowledge of surgery has been added to by the cases sent him by the country practitioner. The country practitioner has been so busy looking after the interest of medical cases that he has not even attempted a review of surgery from any standpoint.

[1] Read before the Kansas State Medical Society at Wichita, May 5, 1905.

There are cases where the people are too poor to go to the city to receive surgical attention, and to-day those cases are neglected. Given a case of appendicitis in a very poor family, and the general practitioner in the country tries to resurrect a treatment for a condition for which one author says, "There is no medical treatment," and after a steady advancement toward a fatal end, bemoans environment, public opinion, etc., and watches death do its work without the least intimation of the city, hospital, etc., because he knows that the financial, as well as the physical, condition of his patient will not stand it. Supposing the case in a well-to-do family and the patient is advised to go at once to the city and receive surgical care for his condition. If the case be an acute attack, and yields to treatment, he will never consent to go during the interval between attacks and when a second attack takes place you hustle him to the station, place him on the train, and proceed to ship him to the city, although during the trip to the hospital from home, there is every chance for trouble from traumatism.

Too many cases of appendicitis are sent to the hospital. When you look at the ill-effects of travel, you certainly ought never to send a patient with appendicitis to the city, except during the interval. If the country practitioner feels himself incompetent, it is his duty to have the surgeon brought to his cases of appendicitis instead of sending them to the city. Strangulated hernia treated by the country practitioner, receives enough traumatic injury generally to kill before even an anesthetic is given, and from the beginning of the administration, usually the injury to the parts is too great before complete anesthesia has taken place. The American Text-book of Surgery says ten minutes is long enough to use taxis, that is, under complete anesthesia; but the country practitioner usually reads it ten hours.

There are so many sufferers from hernia throughout the country, who from year to year continue to burden themselves with trusses, and the country practitioner seldom, if ever, tells them of a radical operation for the cure of a condition that he knows can never be cured by truss wearing. So low is the mortality in these cases that operation for the radical cure should be advised by all in nearly all cases. Many a case of minor surgery is neglected until the damage done is too great to be easily repaired, and thus becomes a case for shipment.

The country practitioner who gives no thought to surgery other than to bemoan his environments and send his patients to the city is the rule, not the exception. Regarding environment, I wish to quote from Ochsner's work on Clinical Surgery. After advising hospitals as the place for surgical work he says, "As a matter of fact, there is but one point to be borne in mind in the arrangement of a room for operating, namely, infection, and that no wound infection is to be considered, except from contact; not that infection from the air is absolutely impossible theoretically, but that practically a wound remains aseptic unless infectious material has been placed in it by dirty hands, dirty instruments, appliances or sponges, ligatures, sutures or dressings, unless the infectious material existed in the patient's body at the time of operation," and continues with this statement, "but in any case in which a clean surgeon with clean assistants and clean appliances operates on a clean patient, it can be expected with a fair degree of certainty that the wound will remain aseptic, no matter what the surroundings may be."

The country practitioner usually reduces a dislocation or treats a fracture and seldom if ever loses a great deal of sleep over the worst cases, yet the city surgeon will approach a dislocation or fracture with the one thought, that it is a walking advertisement of either inferior or average ability, and actually loses more sleep over a simple fracture than an abdominal section. Thus the country practitioner assumes the burden of responsibility that seems to rest heavy on the city surgeon. Why? The public is accustomed to having fractures reduced at home. If he accepts the responsibility and takes the chances that bring little money or prestige and may bring criticism and damage suits, why not attempt operations that bring money and fame with less chance of disgrace. The day is dawning when the country practitioner will refuse longer to act as shipping clerk for his proud city confrères.

That our environments are bad is true; but, with all due respect to the hospital and city surgeon, we can make the average home as sterile, and our hands as surgically clean, and, if capable, we can with impunity attempt the same work with the same assurances of success that the operator in the city has. We have even better chances for success, by having, as a rule, patients who are in the beginning physically able to stand shock and are good subjects to withstand any ordinary complication in a surgical way. It may be true that certain cases belong to the specialist, but it lies with the country practitioner to say whether it is so of surgical cases, whether he shall send all of his major operations to the city or not. Each country pratictioner must be the judge as to where the specialty begins, and that decision must be arrived at conscientiously, leaving in the dark public opinion. No man should allow public opinion to debar him from his duty. We should not overlook our duty toward out patient, be he poor or rich, and should ever hold before us one thought—competency. We should not let conservatism take the place of common sense. Conservative surgery is all right, but the country practitioner is too prone to neglect or omit and call it conservatism, when in reality it is as much a malpractice act to neglect as it is to do wrong in the first place.

Unless there is a radical change, it will only be a short time until surgery will be an extinct

feature of country practice, and if a change is to be made it must be brought about by the country practitioner. He must do more surgery, and competency is to be obtained by study and postgraduate work. Every two or three years should find us spending our vacations at some postgraduate school and visiting the hospitals and preparing ourselves for work. After we have become competent we can more easily overcome the few drawbacks of environment and let public opinion change to suit the occasion.

Speaking of the country practitioner, from a surgical standpoint, I often wonder if the city surgeon does not look upon him as the soldiers did upon "D'ri" in Bacheller's work, "D'ri and I," and think he needs rest, etc. I think it time for the country practitioner to go on guard duty without the countersign, and halt every case of surgery, if he be competent.

MEDICAL PROGRESS.

THERAPEUTICS.

Chronic Acetanilid Poisoning.—Alfred Stengel (*Journal A. M. A.*, July 22, 1905) gives the histories of two additional cases of chronic acetanilid poisoning, both of them of interest from a diagnostic point of view. The first had been regarded as an obscure vascular disorder, and even after the cause was suspected, it offered some difficulties on account of the lack of morphologic changes in the blood. Some recent experimental work of Dr. C. Y. White, however, seems to indicate that these are not always readily producible. Another point of interest mentioned is the denial by the patients of the use of the drug which Stengel is inclined to attribute to a moral disturbance during the continuance of the habit; it agrees with his experience in other cases. After their recovery the patients readily admitted the facts. The polycythemia in one of the cases was also of interest, perhaps the more so as there was with it no splenic enlargement, which is common in chronic acetanilid poisoning. This combination had led him to the suggestion on a previous occasion that some of the cases described by Osler as chronic polycythemia with cyanosis and enlargement of the spleen might be due to acetanilid. Lastly, he calls attention to the ease with which neuralgic symptoms were controlled after the withdrawal of the acetanilid. It seems, he says, that the continued use, instead of controlling the neuralgic manifestations, acts as a depressant, and that they occur with even greater frequency than before taking the drug.

Intravenous Injection of Ergot.—Torald Sollmann and E. D. Brown (*Journal A. M. A.*, July 22, 1905) report the results of experiments, made chiefly on dogs, to determine the circulatory effects of the ergot preparations as found in the market, in therapeutic doses, normally and in the pathologic conditions in which the drug is recommended. Intramuscular injections were first employed, but the effect was so slight they changed to the intravenous method, that used by other investigators. The animals were anesthetized, the injections made into the femoral vein and the blood-pressure tracings taken with a mercury manometer, the connection being filled with 25 per cent. magnesium sulphate. The conclusions reached are, in substance, as follows: The typical effects of the intravenous injection of ergot consist in a large and abrupt fall of blood pressure, followed by a prompt recovery, and generally by a slight and short rise. The volume of the organs varies generally in the same direction as the blood pressure. The changes in the latter are mainly cardiac. This is confirmed by myocardiograms from the intact and excised heart. Ergot causes first a lessening and then an increase of the excursions; both phenomena may occur while the ergot is being injected; the rate of the heart is but little altered. The effect must be directly on the cardiac muscle. There is some oncometric evidence that ergot has a slight vaso-constrictor action, but this is slight and inconstant. There was no evidence of strong constriction or of high rise of blood pressure. With intramuscular injections the preliminary fall of blood pressure is absent. The action is independent of the dose, within wide limits. The relative predominance of fall and rise vary somewhat in different preparations; age, however, does not impair their effect on the circulation. Lowering the blood pressure by any method greatly lessens the effects. Shortly after the destruction of the spinal cord, however, ergot produces a relatively good rise of pressure. Large doses depress the vagus center and the vasomotor endings. It is not acutely fatal, however, in very large doses. The experiments do not point to any useful therapeutic action of ergot in modifying the circulation. The authors, however, do not wish to be understood as denying the clinical evidence in its favor, they merely claim that it lacks experimental evidence in its support. Its peculiar effect on the combs of fowls indicates that certain animals and certain vascular areas are more susceptible to the constrictor action of the drug. It may be so with man; it is conceivable that acting unequally on different organs, it may thus be of benefit in the obscure conditions in which it is recommended. In the face of the negative experimental evidence, however, they think that clinical conclusions should be formulated with caution and conservatism. In conclusion, they notice a peculiar effect, closely resembling that of ergot, that followed the intravenous injection of 0.9 per cent sodium chlorid solution. This occurred in three dogs and only when the blood pressure was high, and best with rather large doses. It was also most noticed when the ether had been removed for some time and ceased entirely when the animals had passed into shock. The article is a long one, with numerous illustrative tracings.

Treatment of Epidemic Cerebrospinal Meningitis with Diphtheria Antitoxin.—G. L. Peabody (*Med. Rec.*, May 13, 1905) gives the results obtained in twenty-two cases of the disease treated in this way by himself and Dr. Jacobi in the Roosevelt Hospital. In all but one the diagnosis was proved by finding the meningococcus in the spinal fluid. Of the twenty-two cases four received the antitoxin only subcutaneously, seven received it at different times both subcutaneously and intraspinously, and eleven received it only intraspinously. In only one case did it seem to cause any unpleasant effect. The mortality of the twenty-two cases, while still uncertain, will go well beyond fifty per cent., and the percentage of recoveries to date is a little over nine. There has not seemed to those who have watched the cases, to have been any influence for either good or evil ascribable to the antitoxin treatment.

Treatment of Epilepsy.—A. Strümpell (*Deutsch. Arch. f. klin. Med.*, Vol. 84, Nos. 1 to 4) states that many cases of epilepsy are not benefited much by the usual bromide therapy, since in the place of an occasional attack of convulsions they will now suf-

fer from chronic bromism, which renders them absolutely unfit for any mental work. If the patient is seen after the first attack, an attempt should be made to prevent recurrence by hygienic measures alone. This is also indicated in those cases where the attacks recur no oftener than every two to three months, and frequently the proper diet, with attention to the bowels and suitable occupation and surroundings, will mean a permanent cure. Unfortunately, the bromides cannot be replaced in severe cases, and even bromipin is not always well tolerated. In certain instances, atropine, either alone or in combination with oxide of zinc, will accomplish much. The preparations of valerian will also occasionally ward off an attack, but no permanent results have attended its use.

Action of Diuretics on the Kidney.—O. Loewi, W. M. Fletcher and V. E. Henderson (*Arch. f. exper. Path. u. Pharm.*, Vol. 53, No 1) have discovered that the intestinal vessels do not contract under the influence of caffeine, and that diuresis is also pronounced in narcotized animals, hence they believe that the slight rise of blood-pressure is not due to an irritation of the vasoconstrictor center, but to direct action upon the heart. The vessels of a kidney entirely deprived of its nerves, are not in condition of extreme dilatation, since caffeine will dilate them still more. This is caused by a direct action of the drug upon the vessel-walls, and also occurs when the nerves are degenerated. In a few cases dilatation did not occur under the influence of caffeine, but even here more blood passed through the kidneys. This latter phenomenon is the real cause of the caffeine diuresis; it may occur without diuresis, but diuresis is never seen without an increased flow of blood through the organs. Experimentally as well as clinically a certain degree of tolerance toward caffeine will be established, since the renal vessels will no longer react toward the drug, but in such cases, urea will still bring about a diuresis. The increased activity of caffeine in nephritis as compared with conditions where the kidneys are healthy, speaks in favor of the Traube-Cohnheim theory of nephritis.

Inoculation of the Horse with Syphilis.—A further contribution to this important subject is made by Piorkowski (*Deut. med. Woch.*, June 8, 1905), in which he describes the later observations on the horse inoculated some time ago with blood taken from syphilitic patients. The latter had been treated with mercury, it being the author's idea that the parasites, being affected by the drug, would give up their poison more readily. Five to ten c.c. were injected every three to four days, and the only sign of a reaction was a slight rise of temperature. Four weeks after the first injection, an eruption appeared, which spread, until after another eight weeks the entire body was covered with papules. The hair fell out in patches, and at the time of the last observation, six months after the experiment was begun, some of the papulæ were still present and new ones were forming. On the animal's back there was a bald spot as large as a child's head. A number of glands were temporarily enlarged. The objection was made that these manifestations might be due to the injection of the foreign albumin, but the author thinks that the reaction was too severe for this. A second horse was injected with blood from the first and soon developed similar lesions, as did also rabbits which received the blood of the second horse. No conclusions are presented, but further observations may throw some more light on the subject.

Value of Theophyllin.—A series of 855 cases, which have been treated with theophyllin, has been analyzed by M. Sommer (*Therap. Monatshft.*, June, 1905) with the following results: In 653 cases the drug accomplished the desired effect; in 64 the improvement was only relative, and in 127 no good results were seen. In 175 patients, theophyllin brought about a satisfactory diuresis after most other diuretics had failed, and in 110 diuresis was much more marked with theophylin than with the other drugs. No difference in action could be detected between the pure drug and the various salts on the market. After-effects were seen in as high as 35 per cent., but in the great majority these were very slight and chiefly gastric (vomiting, diarrhea and nausea). Two patients died soon after taking a powder, but it is impossible to decide if the latter was really responsible, since the cardiac weakness was extreme in each case. Collapse was observed three times, and in a large number such minor disturbances as languor, insomnia and general nervousness. The best results were seen in cardiac hydrops and (contrary to some observers) in acute nephritis, but good can also be accomplished in chronic nephritis, cirrhosis of the liver and in exudative pleuritis. Often the first dose is not well borne, but a tolerance is soon established. At first no more than 0.1 grams should be given.

GENITO-URINARY AND SKIN DISEASES.

Trichorrhexis Nodosa.—M. L. Neidingsfeld (*Jour. of Cutaneous Dis.*, June, 1905) in a discussion of the etiology of trichorrhexis nodosa arrives at the following conclusions: Trichorrhexis nodosa is both a normal and pathological process. It is universally present in long uncut hair as a normal condition, and is probably nature's method of physiologically arresting and stunting an otherwise unlimited and eventually cumbersome overgrowth of hair. When present in excess in a predisposed individual, it becomes a pathological process and abnormally stunts the growth of hair; the nodes are more prominently wounded and are often multiple, separated from each other by uniform intervals of normal hair shafts. Its etiology has been variously attributed to trophic, parasitic and mechanical influences. A mechanical causation is improbable on purely clinical grounds, and is incapable of artificial demonstration. The condition in brushes can likewise not be attributed to purely mechanical causes. A parasitic causation is not commensurate with the evidence thus far adduced from clinical studies, and bacteriological investigations. The most rational explanation of its etiology from physical, bacteriological and clinical investigation, and its analogy to kindred and associated changes in the hair rests in trophic influences, emanating from the metabolism at large, and permeating the hair to its ultimate extent.

Radiology.—During the past year the scientific and practical aspects of the subject of the physics and therapeutics of radio-activity has become of keen interest to the medical world, owing principally to the reports of the wonderful properties of radium and its use in treatment of disease. Many of these reports, even in medical journals, were, considering the superficial data given and lack of scientific methods shown, plainly unreliable. Wm. Sickles (*Wisconsin Med. Jour.*, April, 1905) gives a plain statement of the actual status of radio-activity at the present time. The tendency on the part of mod-

ern writers to include under the term, radio-activity, all the radiations from radium, the X-ray and the ultraviolet rays, is scarcely justified from a purely therapeutic standpoint. There is a great difference between the etheric vibrations of the ultraviolet rays and the X-rays, and the projected corpuscles of radio-active substances. The cathode ray can be demonstrated in a rather "low" vacuum tube, in which it is seen as a bluish line extending from the cathode to the anode. This consists of particles carrying an electric charge, and they may be deviated by a magnet, and will affect a photographic plate. Proceeding from the target and passing through the tube to the outside there is the X-ray, an example of radiation supposed to be produced by the intense disturbance in the ether when the rapidly moving bodies of the cathode ray are arrested by the target inside the tube. The rays from radium consist of three kinds, named the alpha, beta and gamma. "The alpha radiation is very easily absorbed, being unable to penetrate more than a few millimeters of air at atmospheric pressure; the beta ray is more penetrating, while the gamma ray is the most penetrating of all." "Williams has recently shown by some convincing experiments that the beta rays, which deflect them in the same direction as the cathode rays, are analagous and that the gamma ray corresponds to the X-ray." . . . "Pure radium being unstable in air, the salts only, usually the chloride or the bromide, are used." The strength of a specimen of radium is generally referred to that of uranium. The purest specimens of the chloride have an activity of about 1,800,000. "The strength of a given specimen of a radium salt can be crudely measured by its ability to penetrate sheet iron. The finest quality will easily penetrate a mass of iron over two inches thick." Judging from the reports of marvellous improvements, it would seem that American physicians had little difficulty in getting radium, and most of the radium here is known to be useless and of low activity. "Most of the cases treated in this country have been with a radio-active salt of from 300 to 7,000; but two or three small amounts of radium bromide, of 50 milligrams each, have been brought to America, that is of the highest activity, 1,600,000 to 1,800,000. This quality only (higher if possible, certainly nothing lower) should be used for therapeutic experiments."

The medical use of radium will be confined to therapeutics, as radiographs cannot be satisfactorily made with it. A considerable number of cases have been treated here and abroad with varying success, and the same precautions as with X-ray seem indicated. From a number of cases reported from reliable sources it may be stated that radium is useful in a number of cases of skin disease, but nothing definite can be said of it for the present.

Considering the prefatory remarks to this paper, regarding the ignorance of many writers on the subject, it will perhaps not be taken amiss if we point out to the writer several slight inaccuracies in the present paper, and refer him to the article by Dr. Piffard, on radio-logic misinformation in the MEDICAL NEWS, April 29, 1905. Williams will be surprised to learn that he is responsible for demonstrating that the beta and cathode rays are identical and that the gamma and X-rays are the same. It may be, as the author says, that radium is unstable in air, but as no pure specimen of radium has ever been isolated we cannot say for certain, and will thank him for his authority. That the strength of radium may be approximately determined by the penetrability of the rays is scarcely true, and as to the penetration being two inches for the purest specimens, we may say that we did not know that the radium possessed any penetrative power at all, but that the gamma rays had been demonstrated to possess a penetrating power easily discernable through twelve inches of solid iron. Regarding the statement that only specimens of 1,800,000 or stronger should be used in experiments, it is hard to see how one is to use stronger, if that is the strongest; and regarding the statement that weaker specimens should never be used at all, we may add that the most successful experimenter with radium in New York, Dr. Robert Abbe, has performed all his experiments with radium of 300,000 activity and less. Also we respectfully refer the writer to the law or equation formulated by Dr. Piffard connecting the mass activity and result of radium applications.

Measure of X-Rays.—The importance of a reliable method of measuring the X-rays needs no argument, in view of the multiplicity of attempts made to devise such a method since the general adoption of the X-ray in medical science. MILTON FRANKLIN (*N. Y. Med. Jour. and Phil. Med. Jour.*, April 22, 1905) presents a special form of electroscope for this purpose. The X-rays ionize air or other gases through which they pass, rendering them conductors of electricity, and a measure of the quantity of electricity transmitted through a given mass of air under a given pressure will accurately indicate the activity of the ray causing the ionization. The method is substantially analagous to that used for the purpose of measuring the radio-activity of the radio-active elements. In order that the results obtained by different observers at different times be comparable, it is absolutely essential that the electroscopes be identical in dimensions as well as in design. Some form of static electrometer might be used, but the complexity of the instrument and skill required in its manipulation debar it from general use. With a specially designed electroscope of the gold leaf pattern, on the other hand, the whole process of measurement may be completed by anyone in the space of thirty seconds. Variations in the condition of the atmosphere are provided against by the introduction of a dryer in the air chamber, which is sealed. Absorption in the atmosphere is compensated for by placing the instrument at the exact distance from the tube at which it is desired to utilize the rays.

An Instance of Staphlococcic Infection of the Tonsil Simulating a Chancre.—D. W. MONTGOMERY (*Jour. of Cutaneous Dis.*, May, 1905) states that in the diagnosis of chancre in its usual situations, the danger lies in mistaking lesions that are not chancre for chancre, while on the contrary, when chancre occurs in an unusual situation the danger lies in considering it to be some other affection. The author states that in the diagnosis of chancre of the tonsil the following possibilities to error may be found. The lesion is most frequently taken for a simple tonsillitis, or grippe, or a staphylococcic or a streptococcic sore throat. The next most frequent error is supposed to be diphtheria. It is sometimes mistaken for a mucous patch or an epithelioma.

Gonorrheal Pleurisy.—While gonorrheal pleurisy is not so frequent a complication of gonorrheal urethritis as rheumatism and cardiovascular affections, due to the same agent, yet that it is occasionally seen

is shown by Lemoine and Galldis in (*Revue Pratique des Maladies des Organes Génito-Urinaires*, No. 7, March 1, 1905), who report a series of cases. Ten cases are reported in which pleurisy followed an urethral discharge, accompanied in many instances by arthritis, endocarditis and pericarditis. It is to be regretted that no bacteriological examinations were made in these cases, but as the authors were competent observers, who eliminated rheumatism and tuberculosis, the diagnosis is very probable. Dr. Mazza reports the case of a girl of eleven years who had a gonorrheal discharge which was followed by polyarthritis, endocarditis, pericarditis and double pleurisy. In the pleural exudate were leucocytes, endothelial cells and diplococci. Pure cultures of gonococci developed in cultures of agar and blood serum from the pleural fluid. Bertrand's case was taken with pain in the side some days after the appearance of a gonorrheal discharge. Signs of effusion prompted thoracentesis. Fluid was obtained and at the end of aspiration a deposit was withdrawn. Cultures were negative, but the deposit showed by Gram's stain organisms which corresponded with gonococci in their morphology. Cardile's case was that of a young woman who contracted gonorrhea from her husband. Later a pleurisy developed, which lasted two months, without other symptoms. By centrifugalizing the pleural fluid gonococci were demonstrated alone; later they were found associated with another diplococcus. Jicinisky reported a case supposed to be tuberculous pleurisy. A more careful history showed that the patient had had an urethral discharge some months before. Examination of the sputum showed almost nothing but gonococci, and a few days later gonorrheal epididymitis lighted up. Fisher mentions the case of a man twenty-six years old who had had gonorrheal urethritis four years previously, from which time the discharge had been constant. He was suddenly taken with pleurisy, and in his sputum gonococci were present, but no tubercle bacilli. Lemoine and Bombart add another case where gonococci were demonstrated in the pleural effusion. Male, aged thirty years, had gonorrheal urethritis in July, 1896, which was neglected and lasted several months. February, 1897, the patient was taken with pain in the left side of the chest. March 25, 1897, aspiration was performed and fluid withdrawn. It was necessary to aspirate often, and by the end of August, 1897, twenty-five liters had been withdrawn. The pleural fluid showed gonococci in pure culture. A rib was resected to afford better drainage, but the patient sank steadily and died November 21, 1897. In these sixteen cases reported, four were of gonorrheal origin without doubt, as the organisms were found in the pleural fluid. These cases show that the pleurisy may come on with the urethral discharge or be delayed as long as four years. Next the question arises as to how the gonococcus reaches the pleura. The authors think that the most probable avenue of transfer is the blood, since the gonococci have frequently been found in the blood. There are various other suppositions as to the course of the complications of gonorrhea, such as that it is due to toxin or secondary infection or mixed infection, but these theories must give way to the actual finding of the organism.

Ethyl Chloride in the Treatment of Zoster.—To relieve the discomfort and pain which is one of the prominent symptoms of zoster, Morrow (*Jour. of Cutaneous Dis.*, April, 1905) recommends the use of ethyl chloride, acting as a counterirritant. It is used as follows: An area the size of a silver dollar is frozen at a point where the nerve emerges from the spinal column. While this usually relieves the pain along the entire nerve, it is better to freeze areas where the pain is localized. Generally this treatment relieves the pain for a day or more, but in some cases only for a few hours. When this is the case there is no objection to using the ethyl chloride frequently. He reports its use following its successful application upon ten cases.

Ringworm of the Scalp Cured by the X-Ray.—The chief reason why ringworm of the scalp is so obstinate to treatment is shown by Sabouraud and Noiré (*La Presse Med.*, 1904, page 825) to be due to the inability of the various antiseptic preparations employed to penetrate to a sufficient depth to act efficiently, as the root of the hair is inaccessible to external antiseptics. The authors have experimented considerably with microbe toxins and the salts of thallium, with the view of temporarily suspending the functions of the hair papilla. They finally arrived at a solution of the problem by the use of the X-ray, and have had very favorable results. On account of the numerous accidents and permanent alopecia which have followed the use of the X-ray in the hands of many operators, the method as given by Sabouraud and Noiré is particularly to be emphasized. The main point in their technic for the employment of radiotherapy consists in the use of the radiometer of Sabouraud and Noiré. This consists of a circular wafer of paper coated with an emulsion of platino-cyanide of barium in a collodion of amyl-acetate, and has the property of changing color under the action of X-rays in proportion to the quantity of rays absorbed. By comparison of an exposed wafer with a scale of colors it becomes easy to determine the exact amount of exposure necessary to produce a complete depilation without any of the attendant dangers of permanent alopecia. The technic of treatment is as follows: To cure a patch of ringworm of the scalp by the X-ray, place the patch at a distance of 15 centimeters from the center of the focus tube and place at the same time a disc of platino-cyanide of borium paper 8 centimeters from the center of the tube. When this disc has taken the color corresponding to the tint "B" of Sabouraud's radiometer, the operation is terminated. About seven days after the treatment a slight erythema results, and in about fifteen days the hair falls out. Cultures show that the fungus is not destroyed, so consequently, to prevent reinfection, the scalp is thoroughly anointed with an ointment containing oil of eade, the following morning the head is carefully shampooed and a weak solution of tincture of iodine rubbed over the entire scalp. A careful examination at the end of thirty days is made to show that no diseased hairs have escaped. The cure requires about three months, and last year over 327 cases of cures followed this form of treatment.

Changes in the Nails After Acute Diseases.—These are perhaps more common, especially after infectious diseases, than would appear from the scattered references in the literature. Eger (*Berl. klin. Woch.*, May 15, 1905) describes three typical cases in which such changes were observed coming on during convalescence—these were multiple neuritis, typhoid and toxic gastro-enteritis. The effects are usually most marked on the thumbs, less so on the other

fingers and toes, and consist of white spots or transverse furrows, in front of which the nail is very brittle and scaly. This condition appears as the nail is pushed forward into view by the growth of the matrix, and is probably the result of defective nutrition during the course of the illness. The ridge which appears back of the groove is most likely due to a new proliferative process which begins as the general disease subsides, and expresses an effort to get rid of the dead portion of the nail.

OBSTETRICS AND GYNECOLOGY.

Uterine Fibroids.—J. WESLEY BOVÉE (*Journal A. M. A.*, May 27), says that his former publication on the appendages was the only publication in the literature on the subject except the report of a case by Hey Groves and some incidental references in other articles. He republishes here his own four cases and that of Dr. Groves. Such occurrences throw serious doubt on the theory of the efficiency of the removal of the appendages to produce atrophy of existing fibroids, which has been accepted to a considerable extent in Europe and in this country. The possibility of the growths having existed in an undeveloped state before the ablation is admitted, but not considered probable, as is also that of pelvic adhesions acting as a casual factor. That an infectious process of some degree or variety in the uterus may bring about this fibroid degeneration is deemed by the author as highly probable, though problematic. The only adequate theory he finds on which to base a cause for the development of fibroid after double salpingo-oophorectomy is that of the endarteritis noted by Benckeiser, but Bovée wishes the relation was clearer and better substantiated by cases. Such development of fibroids after castration is probably rare, and due to some infrequent cause like this endarteritis obliterans. In the absence of a better explanation he is therefore inclined to accept this one.

Two Cases of Congenital Anomalies of the Female Genital Tract.—G. M. BRILKNER (*St. Louis Med. Rev.*, May 27, 1905) reports two very interesting congenital anamolies of the genital tract, namely, an imperforate hymen causing hematometra and hematocolpos, and a case of atresia vaginæ totalis, with absence of the uterus. The author states that opinion is still divided as to whether or not the development of the hymen is of ectodermal origin. The hollowing-out process, which the solid Müllerian cord undergoes to form the hollow vagina does not extend to the hymen, which, in the normal instance, bears at some parts of its area, a perforation. This he considers as an extension or continuation of the procedure by which the Müllerian duct becomes converted into a series of hollow tubes—tubes, uterus and vagina.

Cæsarean Section in Myasthenia Gravis.—Myasthenia gravis is characterized by a variable degree of weakness of some or all of the voluntary muscles. After prolonged rest these muscles may respond to the will, but rapidly become exhausted again. Facial paresis and ophthalmoplegia give a characteistic appearance, there is no muscular atrophy or reaction of degeneration. The muscles most used are first affected. The sexes are equally attacked, the symptoms following some previous affection, such as influenza, the exanthemata, emotional excitement or over exertion, and in women, menstruation and pregnancy. Sensory symptoms are absent, the prognosis is grave, death occurring in most cases without any pathological structural changes. J. E. GEMMELL (*Jour. Obstet. and Gyn. Brit. Emp.*, April, 1905) has reported a case of pregnancy in which the patient showed marked weakness, being able only to walk but ten yards with a slow waddling gait. Knee jerks, ankle jerks, and plantar reflexes were normal. The lips could not be closed, attempts at smiling gave rise to the "nasal snarl" appearance. There was marked weakness of the palate muscles, thickened speech and occasional regurgitation of fluids through the nose. Sight and eye-reflexes were normal, but the orbital muscles shared in the general weakness. The symptoms became progressively worse as pregnancy advanced. Owing to weakness of the respiratory muscles increasing dyspnea became alarming, and Cæsarian section was resorted to shortly before term as the best procedure for a speedy termination of the pregnancy. The child was a healthy female. There was gradual improvement during the puerperium, but after six weeks' treatment with strychnine she was still quite helpless. Sections of uterine and rectus abdominis muscles showed no pathological conditions.

Vaginal Cleanliness.—The question of the preliminary cleansing of the vagina on the morbidity of the puerperium, is discussed by F. AHLFELD (*Zeitschr. f. Geb. u. Gyn.*, Vol 54, No. 1). He bases his conclusions on statistical and bacteriological investigations. Three per cent. solutions of cresol were employed for the irrigations, and he absolutely denies that any disinfectant effect can be obtained with the one per cent. solution. The average number of cases in which no rise of temperature occurred during the puerperium was usually about 68 per cent., while during the two years in which no irrigations were employed this number sank to about 53 per cent. In the operative cases, in which the cleansing was more complete and thorough, the number of cases in which no fever was present was even greater than the average. In a number of instances in which streptococci were demonstrated in the vagina before douching, a marked decrease in the quantity of growing organisms was noticed within a few hours after the irrigation had been given. The writer claims that if such a procedure is attended by the good results mentioned, there is no reason why it should not be employed, provided that it is not attended by any harmful results, and he does not believe that such occurs in the method advocated.

After Results of the Bossi Method.—This procedure has met with much opposition among a number of obstetricians and Bardeleben declaims very strongly against it, basing his statements on a series of six cases thus delivered. LICHTENSTEIN (*Archiv. f. Gyn.*, Vol. 75, No. 1) attacks this criticism, claiming that the number of cases was too small to serve as a criterion, that the resulting tears were not necessarily due to the instrument, and the after effects on the patients were severe because the tears were not immediately sutured as recommended. Lichtenstein had the opportunity of observing 18 cases, in which the Bossi instrument had been used. In all cases no tears resulted and the women were practically without symptoms. Of the remaining cases, four presented small tears; two, large ones, and the remaining one a bilateral laceration. Interference with conception and subsequent pregnancy could not be proven. No one, the author thinks, would question at the present time, the wisdom of employing forceps, the cranioclast, or perforation when necessity demands them, and similarly he thinks the time is

not far distant when a rapid means of mechanical dilatation will likewise be adopted. The main considerations remain—a definite indication, patience, time, and the proper instrument, such as the perfected dilator of Bossi, or that of de Seigneux.

EYE, EAR, NOSE AND THROAT.

Convergent Strabismus or Squint and the Modern Method of Treating It.—In a review of this subject T. A. Woodruff (*Chicago Med. Rec.*, June 17, 1905) states that in a large majority of cases the visual acuity of the eye that squints is defective at birth, and the brain, perceiving an indistinct and blurred image in its endeavor to use both eyes together, and get binocular single vision, suppresses the image in the squinting eye. The defective eye, thus left to its own resources, has a tendency to deviate from the primary position. From this fact alone one can see the necessity of beginning treatment in the first stages, if a successful issue is desired. It is during the developmental stage of the visual apparatus that much good can be accomplished in remedying the defect and getting parallelism of the visual axes, and it is during this stage that a large proportion of the cases can be cured without the necessity of submitting to operative procedure. The successful treatment of convergent squint depends upon several factors: (1) The beginning of treatment in the earliest stage; (2) the restoration of binocular vision; (3) the improvement of the visual acuity in one or both eyes and correction of the hypermetropia, thereby relieving the accommodation and reducing the excess of convergence; (4) the development of the power of fusion; (5) the establishment of binocular single vision. The accomplishment of these can be best obtained by means of the following: (1) The correction of errors of refraction and improvement of vision; (2) the education of binocular single vision by means of the stereoscope and the amblyoscope before the fifth year, and (3) operative measures. If the deviation is not more than 20 degrees, a free tenotomy of one internal rectus or advancement of one external rectus without tenotomy of the internus is usually sufficient. Where the convergence exceeds 20 degrees an advancement of the external rectus with tenotomy of the internal will probably be necessary.

The Value of Protargol in the Treatment of Gonorrheal Conjunctivitis.—On account of the destructive action the gonococcus exerts upon the eye, not only in the infant, but also in the adult, efforts have been made from time to time to secure a thoroughly reliable and efficient germicide which, in the hands of all practitioners, can be used with absolute safety. F. C. Hotz (*Chicago Med. Rec.*, April, 1905) recommends protargol, which, while possessing almost as great germicidal properties as silver nitrate, is free from the undesirable properties of the latter. He recommends a 20 per cent. solution as being most efficient. In order to obtain a perfect and thorough contact of the solution with every part of the inflamed conjunctiva the author saturates the cotton of an applicator with the solution, lifts the upper lid from the eyeball, slips the applicator between the lid and the eyeball, to the retrotarsal fold, and passes it over this fold from the outer to the inner canthus and back several times, thus, as it were, rubbing the protargol thoroughly into the conjunctiva. Another application is then used to treat the lower fornix and palpebral conjunctiva in the same way. The 20 per cent. solution is applied twice daily until the discharge is greatly reduced, has lost its purulent character and contains no more cocci. During the intervals between the applications the lids should be cleansed as often as necessary to prevent the discharge from crusting up the lid margins. Fresh solutions only should be used. This treatment is so simple and safe that any physician can carry it out, and therefore it is to be hoped that it will be adopted by the practitioner who sees the purulent ophthalmia of infants in the early stage more frequently than the specialist, and therefore is in a position to rescue many a child from blindness by the early and proper treatment.

Radiotherapy in Trachoma.—At the beginning of this year Cohn, of Breslau, reported seven cases of trachoma and follicular conjunctivitis treated successfull, by radium, the action of which he defined as "cito, tuto et jucunde." Selenevsky (*Roussky Varach*, May 14, 1905) finds a theoretical basis for the success obtained, inasmuch as it is assured by several investigators that the beneficial effect of radium on malignant growths is due to its power to decompose the lecithin which forms a substantial element of these growths. As the granulations of trachoma also contain a certain percentage of this substance the effect thereon of radium becomes intelligible. The author picked out seven trachomatous cases of a most pronounced character; the amount of radium used was at first 1 mg., and later 10 mg.; time of exposure five to ten minutes. The tube containing the radium was simply applied over the area treated and slowly moved about without touching the surface. The results were really astonishing: Five of the seven eyes were entirely cured, the other two are in a fair way of becoming so. The absorption of the granules was not accompanied by any untoward effect. The number of sittings varied from eight to fourteen. The author firmly believes that even in cases where the granules are extensive, good results can be obtained with radium, and that the treatment when properly conducted is perfectly harmless.

The Operative Treatment of Empyema of the Antrum of Highmore.—Otto T. Freer (*Chicago Med. Rec.*, July, 1905), after carefully reviewing the Küster operation through the facial wall; the Maiborn-Cooper operation, through the alveolar process; the Caldwell-Luc operation, through the nasal wall; the Mikulicz operation, under the inferior turbinate, and the operation through the middle meatus for empyema of the antrum of Highmore, considers that for the acute, subacute and milder chronic cases the internasal operation through the middle meatus is undoubtedly the best method, for it is easy of performance, inflicts but trifling injury, leaves the nasal interior practically intact and avoids the formidable operation through the facial walls. When the suppuration is marked with much foul discharge, or where the long duration of the disease leads to a suspicion of marked degeneration of the mucous lining of the antrum, the nasal removal of nearly the entire nasal wall is indicated, these being the operations of Rethi and Clavue. These operations the author considers that in the great majority of cases result in a cure and does everything for the patient that may be obtained from even the most radical Caldwell-Luc procedure, and with far less traumatism. It is no bar to a later operation through the facial wall, should it become necessary, and has the advantage that it represents the last and most advantageous step of the Caldwell-Luc operation, without its preliminary mutilation of the facial wall and mouth

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 9, 1905.

RECENT THERAPEUTIC APPLICATIONS OF SEA-WATER.

FROM time immemorial the philosophic mind has sought to penetrate the manifold mysteries of the deep. As one by one its living treasures have come within the close scrutiny of science, the boundless ocean begins to be recognized as the cradle of life, as the original source of the vast organic hierarchy of the earth. In the countless eons during which the sea was the sole environment of protoplasm, there must have developed an intimate and causal relationship between the physical and chemical characteristics of the sea-water and the complex constitution of the primary physical basis of life. Only within the last few years have these relationships been carefully studied, and the results, taken in connection with certain familiar clinical experiences, suggest a rich mine of possibilities in the healing art.

That sea-bathing has a unique therapeutic value in many morbid conditions has been abundantly demonstrated. Very little, however, has been known about the manner in which a dip in the ocean has a favorable effect on the organism. There is practically no cutaneous absorption of any of the saline constituents of the water. The good effects have been attributed to the physical action of the waves, the exercise, the fresh air with its large content in ozone, and the force of the winds. An actual investigation of the effect of sea-bathing and sea-climate upon metabolism has been made by A. Loewy and F. Müller (*Pflüger's Archiv*, July 9, 1904). They found that west winds and an increased force of the waves augment the bodily metabolism. The stimulation of the latter goes hand in hand with the stimulation of appetite, digestion, and psychic functions, and is of reflex origin, the stimuli being various physical factors, such as lower temperature, movements of the air, etc. In the light of other recent researches on the effects of the internal administration of sea-water, it is quite probable that part of the favorable effects of ocean-bathing is to be attributed to the water that is occasionally swallowed.

There is sufficient evidence at hand to support the belief that sea-water has active therapeutic virtues and that these are due to its chemical composition. There has been a nebulous idea in the minds of the laity that skin diseases are favorably influenced by sea-bathing. This conclusion has been crystallized in the observations of R. Abrahams (MEDICAL NEWS, March 26, 1904), who reports the good and prompt effects of a course of sea-baths on many forms of chronic cutaneous disease, particularly pityriasis versicolor, herpes tonsurans, chronic eczema, and pruritus senilis. Since some of these conditions are of parasitic origin, one can readily associate the good effects with the antiseptic qualities of the water.

That sea-water actually possesses germicidal power has been proved bacteriologically and clinically. In the gynecological service of Dr. Leblond at Saint-Lazare, M. Legourd (*Report de Therap.*, Feb., 1905) has discovered a valuable antiseptic power in sea-water, which has undergone electrolysis, and which is termed "hermetin." It is non-toxic and neutral, and contains oxygenated compounds of chlorine in a nascent state. It has produced favorable results in the treatment of affections of the vulva, vagina, and uterus.

Within the past few years the fact has been definitely established that under no other conditions are the various lesions of surgical tuberculosis so favorably influenced as by a residence at the seashore. That the beneficial effects are due not simply to the pure air is proved by the fact that these cases do not get along so well in the country. That the saline constituents of the

atmospheric moisture are responsible for this curative power appears to be indicated by the following interesting experiences.

MM. Robert-Simon and René Quinton (*Gazette des Hopitaux*, June 22, 1905) report their results in the treatment of eighteen cases of tuberculosis by means of subcutaneous injections of sea-water. The latter was made isotonic with the blood, *i.e.*, having the same saline concentration. This was effected by mixing 83 parts of Atlantic sea-water with 190 parts of pure drinking water. The freezing point of the mixture is the same as that of the blood—0.57°. Of the 18 cases treated, 14 were pulmonary tuberculosis. The treatment consisted in the injection, every three or four days, of 100 to 300 cubic centimeters of the above solution. In three cases no benefit was observed. In the remaining fifteen marked improvement was noted. The cough, expectoration, and night sweats diminished or disappeared entirely, sleep returned, and the appetite improved. In seven cases of pulmonary tuberculosis in the first stage, after from one to three months of treatment, there was not only a return to the normal respiratory rhythm, but also a more or less complete disappearance of the subcrepitant and crepitant râles. In three cases presenting themselves during the second stage of this disease, the treatment brought about a marked diminution in the number of moist râles, and in the expectoration. Even in the advanced stage of the disease the subcutaneous injections were followed by good effects. There were noted a total or partial healing of cavities, and a suppression of hemorrhages. One case of lupus of the nose was considerably benefited. Out of three cases of tuberculous glands, one was improved. An increase in weight was observed in all the cases that were otherwise benefited. These results are of no little interest and justify a more extensive trial of this novel method of treatment. This is also warranted on other grounds that are not purely theoretical.

In speculating upon the manner in which the injections of sea-water thus favorably affect the tuberculous process, one would naturally first think of the sodium chloride and attribute the good effects to this alone. The physiological relations of common salt have not yet been entirely worked out. Yet one of the most important discoveries recently recorded in the physiology of this substance concerns its relation to the mechanism of immunity. R. Turró and A. Pi y Suner (*Journal de Physiol.*, Jan. 15, 1905) found that the injection of large doses of saline solution into rabbits increases their resistance to the infections of malignant edema and the streptococcus. This effect is attributed to the fact that the saline solution dissolves a large amount of alexines out of the protoplasm of the cells, and adds it to the bodily fluids, thus increasing their bactericidal power. The degree of immunity depends principally upon the bacteriolytic power of the cells and humors, and this power is directly in proportion to the degree of solubility of the active substances. If a tissue contains enzymes that are but slightly soluble, its defensive power is diminished. If it is easily coagulated the defensive power is destroyed and the organism is helpless. The organism is infected by virtue of the coagulability of its plasmas, and resists infection by virtue of their solubility.

By applying the above results to the explanation of the curative value of sea-water in tuberculosis one may assume that the sodium chloride enables the alexines to be dissolved out of the cells, thus increasing the resistance of the individual.

Another explanation of the good effects of the saline injection may be gleaned from the researches of W. Ercklentz (*Zeitsch. f. klin. Med.*, Vol. 48, No. 3). This observer studied the effect of saline infusions upon the elimination of toxic substances from the organism. A number of rabbits were given subcutaneous injections of the minimal lethal doses of anilin, strychnine, arsenic, ricin, and cantharidin. As soon as the toxic symptoms appeared an intravenous saline infusion was given, with the result that the elimination of the poison was hastened. This result was attributed to an increased diuresis.

Not only laboratory experiments, but also clinical observations, attest the value of normal salt solution in various toxic conditions. H. F. Williams (Medical News, April 25, 1903) has reviewed this phase of the subject and has reported the good results he has himself obtained. Among the various diseases in which the intravenous or subcutaneous injection of normal salt solution has been of value are: Typhoid fever, pneumonia, dysentery, puerperal eclampsia, peritonitis, septicemia, uremia, ptomain poisoning, delirium tremens, acute digestive disorders,

cholera infantum, and other forms of toxemia. In connection with the reputed success of sea-water injections in tuberculosis, one case reported by Thompson is of interest. It was that of a tuberculous woman in whom persistent vomiting was relieved, after fruitless attempts with numerous drugs, by copious subcutaneous injections of salt water.

The expression, normal salt solution, has undergone within the past few years a definite evolution. At first .7 of one per cent. was considered to be the proper concentration of normal salt solution, but later the figure was properly raised to .9 of one per cent. Yet it is questionable whether this represents the solution which is most favorable to the physiological efficiency of the tissues. Thus Ringer's solution, containing, besides sodium chloride, other salts, notably calcium chloride, represents more nearly the normal physiological environment of the cells. In fact, as recent researches have shown, a pure solution of sodium chloride is relatively toxic to the bodily units. Thus Jacques Loeb (*Pflüger's Archiv,* March 28, 1905) has shown that the recently fertilized egg of *Fundulus* develops both in distilled water and in sea-water, but if brought into a salt solution having the same concentration in which salt is present in sea-water it quickly dies. But if to the salt water be added a small quantity of a salt of a bivalent metal, even such poisonous compounds as $BaCl_2$, $ZnSO_4$, etc., the latter will allow the embryo to develop. The young *Fundulus,* which has just hatched from the egg, can live for quite a long time in distilled water or in sea-water, but it will quickly die in a pure solution of common salt. This toxic action may be inhibited by the addition of $CaCl_2+KCl$. Either of these alone is not sufficient for this purpose.

This and other researches of Loeb, and the investigations of Matthews, Fischer and others, have shown that the solution which is most favorable to the life of the tissues is one which contains a number of salts, and these in the same concentration in which they exist in sea-water. The excess, deficiency or removal of one or more of these salts disturbs the equilibrium of the solution, which becomes toxic for the animal cell. The practical application of this fact is obvious. The normal salt solution of the future will be one having practically the same composition as sea-water, if not sea-water itself.

It is easy to explain the reason for this predilection of the animal cell for an environment having the same saline content and concentration as the water of the ocean. During the dawn of life all cells lived amid this environment, and the chemical and physical structure of protoplasm became adapted to the chemical and physical characteristics of the surrounding medium. In spite of the enormous lapse of time, and the complex elaboration of the simple protoplasmic units into the higher animal forms, the former still retain the ingrained habits of their primitive life.

INJURIES TO THE SPINAL CORD.

Severe traumatisms to the spinal cord, from simple shock to complete severance, are daily becoming more frequent. A broken back was once a rarity, and considered perforce to be immediately fatal; to-day it is almost a commonplace, and while not deprived of its most distressingly serious nature, yet its careful treatment may insure a high degree of comfort to the sufferer.

The occasion does not permit of a complete summary of the present attitude toward the minor and major grades of traumatic injury to the spinal cord, yet certain facts have of recent years been brought to the fore which might be advantageously discussed.

Severe injuries, as fracture or dislocation in the cervical region, have been found to be almost universally extremely grave. If death does not immediately follow the accident, the resultant hemorrhage, inflammation or redisplacement is usually fatal.

A strikingly unique injury is reported by James A. Kelly (*Annals of Surgery,* August, 1905), in which there was a forward dislocation of the atlas with recovery. The factor that saved this patient's life was a coincident fracture of the odontoid process of the axis, which, being carried forward by the transverse ligament, prevented the transfixion of the medulla. It is further noteworthy that, notwithstanding the verification of the diagnosis by excellent X-ray pictures, no pressure symptoms developed for a long time after the injury, and that the patient was able to take up his work as a laborer without distress, in spite of a permanent change in the position of head and neck.

From another point of view serious difficulties in definite diagnosis of severe cord injuries are emphasized by the studies of A. Fickler (*Deutsche Zeitschrift für Nervenheilkunde,* Vol.

29, Heft 102), who shows that in lower animals following experimental traumatisms, applied directly to the exposed spinal cord, not as in the experiments of Schmaus, Kirchgässer and others who made crushing blows on the outside of the vertebral column, there may be a true motor paralysis below the site of application of the trauma without any injury to the cord that can be macroscopically or microscopically demonstrated.

Such paralysis might be temporary only. The partial protection afforded by the muscles, spinal column, veins and fatty tissue, together with the dura is considerable. The same clinical picture can be produced experimentally in animals. The concussion imparted to the cord is a swinging movement. The paralysis is not the result merely of the concussion, but is the result of the mildest form of contusion of the cord; the resulting total paralysis, and the rapid recovery from the same are to be explained on the basis of variations in the axis cylinder, and not of molecular alterations. The lesion in the cord is circumscribed, and more marked at the point of contrecoup than at the point of application of violence. If the place of contrecoup is at the foramen magnum, then a lesion of the cord does not occur.

Apart from the localities of coup and contrecoup, the extent of contusion is also determined by the varying consistency of the cord itself. The motion imparted to the cord by a blow is transmitted chiefly in the direction of the blow through the cord, losing in intensity as it proceeds from the point of impact; small waves also start medially from this point; the amount of contusion is proportional to the degree of trauma, the distance from its point of application and the resistance offered by the nervous tissue elements. The least resistant tissue is the nervous tissue; the blood vessels are the most resistant. Only in the case of opening up of the central canal does a flow of lymph play a destructive rôle. Central hemorrhage occurs only with a damage of the nervous tissue, and only when the central veins are in the direction of the line of injury. Thrombosis has little to do with the genesis of traumatic lesions of the cord. The vascular changes appear to cause only late forms of spinal apoplexy.

In view of the recent striking cases of possible regeneration after cord injury, as reported by Harte and Fowler, the result of Fickler's studies of the process of regeneration in the spinal cord is of more than passing moment. He says that the regenerative phenomena following experimental lesions of the cord in animals are not as marked as those following compression of the cord in human beings. Section of the white substance between the anterior horns and the periphery is followed by regeneration of nerve fibers above and below the plane of section. A regeneration of ganglion cells in the cord has not yet been observed. Regeneration of the nerve fibers occurs in many diseases of the cord; whether the disease has already run its course or whether it is slowly developing; it occurs in traumatisms, compressions, syringomyelia and in transverse and disseminated myelitis. It does not occur in the columnar degenerations and in multiple sclerosis.

In order that regeneration may occur, it is necessary that the ganglion cell shall be intact. The first evidence of regeneration is seen one week after the section, and the process advances slowly. Only a comparatively small number of fibers are restored. The functional result is not a very considerable one. The best conditions for a restoration of function in the anterior part of the cord are afforded by compression which, leaves intact the central veins and the general configuration of the cord. A regeneration proceeding from the compression of the posterior roots has not yet been found, and probably does not occur, since the cause of injury of the cord is usually a caries of the vertebræ, which causes tuberculous ulceration of the ganglia of the posterior roots, in which case no regeneration can occur.

ECHOES AND NEWS.

NEW YORK.

New York and New England Association of Railway Surgeons.—The fifteenth annual meeting of this Association will be held at the Academy of Medicine, New York City, November 17 and 18, 1905, under the presidency of Dr. G. P. Conn, of Concord, N. H. One half day of the meeting will be devoted to a symposium on "Injuries to the Head and Spine." Noted surgeons will take part in the discussion. A cordial invitation is extended to the profession.

Medical Department of Fordham University.—The new medical department of this institution will open on September 28, with the following faculty: Anatomy, George A. Leitner; physiology and hygiene, E. Franklin Smith; materia medica and theraputics, Thomas J. Dunn and James N. Butler; chemistry and physics, taught at St. John's College; obstetrics and gynecology, John Aspell and George M. Edebohls; neurology and historical medicine, James J. Walsh. As only first year work is to be undertaken during the present session the full roster of professors is withheld for the time being. Dr. James N. Butler is Dean of the Faculty.

PHILADELPHIA.

Smallpox Epidemic.—Orwin, Pa., a small village near Pottsville, is now suffering with an epidemic of smallpox. The court of the last-named place has appointed Isaac Brown sanitary agent of Porter township, where the disease runs rife.

Enteric Fever Designated as Contagious.—Acting in accordance with the decision reached by the health experts at Washington, D. C., the Bureau of Health will hereafter classify typhoid fever among the contagious maladies. While the houses in which such diseases occur will not be placarded it is to be hoped the mere classification will impress the caretakers of the patient sufficiently to prevent its spread. Perhaps then the mothers and others caring for typhoid patients will better observe the rules of cleanliness and will institute disinfection and fumigation.

Pathogenic Bacteria Found in the Conduits Connected With the Filter Plants.—In a recent letter to the Mayor, Major Gillette, chairman of the commission of experts, pointed out that the daily reports made of the filter during the construction of the conduits show that the *Bacillus coli communis* was found in one place. The writer suggested that the conduits be pumped out in order to determine whether or not the bacteria passed through the filter. It is estimated that in order to accomplish this work four months' time and between $35,000 and $40,000 would be required.

Philadelphia Physicians to Attend the Tuberculosis Congress.—The steamer St. Louis, sailing on September 16th, will have on board Drs. Flick, Walsh, McCarthy and Ravenel; this quartet will attend the Third International Congress on Tubeculosis which will be held in Paris, October 2d to the 7th. Dr. Flick will read one paper on the "Prognosis of Tuberculosis" and another on the "Work of the Phipp's Institute." Dr. Walsh will speak of the "Work of the White Haven Sanitarium" and will read a paper on the "Kidneys in Tuberculosis." Dr. McCarthy will read a paper on the "Changes in the Brain and Nervous System in Tuberculosis." Dr. Ravenel is the American reporter of the Congress.

Indefinite Medical Terms Not Acceptable.—Acting in accordance with the new State law passed by the last Legislature the Pottsville Board of Health will see to it that the law is enforced in its realm and that if any physician fails to abide by it he will be punished. This Board of Health has determined that no undertaker will be given a burial permit who holds a certificate of death with such terms as "heart disease," "accident," "kidney disease," "blood poisoning," "breaking down," as causes of death. If such terms can be avoided and the definite cause of death be given statistics can then be compiled which will be of great value to the scientific medical man. This, however, is not the only advantage of the edict. It will insure an exact diagnosis from the physician who makes visit after visit without studying his cases sufficiently to give him the faintest clue to the nature of the disease present. As matters stand he finds it much easier to flatter the family and concoct some tale which will satisfy them.

Crusade Against Malpractitioners.—The postal inspectators have begun a war upon fakers and malpractitioners and have already held several under bail to wait trial. Inspector Malone has communicated with various "remedy companies" and "confidential doctors," the replies to these letters will be held as evidence against the prisoners. Among the arrested are Thomas Wallace, alias Dr. White, 129 North Ninth Street; Mrs. J. Bright, alias "Dr. Revere," 1102 Mt. Vernon Street; Julius Neblau, alias "Dr. Gordon," "Dr. French," "Dr. Neblau." Of the last named individual Mrs. Bell formerly employed by Neblau testified he was "doctor" anything and anybody as the request might have been. It was she who prepared a registered letter designed to capture Neblau. Coroner Dugan, who carried on a similar campaign against these people last year is now working in conjunction with the postal inspectors. He said that he alone is powerless to attack the fakers, because they do not come under his jurisdiction until they are responsible for some death.

Medical Inspector's Duty.—The systematic work of each school inspector has been clearly defined. He will make daily visits to schools allotted to him and inspect pupils that are set aside by the principal as bearing evidence of being ill. Each day he will examine and make a record of all the pupils, whether ill or not, in one school. This he will continue until all the pupils in his district are examined. He will exclude from school every child suffering from acute disease, whether contagious or not, any form of disease that may be a menace to other children, any form of disease of sufficient gravity to impede the work of the child, and any pupil not presenting evidence of successful vaccination, notwithstanding the certificate the pupil may hold. When a child has been excluded from school the inspector shall call at the home to determine whether or not the pupil is receiving medical attention; if not the case shall be reported to the chief medical inspector. As elicited from the systematic examination the actual number and percentage of children suffering with the following diseases shall be reported to the chief medical inspector: Myopia, hyperopia, strabismus, astigmatism; defects of hearing; spinal curvature, flat foot; acute and epidemic conjunctivitis, obstruction of the lacrymal duct, trachoma; diphtheria, tonsillitis, adenoids; impetigo, eruptions, itch, eczema; phthisis, asthma, bronchitis, rickets, scurvy, scabies or parasitic diseases of the scalp.

Program of Meeting of the Medical Society of the State of Pennsylvania.—The regular annual meeting will be held at Scranton on September 26 to 28, 1905. The morning session of the first day will be devoted to the reports of officers, committees, etc., which will be followed by the program as given below. "Address in Medicine," by S. Solis Cohen, Philadelphia. "The Diagnosis of Pneumonia and Empyema in Children," by Alfred Hand, of Philadelphia; "The Adaptation of the Public to the Principles and Practice of the Prevention of Tuberculosis," by Howard S. Anders, of Philadelphia; "The Diagnosis of Incipient Tuberculosis," by George W. Norris, of Philadelphia; "The Sanatorium Treatment of Tuberculosis," by George A. Kolb, of Erie; "Open Air vs. Confinement in the Treatment of Bone Tuberculosis," by H. Augustus Wilson, of Philadelphia. "Address in Surgery," by Jonathan M. Wainwright, of Scranton; "The Results of Surgical Treatment in Exophthalmic Goiter," by B. Farquhar Curtis, of New York; "Observations on Cancer of the Head and Neck With an Analysis of 110 Operative Cases," by George W. Crile, of Cleveland, Ohio; "Focal Diagnosis of Operable Tumors of the Cerebrum," by Charles K. Mills, of Philadelphia; "Surgery in Relation to Operable Lesions of the Cerebrum," by Charles H. Frazier, of Philadelphia; "The Treat-

of Trifacial Neuralgia by Complete Avulsion of the Peripheral Branches of the Trigeminal Nerve," by Ernest La Place, of Philadelphia; "The Essentials of Successful Roentgen Therapy," by Charles Lester Leonard, of Philadelphia; "The Adjustment of Radiation for Various Physiological Effects," by Russell H. Boggs, of Pittsburg.

Second Day.—"Address in Neurology," by E. E. Mayer, of Pittsburg; "Herpes Zoster Exophthalmicus," by Edward Stieren, of Pittsburg; "The Practical Value of Some Old Remedies," by John V. Shoemaker, of Philadelphia; "Some Color Comparisons in Medicine," by Henry E. Wetherill, of Philadelphia; "Insanity in the Aged," by Charles W. Burr, of Philadelphia; "Report of Diaphragmatic Hernia with Complete Extrusion of Stomach and Spleen," by J. Bruce McCreary, of Shippensburg; "Address in Otology," by Michael V. Ball, of Warren; "Thyrotomy vs. Laryngectomy, Notes on the Frequently Malign Nature of Chronic Hoarseness," by Chevalier Q. Jackson, of Pittsburg; "The Present Treatment of Squint," by William Campbell Posey, of Philadelphia; "The Mastoid Operation," by Edward B. Dench, of New York City; "Mastoiditis, Its Importance in Practice," by S. Makuen Smith, of Philadelphia; "The Subcutaneous Resection of the Septum," by William L. Ballenger, of Chicago; "Acute and Chronic Inflammation of the Accessory Sinuses of the Nose," by W. G. B. Harland, of Philadelphia; "Can the Deaf Child Be Taught to Hear," by G. Hudson Makuen, of Philadelphia; 'Address in Hygiene and State Medicine," by George W. Wagoner, of Johnstown; "Protective Inoculation Against Typhoid Fever," by H. Bergey, of Philadelphia; "Typhoid Fever," by Seneca Egbert, of Philadelphia; "Pernicious Anemia," by J. A. Lichty, of Pittsburg; "Chronic Rheumatism," by Charles F. Painter, of Boston; "The Differential Value of Blood Cultures," by David L. Edsall, of Philadelphia; "Address in Obstetrics," by Ella B. Everett, of Philadelphia; "Estopic Gestation," by Charles P. Noble, of Philadelphia; "Uterine Curettage—Its Indications and Contradictions—Its Technic and the Complications Which May Attend and Follow the Procedure and Their Proper Treatment," by E. E. Montgomery, of Philadelphia; "Pseudomyoma Peritonei," by Barton Cooke Hirst, of Philadelphia; "The Significance and Management of Chronic Uterine Hemorrhage," by George E. Shoemaker, of Philadelphia; "The Technic Employed in the Last One Hundred Laparotomies with a View of Restricting the Employment of Drainage," by L. Jay Hammond, of Philadelphia; "Movable Kidney," by H. D. Beyea, of Philadelphia; "Some remarks on Pulmonary Embolism, Secondary Abcesses, Toxemia, Infectious Jaundice, Intestinal Obstruction and Secondary Pertitionitis as Complications of Appendicitis," by John B. Deaver, of Philadelphia. "Appendicitis—Treatment of Septic Peritonitis," by Charles H. Ott, of Sayre; "The Management of Pus Cases in Abdominal Surgery," by Reed Burns, of Scranton; "Drainage in Septic and Infectious Peritonitis," by Joseph Price, of Philadelphia.

Third Day.—"The Office Treatment of Hemorrhoids," by W. M. Beach, of Pittsburg; "Report of a Case of Acute Myelitis of Toxic Origin," by Herman B. Allyn, of Philadelphia; "Three Cases of Meningocele that Recovered," by George W. Guthrie, of Wilkesbarre; "Additional Observations upon the Treatment of Empyema, with Special Reference to Irrigation of the Pleural Cavities," by P. Y. Eisenberg, of Norristown; "Notes on the Diagnosis of Acute Hemorrhagic Peritonitis," by J. C. Wilson, of Philadelphia; "Clinical Examination of the Feces," by J. Dutton Steele, of Philadelphia; "Brain Abcess with Sudden Exophthalmos and Blindness, Death; Autopsy;" by Edward B. Heckel, of Pittsburg; "The Early Recognition and Treatment of Intestinal Obstruction with Report of Some Unique Cases," by J. C. Bloodgood, of Baltimore; "Wandering Gallstones," by William L. Estes, of South Bethlehem; "Surgery of the Gallbladder and Ducts," by J. M. Baldy, of Philadelphia; "The Direct Fixation of Fractures," by John B. Roberts, of Philadelphia; "Fractures of the Head of the Radius," by T. Turner Thomas, of Philadelphia; "The Question of Lowered Gastric Secretion," by Charles G. Stockton, of Buffalo; "The Surgery of Non-Malignant Diseases of the Stomach," by John B. Murphy, of Chicago; "The Surgical Treatment of Cardiospasm," by Edward Martin, of Philadelphia; "The Treatment of Benign Stenosis of the Pylorus and Duodenum Resulting from Spasm and Scar Tissue and from Abdominal Adhesions," by Albert Bernheim, of Philadelphia; "The Symptomatology and Diagnosis of Cancer of the Stomach," by John J. Gilbride, of Philadelphia; "Gastroenterostomy—Its Indications and Its Technic," by William L. Rodman, of Philadelphia;; "The Conservative Treatment of Hypertrophied Prostate," by H. M. Christian, of Philadelphia.

CHICAGO.

Condemnation and Destruction of Food.—The food inspectors condemned and destroyed 88,677 pounds of meat at the Union Stockyards, including three hogs bearing the Government inspection tag. Within the loop district, the inspectors condemned and destroyed a large quantity of immature veal, rotten poultry, berries and other fruit, and 121 barrels of spoiled fish, including three barrels which were being delivered to a curing and smoking-plant.

Typhoid Fever.—Although there were twelve deaths from typhoid fever, according to the *Bulletin of the Health Department* for the week ended August 26, the laboratory examinations of suspected cases for physicians warrant the anticipation of a decline of this mortality. Out of 72 examinations, only 18 gave positive reactions to the Widal test. The disease is most prevalent in the Southeastern part of the city where the water supply is inadequate.

Health Bureau in Schools.—With a view to safeguarding children against the spread of disease and at the same time improving the sanitation of houses in the congested quarters of the city, the Board of Education of Chicago is planning the establishment of a Bureau of Health. Many of the trustees heartily favor the plan, and if enough votes can be secured in the Board, the scheme will be put to a practical test as soon as the public schools are opened for the fall term. The plan is to have the schools visited by competent medical inspectors, with a view to learning from the school children of cases of illness in their homes. As soon as information is obtained, the afflicted household will be visited, and every effort made to guard against spread of the disease and also to improve the sanitary conditions. Teachers will be requested to report all cases of illness to the Bureau and also the addresses of all houses which they have reason to know are not sanitary.

GENERAL.

The Healthy Soldier.—Out of a total of 242,183 officers and men in the British army, 183,598, or 758.1 per 1,000, were admitted to hospital in 1903, says the annual report of the Army Medical Department, issued June 10, 1905.

Only Two Cholera Cases at Hamburg.—Baron Bussche, German Chargé d'Affaires in this country, says an official telegram received from the foreign office in Berlin, states that only two cases of cholera have occured at Hamburg, and not sixty as reported.

Congress of Criminal Anthropology.—The sixth Congress of Criminal Anthropology will meet at Turin on April 28, 1906, under the presidency of Professor Lombroso. An exhibition of criminal anthropology will be held in connection with the Congress.

New Hospital for Epileptics at Moscow.—The town council of Moscow, says the *St. Petersburger Medicinische Wochenschrift*, has decided to erect at once an asylum for epileptics, for which a special fund of 700,000 rubles is at the council's disposition. The first instalment of the building will accommodate 150 patients.

Deaths of Eminent Foreign Medical Men.—The deaths of the following eminent foreign medical men are announced: Dr. Hyernaux, formerly professor of midwifery in the University of Brussels, at the age of 80 years; Dr. Josef von Metnitz, extraordinary professor of odontology in the University of Vienna, at the age of 43 years; Dr. Walter Flemming, formerly professor of anatomy in the University of Kiel, at the age of 62 years. His published researches relate to embryology and cell division.

Leprosy in Roumania.—Leprosy is said to be on the increase in Roumania. Till 1895 no special precautions were taken, the disease not being considered contagious. Since then, however, so many cases have been discovered that the authorities became alarmed, and the rebuilding of an ancient monastery at Arnota, on the sea-shore, for the interrment of lepers was resolved on. It is alleged that the prevalence of the disease has greatly increased in the districts through which the Russian forces passed in 1877-78.

Professor Goldwin Smith on Longevity.—Professor Goldwin Smith, who recently celebrated his eighty-second birthday at Toronto, when asked by a correspondent of the *Daily Chronicle* if he had any message to his fellow-men appropriate to the occasion, is reported to have delivered himself as follows: "I have the secret of longevity. I have never been abstemious, and have lived pretty much as I liked, but I have always observed moderation. In my youth in England I lived a very active life, following the hounds and mountain-climbing in Switzerland being my favorite recreations." *Brit. Med Jour.*

A Woman Professor of Anatomy.—Miss Florence R. Sabin has been appointed Associate Professor of Anatomy in the Johns Hopkins University. Her name is well known to anatomists by her work on the nervous system. Miss Sabin, it may be stated, is not the first woman who has been professor of anatomy. In the sixteenth century Alessandra Giovanni taught that subject at Bologna, and Anna Manzolini occupied a Chair of Anatomy in the same university in the middle of the eighteenth century. Maria Pettracina was Professor of Anatomy in the University of Ferrara toward the end of the same century. She was the author of several works on a subject which is exciting great interest at present, namely, the physical education of children.

International Congress of Anatomy.—The first International Congress of Anatomy has just been held at Geneva under the presidency of Professor Eternod. Five anatomical societies took part in the Congress, namely, the Anatomical Society of Great Britain and Ireland, the German Anatomische Gesellschaft, the Association of American Anatomists, the Unione Zoologica Italiana, and the French Association des Anatomistes Nearly two hundred representatives of anatomy, histology and embryology were present. The scientific proceedings were of the greatest interest to specialists, and the social entertainments, official and private, were on a generous scale. It was decided that the next meeting of the Congress should be held at Bordeaux, at Eastertide, 1906, under the presidency of Professor Viault.

International Medical Congress.—Final arrangements have been perfected for the trip of the American party to the International Medical Congress at Lisbon, next spring. The party will sail April 7 on the North German Lloyd steamer "König Albert," for Gibraltar, visiting Algerciras, Seville, Cordova, etc., spend a week in Lisbon during the Congress, returning to New York on Wednesday, May 9. This trip may be made comfortably in a first-class steamer both ways, all expenses paid, including board and lodging while in Lisbon, for $300. A number of side trips are being added, and tickets will be good returning through Europe, if desired, at a slightly increased cost. All those who contemplate the trip are cordially urged to make reservation with Dr. Chas. Wood Fassett, of St. Joseph, Mo., at once, in order to secure desirable berths on the steamer and good hotel accommodations.

Foreign University Intelligence.—Berlin: Dr. Heine has been recognized as privat-docent of otology.—Bologna: Dr. Canepele, of Rome, has been recognized as privat-docent of oto-laryngology.—Breslau: Dr. Göbel has been recognized as privat-docent of surgery.—Erlangen: Dr. Erwin Kreuter has been recognized as privat-docent of surgery.—Greifswald: Dr. Sobotta, of Würzburg, has declined the chair of anatomy.—Jena: A new clinic for nervous diseases has been erected in connection with the psychiatric clinic.—Pavia: Dr. Adelchi Negri has been recognized as privat-docent of general pathology.—Pisa: Dr. Agostino Bruno has been recognized as privat-docent of internal pathology.—Rome: Dr. Angelo Chiavaro has been recognized as privat-docent of odontology.—Tübingen: Dr. Harms has been recognized as privat-docent of ophthalmology.—Vienna: Dr. Gustav von Wunscheim has been recognized as privat-docent of odontology.

Embalming in Ancient Egypt.—A recent number of the *Revue des Deux Mondes* contains an article by Professor Lortet, of Lyons, in which recent discoveries in respect to embalming in ancient Egypt are described. More than seventy yards of cloth of a width of about 12 inches were used in wrapping a mummy. This cloth was impregnated with a resinous alkaline solution, to which Professor Lortet attributes the preservation of the tissues. Ten large jars, carefully stoppered, full of a yellowish powder, have been found in a tomb near Thebes. On analysis the powder was found to contain an aromatic resinous substance and a large proportion of sodium salts, with some sand and clay. The resinous substance is evidently an extract of various aromatic substances in which myrrh predominates. Cloth dipped in water in which some of this powder was dissolved presents the same appearance and odor as the cloth in which mummies are wrapped.—*Brit. Med. Jour.*

Noted Men Among the Suicides.—A writer in a London periodical has recently compiled a list of the men of noble birth and high station who within the past

century or so have ushered themselves out of the world. The list includes Prince Ludwig, of Austria, who slew himself a few years ago because of a love affair, and Sir Hector MacDonald, the hero of the Boer War, who killed himself in Paris rather than face disgrace, and there are many others; but the list does not include the host of Chinese officials who have committed *harakiri* in very recent times, and often under what would be considered elsewhere as very slight provocation. There is no country in the world where self-slaughter is so common as in China, or where it is regarded so lightly. Statistics on this particular subject are unreliable, but one authority on China estimates that over twenty-five thousand persons die by their own hands in that country every year. In India suicide among the wretched victims of the child-marriage system rolls up a great total every year. Among strange motives for suicide we may include that of Lieutenant Jovanovitch, of the Servian army, who killed himself because he was not allowed to share in the plot against King Alexander and Queen Draga. He had the same idea of "honor," probably, that led a young German officer recently to lay violent hands upon himself after he had been treated scornfully by his brother officers for not using his sword on a drunken private who had ventured to "insult his uniform" with some personalities.

Curious Facts About Suicide.—Says *Leslie's Weekly* on this subject: Professor William B. Bailey, of Yale, has brought out some interesting facts based on 29,344 cases of suicide, covering the period from 1897 to 1901. Using the 10,000 unit, he finds that 7,781 males and 2,219 females found life intolerable, and, despairing of mending, ended it. This leaves the ratio of cowardice 3½ to 1 in favor of feminine courage. Almost two-thirds of the suicides occurred between the ages of twenty and fifty. Curiously enough, there are more married than single suicides. While married men are more likely to take the plunge than married women, single, widowed and divorced women are more prone to kill themselves than unattached males. Business losses are more likely to drive people to suicide than ill-health, insanity, disappointment in love, or strong drink. Monday is the favorite day for the rash deed, while few take the step on Saturday. Professor Bailey's explanation is as follows: "For those who have endured throughout the week there is pay-day at hand, followed by a day of rest." Among the males Monday is preeminently a day for suicide. Females prefer Sunday to Monday. Religious excitement may have something to do with this, but nearly a third of the domestic troubles leading to suicide come on Sunday. More than one-fourth of the suicides from financial trouble and ill-health among females occur on Monday. They apparently lack the courage, in their weak or impoverished condition, to take up the struggle of a new week. Of 10,000 cases, 3,687 occurred in the twelve hours before noon. Beginning with midnight, there is a continuous increase until 6 P. M. The three hours from 6 to 9 P.M. show a falling off, while from 9 o'clock till midnight is the period of greatest frequency. Some years ago it was discovered that a large number of suicides wore congress gaiters. Just why was not exactly determined. There are many other curious features that call for comment and explanation.

Fever Crisis Reported to Be Passed.—Statements indicating that the crisis in the yellow fever situation of New Orleans has passed; that the campaign of science is meeting with unbounded success; and that the fever will be practically forgotten by frost, were printed last Friday over the signatures of the leaders in the campaign of eradication—Surgeon White, Presidents Kohnke and Souchon of the Boards of Health, Dr. Beverley Warner, Dr. Metz of Tulane University, and Chairman Janvier of the citizens' committee. Dr. White says: "The work begun by the city Board of Health and continued by the Marine Hospital Service has undoubtedly been effective in holding the infection in check. We may say without undue self-congratulation that the disease is being gradually worked out. It must be apparent, for the lists of cases and deaths, taken on the average, week by week, are growing steadily less." President Schwing, of the Louisiana Press Association, has issued an address to the newspapers of the State inviting a discussion of the question of Federal control of the quarantine, thereby making impossible in the future such conflicts as have occurred in the South this year. Vicksburg and Natchez, which had most stringent restrictions against infected points, have appealed to the Marine Hospital Service for a fumigation system in order to enable them to move goods. Two cases of fever have been reported at Pearlington, Miss., an important lumber point at the mouth of the Pearl River. Leading citizens have met here and formed the New Orleans Health Association, a permanent organization, with Charles Janvier as president. The new association will endeavor to further the establishment and equipment of a permanent isolation hospital, where fever cases will be taken, as they are at Havana, immediately after they enter this port. So strong is the sentiment in favor of the early completion of the water, sewage and drainage work, that plans are now being considered for an appeal to the Legislature to provide the money necessary for additional speed in construction.

Missouri Valley Medical Society.—This society held its annual meeting in Council Bluffs, Ia., on Thursday and Friday, August 24 and 25, with an attendance of one hundred. Dr. S. Grover Burnett, in his presidential address entitled "Oslerism Bearded; or, A Study of Age in Relation to Work," called attention to the fact that Dr. Geo. M. Beard was entitled to priority in suggesting the uselessness of man above forty years of age. Dr. Beard claims that those who have done their best thinking before forty do their best mental externalizing afterward. Beard has shown us that 70 per cent. of life's work is done by the forty-fifth year, and 80 per cent. is finished by the fiftieth year. Also that only 25 per cent. more actual work is accomplished from thirty to forty years of age than is done between forty and fifty years of age; thus, man's retirement at forty would mean a loss to the world of a sum equal to three-fourths of his work done from thirty to forty years of age, to say nothing of the auxiliary unfinished business accumulated before forty and requiring concentrated experience which comes after forty, to shape it into a thing of value. The last half of man's life is unquestionably the best and most favorable part of it; especially if he devotes the first half to thought. Faddism is the product of immature sentiment, which age and experience and careful investigation will always cure. Papers were read by Drs. Le Roy Crummer, A. C. Stokes, W. O. Bridges, A. P. Condon and J. P. Lord, of Omaha; Fenton B. Turck and W. F. Waugh, of Chicago; Daniel Morton, of St. Joseph; J. W. Kime, of Fort Dodge, Ia.; Herman E. Pearse and C. B. Hardin, of Kansas City; T. N. Bogart, of Excelsior Springs, Mo. On Thursday evening the society was entertained by the local profession at Lake Manawa. An amendment to the constitution was read, changing the annual meeting to the first week in September. The secretary's report showed a healthy condition of the society, 41 new members having been added during the year. The Buchanan County Medical Society extended an invitation to hold the next

semi-annual meeting in St. Joseph, in March, 1906, which was accepted. The election of officers for the ensuing year resulted as follows: President, Dr. John E. Summers, Jr., of Omaha; First Vice-President, Dr. C. H. Dewitt, of Glenwood, Ia.; Second Vice-President, Dr. C. B. Hardin, of Kansas City, Mo.; Treasurer, Dr. Donald Macrae, of Council Bluffs, reelected; Secretary, Dr. Chas. Wood Fassett, of St. Joseph, Mo., reelected.

Cumberland Valley Medical Association.—The doctors of Maryland and Pennsylvania, comprising the entire Cumberland Valley, met last week in annual convention at Mt. Holly Park. There was an attendance of about eighty. Dr. V. M. Reichard, of Maryland, presided and read an eloquent and scholarly address upon "The Position of the Medical Profession at the Present Day." The convention was opened with a cordial address by Major James Evelyn Pilcher, in which, on behalf of Cumberland County, he extended the heartiest of welcomes and placed the keys of Old Mother Cumberland at the disposition of the association. Dr. J. B. McCreary described the wonderful Shippensburg case of transposition of the internal organs, which has been referred to several times in the newspapers, and which is a unique case in medical annals. Dr. Charles F. Palmer, of Chambersburg, read an interesting paper upon "Our Relations to the World at Large," and Major Pilcher presented a memoir upon the "Medical Lessons of the Far East," in which he illustrated, by the success of the Japanese operations, the importance of state medicine and of the active participation in public affairs by physicians. It was one of the best papers ever read before the society. The scientific work of the day closed with a paper upon "The Influence of Eye Strain," by Dr. A. C. Maisch, of Hagerstown, Md. The meeting was then adjourned to the Holly Inn where at three o'clock a largely attended and elegant banquet was served, in the course of which delightful music was furnished by an orchestra composed of the daughters of Dr. W. T. Phillipy, of Carlisle. Major James Evelyn Pilcher was toastmaster and presided in his usual happy vein, while responses were given to the following toasts: "The Medical Man's Vacation," by Dr. J. Bruce McCreary, of Shippensburg; "The Terrapin and the Doctor," by Dr. Robert W. Ramsey, of Chambersburg; "The Ladies," by Dr. H. C. Devilbiss, of Chambersburg; "The Revised Code," by Dr. L. H. Keller, of Hagerstown; "Surgery in the Country," by Dr. V. M. Reichard, of Fairplay, Md.; "The Triumphs of Medicine," by Dr. J. B. Amberson, of Waynesboro; and "The Home Guard," by Dr. Harry A. Spangler, of Carlisle. The following officers were reported and unanimously elected for the coming year: President, Major James Evelyn Pilcher, of Carlisle; First Vice-President, Dr. H. P. F. Unger, of Mercersburg; Second Vice-President, Dr. A. C. Maisch, of Hagerstown; Third Vice-President, Dr. George C. Borst, of Newville; Secretary, Dr. J. J. Coffman, of Scotland; Assistant Secretaries, Drs. P. R. Koons, of Mechanicsburg; H. C. Devilbiss, of Chambersburg; T. C. R. Miller, of Mason-Dixon; Treasurer, Dr. J. J. Koser, of Shippensburg.

Fight Against Lead Poisons.—The International Labor Office of Basel (Switzerland), which was organized four years ago by the International Association for Labor Legislation, has invited an international competition for the prevention of lead poisoning, and offers a number of valuable prizes for treatises on this subject. This association was founded by persons advocating the legal protection of workmen, among whom were prominent statesmen and scholars of Europe. Sections of the association have been formed in the following countries: Austria, Belgium, France, Germany, Great Britain, Hungary, Italy, Netherlands and Switzerland. The International Labor Office is subsidized by the Governments of the following countries: United States, Belgium, France, Germany, Hungary, Italy, Luxemburg, Netherlands, Sweden and Switzerland. According to its rules the International Labor Office has to serve as a scientific organ and it has been entrusted with the task of preparing and publishing a bulletin, containing an account of all the new laws concerning the hygiene and safety of the working classes, including parliamentary reports, as well as discussions and resolutions of congresses, concerning the legal protection of labor. I.—The prizes offered are as follows: (1.) One prize of $1,200 for the best treatise on the prevention of lead poisoning in the operation of mining and milling lead ores or ores containing lead. (2.) One prize of $2,400 for the best treatise on the prevention of lead poisoning in smelting and refining works. (3.) Two prizes, viz.: One first of $600; one second of $360, for the best treatises on the prevention of lead poisoning in the chemical application of lead, as in white lead works, manufacture of other lead paints, of electric accumulators (storage batteries), etc. (4.) Four prizes, viz.: One of $360; one of $240; two of $180 each, for the best treatises on the prevention of lead poisoning in the trades of house, ship, coach-painting, interior decoration, varnishing and the like. (5.) Four prizes, viz.: One of $360; one of $240; two of $180 each, for the best treatises on the prevention of lead poisoning in those trades where raw and manufactured lead are consumed or handled on a large scale, as in type foundries and printing-offices. II.—Each treatise to contain a systematic review of the special causes giving rise to lead poisoning, in conjunction with a description of the various processes of manufacture, pointing out the dangers occasioned at every phase of procedure, including handling and transportation. Reference to be made also to the causes due to working at places in which a prolonged occupation is liable to affect the health, to want of cleanliness, lack of proper guidance and instructions, carelessness, poor and inadequate food, irrational way of living and unhealthy dwellings of the workmen. In connection with the statement of the causes of lead poisoning, measures for their prevention are to be proposed. III.—Substantial evidence should be given for the proposed preventives as regards their technical, hygienic and economical feasibility. IV.—The comparative injuriousness of the different phases of manufacture as well as of the conditions referred to in section II. must be demonstrated as far as possible by a properly graduated classification of the risk of lead poisoning, from the highest to the lowest degree. V.—In proposing new installations or alterations of the existing mode of operation, the probable increase or decrease of expenses incurred by the change should be approximately stated—*e. g.*, in proposing mechanical appliances to supersede manual labor the primary cost of these, as well as the increase of working expenses by depreciation, and interest on the capital invested would have to appear, as well as the saving of wages or other factors of economy—viz., the avoidance of fluctuations and changes in the working staff and, in consequence, the maintenance of a properly trained crew with a corresponding improvement of their capacity. VI.—It is desired that the treatises should promote the development of the present provisions of the various States by outlining or drafting legal or administrative regulations or suggestions to the proper authorities, aiming at the realization of the preventive measures proposed by the competitors. Short precepts against the danger of poisoning might also be given, preferably in a form

suited for posting in workshops, building grounds, etc. VII.—A clear and concise summary of the measures proposed by the competitors is to be given at the end of the treatise. VIII.—The papers may be written either in English, French or German. Already printed books cannot be taken into consideration by the jury. The ready manuscripts must be put in an envelope bearing only a motto, and lodged with the International Labor Office at Basel on or before the 31st December, 1905. The full name and address of the author should be stated under a separate sealed cover bearing on its outside the same motto as above. Contributions arriving later than the 31st December, 1905, will be excluded from the competition. IX.—By the award of a prize the International Labor Office is entitled to publish a treatise, leaving, however, its author the exclusive property; the office may also concede to the authors the right of publishing their treatises. Manuscripts which are not secured for publication will be returned to their authors. X.—In case the jury should not see fit to award the total sum of $6,480 reserved for the prizes, the remainder shall be employed upon recommendation of the jury by the International Association of Labor Legislation, for other purposes concerning the hygienic welfare of the working classes. All letters, inquiries and other matters pertaining to the present competition, are to be addressed to the International Labor Office, at Basel (Switzerland).

OBITUARY.

DR. SIEGFRIED MARTUS, of New York, a specialist in skin diseases, who had been connected with the staff at the Mount Sinai Hospital for fourteen years, died last Thursday, at the New York Hospital, from an operation for appendicitis. He was ill only a few days. He was born in Russia in 1862, and after receiving his education at Posen and in the University of Berlin came to this country. He was one of the experts in the X-ray department at Mount Sinai, medical adviser of the Hebrew Technical Institute, a member of the County Medical Society, the German Medical Society and several other organizations.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Regular Meeting, held May 22, 1905.

Treatment of Diarrhea in Children.—The scientific business of the evening consisted of a discussion of the summer diarrheas of children, which was begun by Dr. Joseph E. Winters, of New York, and participated in by prominent pediatrists from many cities. Dr. Winters said, in opening the discussion, that there is a confusion of terms with regar ' to summer diarrhea which sometimes makes this affection include dysentery. Diarrhea, however, never becomes dysentery, and never leads up to dysentery. Dysentery is a specific infectious disease. Both diseases may coexist in the same subject or diarrhea may so weaken an infant as to leave it open to attack by dysentery, but the diseases are absolutely distinct. The necessity for a review of notions with regard to treatment can be best realized from the fact that while there were about 2,700 deaths in Greater New York during the summer of 1903 from diarrhea, there were over 3,800 in 1904. Last summer was a more cool and salubrious season than that of 1903, and should naturally have been associated with a lessened instead of an increased mortality. This throws a shadow over science, and seems to indicate its hopelessness in the face of this serious condition.

Food Disorder.—Summer diarrhea is purely a food disorder, and is eminently preventable, yet it registers more deaths than any of the infections. It is evident there has been a gross mismanagement of the diet of infants in Greater New York. Barley water, rice water, egg water, and the like, has been substituted for milk in the feeding of infants till weakness and collapse have ensued with fatal termination. The first step in the treatment of diarrhea of infants must be the removal of the cause. This means that all irritant materials must be kept out of the dietary before the child falls sick, and then, after the illness has begun, they must be removed from the intestinal tract.

Necessity for Purgation.—In the folds of the intestinal tract curds of milk, the seeds of fruit, and other irritating material catch and excite inflammation. These must be removed before the irritative inflammation will subside. The best purgative is castor oil, given ice cold, and repeated if it is rejected after an hour. The only reason for the giving of opium must be not to stop the diarrhea, but to release the spasm which keeps the irritative material in certain parts of the digestive tract and causes this to surrender all septic matter. Any further source of irritation must be avoided, and consequently for twenty-four hours the infant must receive only water. Feeding during diarrhea is fatal; in young infants hot water, given by the bottle, will often relieve their discomfort. If there is temperature, cold water should be given, which will help to lower the temperature. Hot water, if given fifteen-drop doses on the tongue every hour, or oftener if necessary, checks vomiting when nothing else will accomplish that purpose.

Treatment of Convalescence.—If at the end of twenty-four hours the diarrhea has ceased, and there is no more vomiting, the patient may be given weaker food. Barley water and peptonized food should not be given to young children. They are eminently unphysiological. Proteid excess is fatal in the summer. On the other hand, the use of pernicious dextrinized cereals cannot but do harm. Milk is the only food resource in children under one year of age. For children under three months of age, the upper ounce of the cream of a quart bottle of milk which has stood for sixteen hours, kept on ice all the time, should be added to an ounce of water, and two tablespoonfuls of lime water. One ounce of this mixture may be given every four hours. Filtered, unboiled water should be used, and if at the end of twenty-four hours the child continues to improve, then an ounce of this food may be given every two hours.

Abuse of Water.—There was a time not so long since, when, if children did not take their food properly, they were not likely to obtain the amount of liquid necessary for their subsistence. Then came the realization of the necessity for water occasionally. Now there has come a tendency to exaggerate in this matter. Water, if given too frequently, especially on a weakened stomach, is not carried out of the stomach, and is apt to produce irritation and atony of that organ. Water should not be given oftener than every three hours, so as to enable the stomach to pass it on to the intestines, as no water is absorbed in the stomach itself.

Death-Rate in Older Children.—The anomalous death-rate of infants from diarrhea last summer was due to the unjustifiable use of cereals at a time when

nature had not supplied the digestive juices necessary for the proper preparation of such material. In older children the increase in the death-rate was due to the excessive use of animal broths. These are destitute of constructive elements, and are only stimulants. Beef juice should be interdicted whenever the stools become offensive, and whenever the nervous system is overstimulated by them. Vegetable proteids should be employed. Cereals check waste, and are indispensable in the second year of life. Gruels made with water and butter and salt are of excellent service, but should not be made with milk. Animal broths should not be administered at the same time with them, nor immediately after them.

Choice of Cereals.—The best cereals are, in their order, barley, imperial granum, rice, arrowroot, and then the others. Imperial granum and arrowroot should be cooked for three hours. Rice, as a rule, does not need to be cooked so long, neither does barley. If the child refuses to take the cereal food, then this should not be forced upon it. Hunger will usually compel the child to take food at the proper time during the second year, and as in adult life the disinclination for food is respected, so it should be in these children, whose feelings can be trusted to assert themselves. There need be no fear of the child allowing itself to become too weak for want of food, provided, always, that the food is nicely prepared and offered to it.

Chronic Diarrhea and Condensed Milk.—In chronic diarrhea Dr. Winters has obtained the best results by the use of condensed milk. He has found it hard to understand just why this has proved so beneficial. It is a matter of very definite experience, however, and the condensed milk regimen has not failed him once in years. Sometimes the effects produced seem almost miraculous. It is often hard after the child gets well to keep the mother from continuing the use of the kind of food that has proved so helpful. A change, however, must be made after a time, otherwise there will inevitably develop scurvy, or rachitis, or some of the deforming types of malnutrition. Gradually and surreptitiously cream must be added to the child's feedings of condensed milk, until finally it is all replaced by cream and milk.

Abuse of Irrigation.—Dr. Winters considers that irrigation of the bowels is a much-abused and overrated remedy, and an overused method of treatment. It produces distention, adds to the patient's discomfort, increases the congestion, and is sure to be harmful rather than helpful if repeated frequently. A small enema may be given to help the castor oil, but more than this should not be employed. In the variations of remedies much harm has been done, and new methods of treatment must not be adopted lightly, nor before proper realization of their possible effect.

Infant Feeding.—Dr. Artnur B. Meigs, of Philadelphia, said that the question of infant feeding had been a puzzle until the solution by imitation of human milk as early as possible had been reached. For ill children, dilution of the usual diet is the important feature of treatment. The idea of substituting a cereal for milk can scarcely be entertained during the first months of life, for it is poor in nutriment value, because of the lack of digestive power, and is likely to lead to disturbance. For older children the use of a cereal is admirable. In this matter it must not be forgotten that the old-fashioned flour ball is excellent, though in recent years neglect of this method has been the rule. Milk is the only complete food for children, and should not be withdrawn from the food. Its use is the sheet anchor in all diarrhea, but it must be so diluted as not to prove a source of irritation, and must be in such a state of purity as not to add further microbic disturbers already in the intestines. Dr. Meigs dreads the use of a purgative in case of children's diarrhea, and considers that admirable judgment is needed lest the purgative effect is overdone. Not infrequent it happens that an entirely wrong effect is produced by the use of purgatives.

Starvation Treatment.—Dr. William H. Wells, of Philadelphia, said that the first indication in the treatment of diarrhea must be that there shall be no food until the acute stage of the affection is past. Absolute abstention from all food must be insisted on as long as there are acute symptoms. Flushing of the bowel with sterilized water or with normal salt solution undoubtedly does good, though usually not more than two or three flushings during the day should be directed. At the beginning of the affection a purgative is of excellent service because it removes irritant material. Castor oil seems the best, but calomel in minute doses produces an excellent effect and has none of the difficulties of administration of castor oil.

Hypodermoclysis.—Dr. Wells is sure that in some cases in which the diarrhea of colliquative form has carried off large amounts of water, and so caused intense prostration, and in which vomiting does not permit the introduction of liquids in the system in the ordinary way, he has saved life by hypodermoclysis. Normal salt solution is employed for this purpose, and is introduced directly beneath the skin. This method is much better than the use of large quantities of fluid by the mouth, which is almost sure to be injurious.

Question of Cereals.—Cereals should not be employed for diet in children under nine months of age. Some children have the faculty for digesting starchy material, but most have not. When the infant is weakened by summer complaint, then the starch digestive faculty is decreased, and the result of giving cereals cannot but be harmful. In Dr. Wells' experience, condensed milk has not proved to be as beneficial for any form of diarrhea, even the chronic variety, as some practitioners claim. When he has found it of use, it was usually the unsweetened variety. It is evident, however, that for the diet of children, no general rules can be laid down, but each child must be treated as an individual, and the reaction of each little patient's system to various forms of food carefully noted.

Cereal Decoction.—Dr. A. D. Blackader, of Montreal, said that it seemed very inadvisable to give cereals to any extent to children under six months of age, since they have a very imperfect digestion for starchy materials. The starchy digestion in the upper digestive tract is very imperfect. The succus entericus helps out in starch digestion in not a few cases, but this is only in the normal health of the child. Irritation increases the digestive juices at first, but later decreases them, and consequently diminishes the hope of starch digestion. There is an increase of fluid in the digestive tract, but this is illusory, and does not contain digestant materials. The use of cereal for diarrhea only gives additional material for fermentation, which further adds to the irritated condition. In Dr. Blackader's experience predigested cereals have not given very favorable results, and pure water or carefully prepared whey

seem the only materials that should be given during the existence of acute symptoms.

Animal Broths.—Dr. Blackader considers that the nutritive value of animal broths is very low. They serve only to stimulate the digestive glands, but when these are already overirritated may serve only to increase the irritation. Dr. Blackader suspects that beef broths may encourage bacterial growth. Laboratory experience would certainly seem to show that beef juice might be expected to have this effect. As a rule the stools are more foul-smelling when beef broth is given, and this would seem to indicate the growth of undesirable bacteria in the intestinal tract.

Child Individual.—Dr. E. M. Buckingham, of Boston, said that in discussions of the illnesses of children sight is frequently lost of the most important fact, namely, that the child is an individual, and must be treated as such. There is no definite formula for mother's milk, but nature provides different kinds of milk for each individual in accordance with the nature of the child and its relation to its mother. It must not be forgotten that the child's muscles and glands are weak. The stomach must not be overloaded, and the digestive glands must not be asked to furnish much material. In making a substitute for mother's milk the modification must be made to suit the individual and not according to a table of figures. The fats, proteids and salts of cow's milk, it has been pointed out, are not of the same chemical constitution as those of mother's milk. Care must be exercised, as far as possible, to make a formula to suit the individual child. Percentages for children should not be prescribed in the ordinary house visit, but should be made out carefully in the office, suggesting only at first a preliminary formula. The most important thing is to remember how much effect even small changes in the food may have on the infant.

Cereals.—These may be given either as food or as drugs. If given as food to young infants, trouble will ensue, since the glands are not developed for their digestion. The pancreas has a ferment that will digest in some children, but this is not always present. When milk is not boiled, cereals may be tried, but with great care, and with a constant feeling that it is better to be sure than to be sorry. Cereals may be used as a drug, in the sense of mechanically breaking up the curd of milk. This is shown by experiments in the test tube, which are extremely crude.

Reason for Different Results Reported.—Different physicians get very different clinical results. There seems to be no doubt that the difference is really in the babies. Those who do not use starch at all in the dietary seem to have more confidence in their results than those who employ it. Undoubtely if milk is good for the well child it should be good for the ill child. Of course, it must be properly diluted for the weakened digestive juices. The fear of the child's starving is overdone. Children can stand lack of food for a considerable period, and it is less of a drain on them to be without food than to be given food that only increases the irritation in their intestines and makes their condition worse. A little brandy occasionally helps the child to stand the period of starvation, yet does not irritate unless it is given in sugar, which is sometimes recommended, but not as the result of experience. At the beginning of an attack of diarrhea the bowels should be emptied once. The best remedy for this is castor oil, and if it is vomited calomel should be employed.

Use of Water.—When there are many dejections, water should be given rather freely, because the fluid is being drained out of the child's system. If there is fever, ice water may be employed with advantage. Not infrequently it happens that there is at first some vomiting of the water, but then it is retained and the child sleeps. There seems to be no indication for lavage. At the beginning a large injection may be employed, but its repetition is likely to do harm. Even more than any remedy the child needs rest, and this must be of mind as well as of body. While it must not be handled or carried, any noise in the room, and especially any talking, is sure to prove a source of annoyance. If there is frequent irritative diarrhea, opium should be employed, and the best form is that of the liquid Dover's powder. The presence of ipecac in this makes it of special service. Once there has been an attack of diarrhea, it must not be forgotten that the child will probably not be able to take ordinary food until after the hot weather is over. If the child suffers from dysentery then irrigation should be freely employed, though in diarrhea this remedy would prove harmful.

Classification of Diarrhea of Infants.—Dr. John Lovett Morse, of Boston, said that he found himself compelled to disagree with much that Dr. Winters had said. For him there are two classes of infantile diarrhea; the one due to bacteria, the other not. Non-bacterial diarrhea may be caused by heat or cold, or by the nervous system, but is not inflammatory Most of the diarrheas of children, however, are bacterial in origin. There are many different forms of bacteria for causing the disease, and not one specific type. The first requisite in the treatment of diarrhea is pure fresh milk. There are four stages in the treatment. While the irritative material is present a purgative should be given, and the best is castor oil, the next is calomel. If the vomiting is persistent, then the stomach should be washed out. Irrigation of the colon should be employed once, though not more. After purgation comes starvation. This is to be considered, however, as referring only to food, and not to water. At least as much water must be given as the child would ordinarily get in its food. There need be no danger of hurting the child by starvation treatment for forty-eight hours at least, and Dr. Morse has seen absence of food continued for seventy-two hours or longer without serious results. If the starvation treatment could be kept up long enough, the diarrhea could be starved out; but unfortunately the baby dies before this period sometimes. When the readministration of food is begun milk should not invariably be employed, but the food should be chosen according to the indications.

Kinds of Food.—Bacteria grow readily in milk, but there are also forms of bacteria in these cases that grow in carbohydrate. As a rule, if the stools are sour, it is because of the growth of carbohydrate-loving bacteria. If they are foul, then it is because of the presence of bacteria that grow more readily in proteids. If the stools are foul, carbohydrate should be given; for sour stools, the proteids. Barley water really continues the starvation treatment while keeping up the supply of water, and satisfying the child's stomach to a certain extent, as well as the minds of the parents. When diarrhea is persistent the fats in the diet should be kept low. When there are a number of small stools, indicating the presence of ileocolitis, then food containing as little residue as possible, and which is absorbed high up in the intestine, should be employed. For this pur-

pose whey is best. Whenever there is long-continued diarrhea opium may be of service. It should never be given in acute cases, however. Other drugs are not worth mentioning. Irrigation of the bowels has its place when there are a number of stools containing blood, evidently coming from low down in the intestines. Irrigation should be employed not oftener than three times in twenty-four hours. When children are over three months, a small amount of starch may be given, but it must be remembered that such children will digest sugar rather easily. Each case must be treated as an individual, and not as a type of disease.

Infantile Diarrhea in the Country.—Dr. R. C. Newton, of Montclair, N. J., said that there were very few deaths from diarrhea in the country, and this is evidently due to the purer milk as food, and the absence of excitement and noise. The nearer the baby is to the cow, the less danger there is from artificial feeding, showing that it is not so much the unsuitability of the milk from the chemical standpoint as because of the changes that take place in it during transportation, and its retention before feeding, that cause diarrhea. Certainly it does not seem advisable to give starchy foods to young children. Beef juice and soups and broths have a distinct tendency to make the children more nervous than before.

Importance of Early Treatment.—Dr. John Dorning, of New York, said that more can be done for the child in the first twelve hours of a diarrhea than in the next twelve days. Dr. Dorning considers that cereal gruel as a diluent for milk has a distinct place and he is sorry for its condemnation. It serves to break up the milk curd, and makes it more easily digestible. General rules for baby feeding, however, have many exceptions, and the only rule is each baby for itself. Opium is a dangerous drug for children, and the less it is given the better. Subnitrate of bismuth, however, given in doses of five to ten grains every three hours, is undoubtedly of service. At the beginning of a diarrhea one or two irrigations should be given, but not more. Cleanliness, as a rule, is not enough insisted on in these cases, and as a consequence, children become secondarily infected. After the handling of the napkins the hands should be thoroughly washed before the baby's food or clothes are touched.

Dr. Floyd Crandall said that the principle that what is good for the well is good for the ill does not hold in adults in fevers, since no one would think of giving steak and potatoes; why, then, in children? The question of cereals is still open, but there is no question that milk should be stopped at once, though water should be given freely. Dextrinized cereals have proved of service in Dr. Crandall's hands.

Dr. Walter Lester Carr gave a set of statistics in which, in England, artificially-fed children got on better than nursing children. This is evidently one of the anomalies of statistics.

Lime Water in Diarrhea.—In closing the discussion, Dr. Winters said that lime water must be the great standby of the physician in treating children's diarrhea. No one had ever treated children's ailments successfully without administering lime water freely. It breaks up the curd of milk better than does the cereal. The use of lime water in large quantities is one of the things for which the present generation must thank the teachings of Dr. Meigs, of Philadelphia. He it was who first showed that cow's milk was entirely too rich in proteids, and that human milk only contained one per cent. of proteid material. This has since been verified by investigators all over the world. The best way to reduce the proteids in cow's milk is to use lime water freely. Without the addition of one-fourth lime water to cow's milk the baby will not be kept well, nor will it get well when once ill. In baby feeding two things particularly are needed—more attention to the individual baby, and more dependence on clinical experience, rather than on the results of laboratory work. The laboratory has failed over and over again in its suggestions. Experience is a sure guide.

CHICAGO MEDICAL SOCIETY.

Regular Meeting, held April 12, 1905.

SYMPOSIUM ON SURGICAL ANESTHESIA.

Ether or Chloroform.—Dr. H. D. Peterson discussed the choice of ether or chloroform, methods of administration, dangers and after-effects. He said the relative value of these two anesthetics depends upon the safety. Safety is measured by the action of the drug and experience of the anesthetist. Chloroform, being more depressant and toxic, is less safe than ether. Statistics have proven the death-rate to be higher with chloroform than with ether. The choice of anesthetic is to be decided by the condition of the patient and experience of the administrator. There are few contra-indications for ether, more for chloroform. Heart disease, shock, prolonged operations are urged against chloroform. Chloroform is an unsafe anesthetic in the hands of the unskilled. The author recommends the closed method for ether, the open for chloroform. Each should be commenced by slow application. A minimum amount should be added after stage of surgical anesthesia is reached. As to the dangers, they are few if ether is used. Death from ether is usually due to inattention or carelessness of the anesthetist. Warning is always given. Chloroform is sudden in action; little or no warning is given. Close watch of the patient is necessary when chloroform is used. Recovery varies with the dose given. A minimum dose is followed by the quickest recovery. The patient should be watched until conscious enough to clear his own throat of mucus. As to after-effects, vomiting is often prevented by allowing the inhalation of vapor of aromatics, vinegar or acetic acid. Normal saline solution per rectum or by hypodermoclysis aids in the rapid elimination of a general anesthetic

Spinal Anesthesia.—Dr. A. E. Halstead read a paper on this subject. The objections to the use of spinal cocainization, that are usually made, were stated as follows: (1) That they are immediate and remote dangers, which are considerable. (2) That it is uncertain in its action, both as to producing surgical analgesia and as to its duration. (3) That attempts at introducing cocaine sometimes fail. (4) That unpleasant after-effects result.

Technic.—In all of his cases the technic employed was that followed by Tuffier. The steps are: (1) Preliminary hypodermic of morphine, ¼ gr. (2) Careful preparation of lumbar portion of the back, extending around as far as the middle of the crest of the ilium. (3) Sitting posture, if possible, with the body bent forward in the "scorching position." (4) Recognition of the fourth lumbar spine, which is found drawing a line from the highest point of one iliac crest to the same point on the opposite side. (5) The needle is introduced just below and to one side of the tip of the fourth lumbar spine, and is directed upward, for-

ward and toward the median line for a distance of from 2 to 3½ inches. When the membranes are penetrated a distinct diminution of resistance is noticed. As soon as the needle enters the spinal canal the spinal fluid usually begins to drip from the needle. At first, it may be blood-stained, but soon becomes clear. If, after reaching the canal, no fluid escapes, its flow may be hastened by having the patient cough. A stylet may be passed into the needle to remove any obstruction that might be present.

Surgical Indications for Spinal Cocainization.—In operations upon the lower half of the body, when, from kidney, lung or heart disease, a general anesthetic is dangerous, and where infiltration anesthesia or analgesia from neural injections is not possible, spinal analgesia can be employed. In strangulated hernia or intestinal obstruction from other causes, and perforations, where considerable time may be required, thus contraindicating the use of local anesthesia, spinal cocainization is an ideal method of securing analgesia, first, because the patient remaining conscious is not so likely to drown in fecal vomit; second, because the shock from the puncture is practically *nil*. In traumatic surgery of the lower extremities, the use of spinal cocainization "blocks" the reflexes and eliminates the great risk of shock. In amputations about the hip, when the shock from the operation is generally severe, and often fatal, after cocainization of the cord the amputation may be performed without any change in the pulse rate. In this class of operations if, for good reasons, unconsciousness is essential, as it sometimes is, a small amount of ether and chloroform may be administered to secure this end. The spinal cocainization insures the required analgesia The author believes spinal analgesia is contraindicated in all cases in hysterical women and young children and in the insane. It should be used only when its action can be explained to the patient, and thus cooperation secured. He does not consider any ordinary heart lesion a contraindication to its use. It goes without saying that any marked idiosyncrasy for cocaine should constitute a positive contraindication against spinal analgesia.

Nitrous Oxide Anesthesia.—Dr. Weller Van Hook stated that the thoughtful surgeon, who in the course of each year must anesthetize many human beings, is obliged to contemplate with growing horror the inevitable death list of those whose taking off is due solely in his effort to abolish consciousness for a few minutes. Although death takes place from the administration of the major anesthetics in only one case in 3,500 to 14,000 or 15,000, even this proportion becomes after a while oppressively great and forces the operator to seek new and safer methods. He did not hesitate to say that one of the very greatest needs of surgery at the present moment is to find a simple method of temporarily abolishing consciousness at once practical and devoid of evil consequences. Of the principal anesthetics, nitrous oxide and ether are admittedly the safest, and their combination has long been regarded as valuable and comparatively free from danger. No modern hospital is complete in its equipment without apparatus for administering nitrous oxide gas. It is not necessary to detail the multitude of uses to which its brief anesthesia can be put. Inasmuch as gas alone produces a lethal asphyxia in from three to five minutes, oxygen must be utilized when cyanosis becames pronounced. The addition of about ten per cent. of pure oxygen makes it possible to continue anesthesia with nitrous oxide gas a comparatively long time without much risk. Unfortunately the combination makes necessary a complicated and bulky apparatus. Furthermore, the use of the two gases is rather difficult until the anesthetizer by practice has become expert. This difficulty renders it next to impossible to entrust to hospital assistants, whose term of anesthetic service is necessarily brief, so complicated a duty. If, however, oxygen is admitted to the mask with air from time to time as it is needed, the apparatus demanded can be simplified to a practical point. The apparatus which the writer uses for this purpose is the ordinary dental outfit, the facepiece being that of Harrington. The portability and convenience of the steel bottles containing the liquefied gas and the inhaling apparatus leave but little to be desired in hospital practice. Instead of the 250-gallon bottles used in institutional work, a 100-gallon bottle weighing approximately nine pounds can be used in private practice. It was many years ago that the idea was conceived of using nitrous oxide to abolish consciousness, followed by ether to maintain that state. It was easily discovered that if air is admitted to the mask after nitrous oxide anesthesia has been induced, the patient will recover consciousness to such a degree that the ether anesthesia can be inaugurated only with difficulty, the patient often struggling violently. The ideal way of changing from one to the other of these anesthetics is by gradually adding ether vapor to the inhaled gas. Various complicated apparatus have been invented for this purpose. They are cumbersome, delicate, difficult to manipulate or fragile. In order to render practical the use of these anesthetics in combination, the writer has had made a simple cap to contain a piece of gauze saturated with ether which can be applied to the nitrous oxide apparatus at the moment of making the change, so that no air will be admitted to the mask until after the patient has inhaled the desired amount of ether. With this apparatus, the writer and his associates have anesthetized many hundred patients with satisfactory results. The combination of nitrous oxide with ether is recommended to all as a comparatively safe, rapid and comfortable method of inducing anesthesia.

Dr. Emil Ries discussed scopolamine-morphine anesthesia, and Dr. William E. Schroeder nerve blocking and cocaine-adrenalin-anesthesia.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.[1]

Laboratory of clinical pathology, Cornell University Medical College, May 24, 1905.

Vice-President, Edward K. Dunham, in the Chair.

Members Present.—Atkinson, Auer, Brooks, Burton-Opitz, Crampton, Davenport[2], Dunham, Emerson, Ewing, Field, Flexner, Gies, Herter, Levene, Levin, Lusk, Meltzer, Mendel[2], Morgan, Noguchi, Norris, Oertel, Opie, Richards, Salant, Sweet, Torrey, Wallace, Wolf.

Members Elected.—Joseph Erlanger, Otto Folin, E. O. Jordan.

ABSTRACTS OF REPORTS OF ORIGINAL INVESTIGATIONS.

Contributions to the Study of Sulphur. I. The Metabolism in Brombenzol Poisoning.—By W. Mackim Marriott and C. G. L. Wolf.—Baumann and his pupils investigated the effect of the administration of the halogen derivatives of the hydrocarbons, and found that one of the results in the disturbance which followed was the elimination of halogen aromatic mercapturic acids, which he regarded as derivatives of cystin. Later,

[1] Proceedings reported by the Secretary, William J. Gies, Ph.D., of New York. The authors of the communications have written the abstracts. The Secretary has made a few abbreviations.

[2] Non-resident member

Friedmann investigated these compounds and was able to confirm Baumann's view. The mercapturic acids are derivatives of cystēin, the reduction product of cystin.

This study is a part of an investigation of cystinuria, the view, which has been advanced by previous observers, being taken that the process in brombenzol poisoning is an experimental cystinuria. Dogs were used in these experiments, and were fed on a uniform diet. The animals were catheterized once a day. Analyses of the urine, as complete as possible, were made. The feces were examined for nitrogen and fats.

During the period of administration of the brombenzol the nitrogen and urea were somewhat increased. The urea followed the total nitrogen closely. The preformed ammonia remained at a level below that of the fore period. The kreatinin estimations did not give results of any distinctness.

The investigation of the partition of sulphur led to the result that while the total sulphur excretion was not increased during the experiment, there was almost complete suppression of the alkali sulphates. The excretion of neutral sulphur, represented for the most part in this case by parabromphenylmercapturic acid, was increased 400 per cent. The curves representing the alkali and neutral sulphur were antipodes. The ethereal sulphates rose markedly during the feeding period. In one experiment it was shown that during the first two days of the administration, the total sulphur excretion remained constant while the total sulphate-sulphur fell rapidly. This period is being made the subject of closer study.

The chlorin and phosphorus excretion remained practically constant during the experiment. There was increased nitrogen and fat elimination in the feces.

On section, the animals showed ulceration of stomach and intestines. Microscopically, the liver and kidneys were markedly degenerated. The investigation is being continued.

On Experimentally Produced Variations in the Energy of Tumor Growth.—By Leo Loeb (Presented by James Ewing).—Inoculations of different tumors (sarcomas of the thyroid, mixed tumor of the submaxillary gland) through several or many generations have shown that, under the influence of experimental conditions, the energy of the tumor growth varies in a definite way. The rate of growth is relatively slow in the animal originally affected with the tumor; after the inoculation into the first generation, there is a certain latent period, after which the tumor begins to grow. The growth of the first generation is more rapid than it has been in the original animal. After the inoculation into the second generation, the latent period is abbreviated, in some cases more, in others less, and the succeeding growth is likewise more rapid than the growth in the original animal, or in the first generation. From now on, a further shortening of the latent period, or an increase in the rapidity of tumor growth, does not take place in the succeeding generations. Duration of the latent period and rapidity of growth may remain stationary through many generations, or the energy of the tumor growth may even somewhat decline.

These facts permit the conclusion that transplantation of a tumor has a tendency at first to increase the energy of tumor growth and that this increase may be cumulative. That this increase does not continue in succeeding generations may perhaps be explained by the existence of counteracting influences, the actual existence of which can be demonstrated as shall be shown later.

The energy of tumor growth can be increased directly and not only indirectly, merely by removal of the tension of the surrounding capsule or by better conditions of nourishment. Such a direct stimulating effect of the wound upon the cell growth causes probably a phenomenon not infrequently observed by surgeons, namely, the increase of malignancy in recurrent tumors. It is also possible to diminish the energy of tumor growth. In the course of tumor inoculations it not rarely happens that certain tumors remain stationary or even retrogress apparently spontaneously. This is especially found in the course of later inoculations and it probably indicates that after many inoculations one or several of the factors determining a vigorous tumor growth become gradually weakened. In such cases one can observe that even a long time after the expansive growth of such a tumor piece has ceased, many mitoses are present in the cells of the stationary or retrogressive tumor.

It is possible to diminish the virulence of tumor cells directly by subjecting them to certain physical or chemical conditions. By heating tumor cells up to 43° or 44° C. for half an hour outside the body, or by leaving them before inoculation, in glycerine from twelve to twenty-four hours, and washing them afterwards in .85 per cent. sodium chloride solution or by keeping them one or two days in N/700 KCN solution, before transplantation, we are able to diminish considerably the energy of the succeeding tumor growth and to increase the period of latency . In the author's recent tumor inoculations of a salivary tumor, a similar action of glycerine in increasing the period of latency was found to occur. Frequently such tumors remain stationary after a short preceding period of growth. In the first experiments of this kind in rat tumors, it was found that a temperature of 45° C. during half an hour kills the tumor cells. Jensen found a similar sensitiveness in his mouse tumors. Sticker's lymposarcoma could be heated up to 45° C. without being killed. The power of resistance of different varieties of tumor cells varies somewhat therefore and the means to be adopted to obtain a diminished virulence in the growth of an inoculated tumor will vary accordingly. In this connection, it might be mentioned that these facts may perhaps find a practical application in so far as pieces of tumor previously subjected to such treatment might be used to procure active immunity against tumor growth. That such active immunity is possible, at least in the case of certain tumors, is especially indicated by the observations of Sticker.

If we now wish to analyze the cause of this decrease in the rate of the growth of tumor cells we have to consider several possibilities. It might be that the physical or chemical means employed kill most of the cells and leave only a few cells alive able to give origin to the developing tumor. Two facts speak against such an interpretation. In the case of any tumor transplantation, the growth starts from a relatively small number of cells, in so far as the central part of the transplanted piece becomes necrotic. In his first series of tumor transplantations the author obtained well growing tumors, after injecting a cystic tumor fluid into rats. In such cases one or very few cells must have given rise to the tumor growth, and these tumors developed in a few cases quite rapidly. Such an explanation is therefore probable. Further, we would have to consider the possiblity that the means employed to decrease the virulence of tumor cells are favorable to the growth of bacteria and that they inhibit in this way the development of tumors. It is certain that bacterial toxins frequently act unfavorably upon the growth of tumors. Against this explanation, however, the objection can be raised that tumors with experimentally diminished virulence did not show any signs of putrefaction, nor did they, after inoculation, cause a formation of abcesses, occurrences which are frequent after transplantation of infected material. It

is, therefore, most likely that the cause of this decrease in virulence is the result of the direct decrease in the vitality of the tumor cells as expressed in their energy of growth. It is, however, desirable to further analyze these facts in future experimental work on tumors, especially as the character of such work of necessity limits the number of experiments a single observer can make. With this restriction it may be stated that the observations here recorded point to the conclusion that it is possible to cause an experimental increase or decrease in the energy of tumor growth, and that these variations may be caused by direct stimulating or depressing influence upon the tumor cells and that such a stimulation effect may be cumulative.

Demonstration: Photographs and Plumage-charts of Hybrid Poultry, with Remarks. Charles B. Davenport exhibited photographs and plumage-charts of four hybrids between different races of poultry, and also of their parents, and remarked on the nature of the inheritance illustrated by each example.

Experimental Cirrhosis of the Liver.—By Richard M. Pearce.—Presented by Eugene L. Opie. The experimental studies upon which this communication is based were suggested by an investigation of the necrosis produced in the liver of the dog as the result of injecting hemolytic immune sera of high hemagglutinative power (*Journal of Medical Research*, 1904, xii, 329). These necrotic lesions, which are due apparently to an obstruction of the circulation by thrombi composed of fused red blood corpuscles, vary in position and extent according to the dose of serum administered. Small doses cause more or less isolated lesions which may occupy any portion of the lobule; large doses produce a diffuse necrosis which spares only the tissue about the larger portal spaces. The uniformity of this necrotic lesion suggested the importance of a study of the repair process which would naturally follow in animals recovering from the acute toxic effects of the injected serum. The extent of the destruction precluded complete regeneration of liver parenchyma and if the defect was repaired by connective tissue proliferation, the resulting histological picture would be, except for a difference in the relation between the new tissue and the remainder of the lobule, analagous to cirrhosis in man.

Methods.—Dogs were injected either in the smaller branches of the femoral vein, or in the abdominal cavity, with serum obtained from rabbits which had received repeated injections of red blood corpuscles of the dog. The dose usually employed was 1 cubic centimeter of serum to 500-800 grams of body weight and the animals were killed at intervals varying from 48 hours to 36 days.

Results.—A majority of the animals die after intervals varying from 4 minutes to 48 hours. In those surviving, hemoglobinuria was a constant phenomenon usually appearing within 18 to 24 hours, persisting 3 to 4 days, and followed for several days by the presence of bile pigment in the urine. The first evidence of repair was mitosis of the liver cells lying at a slight distance from the necrotic areas. The earliest period at which this was seen was 38 hours after injection. At 48 hours the proliferation of endothelial and connective tissue cells was evident and this increased so rapidly that by the fifth day the necrotic tissue was largely replaced by young granulation tissue in the midst of which dividing liver cells could be found in considerable number. The young tissue later assumes a more fibrous apppearance, the new blood vessels become prominent, and newly formed bile ducts appear in the midst of the stroma. A development of liver cells from these new bile ducts is readily demonstrated. Multinucleated liver cells containing four to twelve nuclei are very abundant in the late stages. An interesting phenomenon is the engloblng and removal of the hyaline remains of necrotic liver cells by large multinucleated masses of protoplasm. These giant cells, essentially foreign body giant cells, are derived in part from endothelial cells, but may have all the characteristics of true hepatic cells and are, he is convinced, multinucleated liver cells with phagocytic properties. The oldest lesion obtained (36th day) presented an appearance analogous in histological structure to early cirrhosis as seen in man, differing only in that the new connective tissue surrounded the islands of liver tissue persisting about the portal spaces, instead of having a distinctly perilobular arrangement. Macroscopically, this liver was much firmer than normal, deeply bile stained and had a finely granular surface. Thus we have a form of experimental cirrhosis affecting the liver in a diffuse but uniform manner, and more typical than any previously described in the literature.

The observations thus briefly outlined, while of importance in explaining the histogenesis of cirrhosis, and incidentally of various processes of repair in liver tissue, do not aid in the elucidation of the etiology of cirrhosis in man, nor do they explain the peculiar arrangement of the connective tissue in human cirrhosis. They demonstrate, on the other hand, however, that cirrhosis may follow extensive primary destructive lesions, a view not yet fully accepted, and thus support the contention of Kretz that cirrhosis is essentially the result of a series of repair processes following repeated injuries of liver parenchyma. The earlier lesions closely resemble acute yellow atrophy of the liver in man and are, the author believes, of considerable importance in explaining the pathogenesis of this process.

Experimental Arteriosclerosis.—By Richard M Pearce and E. McD. Stanton. (Presented by J. E. Sweet.)—Within the past two years several French and German writers (Josué, Erb and others) have described under the various name of calcification, atheroma or arteriosclerosis, a lesion of the aorta of rabbits produced by the intravenous injection of adrenalin. These experiments have been repeated for the purpose of making detailed histological studies and in the hope of throwing some light upon the histogenesis of arteriosclerosis in man.

Methods.—Rabbits have received injections of 1-1000 solution of adrenalin in the ear vein. An initial dose of 3 minims repeated every other day has been the usual procedure. In other instances the dose has been gradually raised until a dose of 20 to 25 minims was given every day. The animals have been killed after periods varying from a few days to 8 weeks.

Results.—The vascular lesions produced are limited to the aorta and exhibit a more or less definite sequence. Rabbits receiving 5 to 6 injections show no gross lesions, but histologically important changes in the media are evident. These consist of focal areas of degeneration in which the muscle fibres are destroyed without alteration of the elastica. Later the degeneration is more extensive and involves the greater portion of the middle zone of the media. At this time changes in the elastic tissue appear; the fibers become swollen, stain irregularly and in some places appear to be fused together Special stains show a small number of minute fat droplets in such areas. After 12 to 15 injections very definite lesions are evident macroscopically. The aorta is more or less distorted in shape, rigid and non-elastic. Irregular dilatations alternate with elevated brittle areas of calcification. Distinct atheroma with ulceration is seldom seen In the experiments continued for six to

eight weeks the process becomes very diffuse and small dilatations of the thinner portions of the aorta assume the appearance of aneurisms. At this stage the destruction of the elastic fibers is extreme and all degenerated areas are infiltrated with lime salts. Cellular infiltration and repair about such areas has been seen in a few instances and experiments are now under way to determine the frequency and extent of this reparative process. The changes in other organs include enlargement of the heart, edema and congestion of the lungs, and degenerative changes in the liver and kidney, and occasionally in the heart and other muscles. Whether the vascular changes are due to a primary toxic action of the adrenalin or whether they are the result of the increased arterial tension which it causes, cannot be determined from these experiments. This question of etiology must be settled by other methods of investigation. The chief value of the studies herein briefly summarized lies in the application of this comparatively simple series of changes to the more complicated vascular lesions occurring in the arteriosclerosis of man.

On the Chemical and Physiological Properties of Ricin, with Demonstrations.—By Thomas B. Osborne and Lafayette B. Mendel.—A chemical study of the castor bean has indicated that this seed contains proteins of the same character as the other oil seeds which have been examined, namely, (1) a considerable quantity of a globulin which can be obtained in octahedral crystals; (2) a much smaller quantity of an albumin, coagulating at about 66° to 70° C. the temperature a which it separates depending to a large extent on the rate of the heating and other conditions; (3) proteoses which appear to belong to several of the newly recognized groups of this class of substances. The satisfactory separation of the various types of proteids was accomplished largely by the use of fractional salt precipitation and dialysis. The toxic constituent of the castor bean has been investigated under Kobert's guidance by Stillmark, who applied the name *ricin* to proteid material which he separated. The product which Stillmark regarded as relatively pure must have been a mixture of proteids and have contained only a small proportion of the toxic compound. Cushny made a more careful study of ricin and obtained a substance of sufficient toxicity to produce death in animals with a dose of 0.04 milligram per kilo of body weight. He regarded the toxic compound as proteid in nature. Among subsequent investigators Jacoby has denied the proteid character of ricin. He digested his toxic preparations with trypsin and obtained solutions which retained their toxicity although apparently no longer giving proteid reactions. Brieger, however, failed to prepare toxic preparations free from proteid material.

The efforts of the authors have been directed especially to the possibility of isolating the toxic constituent of the castor bean and determining its chemical nature. The toxic action has been found to be associated wholly with the preparations containing the coagulable protein and never with those free from the albumin already mentioned. The toxicity of the products consisting chiefly of this albumin was extremely great, the most active preparation proving fatal when administered subcutaneously to rabbits in the small dose of 0.0005 milligram per kilo of body weight. Each sample of ricin prepared by the authors showed characteristic agglutinating properties in its behavior towards blood erythocytes, in marked degree; and the pathological findings after intoxication were typical. The other proteins of the seed are devoid of the properties noted for ricin, thus demonstrating the applicability of the methods of separation employed. The toxicity of the active preparations is proportional to their content of coagulable albumin, the purest specimens containing, as their analysis shows, little else than proteid. Thus far their determinations have shown that this ricin prepared by the authors does not differ from ordinary proteins in composition, heat coagulation, color reactions, precipitation reactions, specific rotation, or in the state of combination of its notrogen. By tryptic digestion the agglutinating power of pure ricin may be greatly impaired or destroyed. The experience of the authors lends no encouragement to the attempts to "purify" such toxins by methods designed to eliminate proteid substances from the active materials.

On a Method of Determining Indol, with Demonstrations.—C. A. Herter and M. Louise Foster. The method described by the authors constitutes a rapid and accurate means of determining indol. It is based on the fact that indol, in slightly alkaline solution, readily condenses with naphthoquinon sodium mono-sulphonate, and forms a blue crystalline compound which is only very slightly soluble in water and is readily extracted by chloroform from a watery solution or suspension. The condensation compound results from the union of two molecules of indol with one of the naphthoquinon sulphonate. The union does not occur as in the case of compounds with amins, with the elimination of the sulphonic acid group, but occurs between one of the carbonyl groups of the napthoquinon compound and the imid group of the indol. The new compound is therefore a diindyl-naphthoketone mono-sulphonate. The solubility of this substance in chloroform is about one part in 4,000 of the solvent, and is sufficiently great to permit a rapid and thorough extraction of the substance. Chloroform containing the diindyl compound has red color, very like that of hemoglobin. Owing to this circumstance, the condensation compound in chloroform can be approximated colorimetrically in a convenient manner by comparing the tint of the solution with that of the orange-red glass scale of the Fleischl hemoglobinometer. Where more accurate results are desired the chloroform is evaporated and the residue of the diindyl compound weighed. It was found that the method here indicated serves for the recovery of a very large percentage of indol from peptone solutions or bouillon. From solutions containing a little proteid the indol may be recovered almost quantitatively. The presence of a large proportion of proteid may cause the retention of considerable indol. The distillation should be carried on directly, without steam, from the acidified fluid. The presence of indol in a small fraction of distillate is best ascertained by boiling the acid solution with a few drops of a 2 per cent. alcohol solution of dimethylamidobenzaldehyde. Skatol forms an homologous and similar compound with naphthoquinon, but the substance is violet rather than blue.

Anesthesia Produced by Magnesium Salts. A Preliminary Communication with Demonstrations.—By S. J. Meltzer and John Auer. The authors exhibited to the society two guinea-pigs which were deeply narcotized by injections of magnesium sulphate. One of these animals had been similarly narcotized twice before, and fully recovered each time. In their physiological and toxicological studies of magnesium salts the authors found that by subcutaneous injections of certain quantities of sulphate or chlorid of magnesium, animals can be brought into a state of deep anesthesia, during which any operation can be performed upon them without the least resistance. If the dose of the salts is not too large heartbeat, blood pressure and respiration remain nearly normal. It was tested on dogs, cats, rabbits, guinea-pigs, white rats and frogs. A grain and a half of magnesium

sulphate is about the effective dose for most of the animals. The chlorid has to be used in smaller doses in proportion to its smaller molecular weight. Particulars will be reported later. The authors wish to emphasize the fact that these salts are very poisonous when certain maximum doses are exceeded.

Enzymes and Anti-enzymes of Inflammatory Exudates.—By Eugene L. Opie. Exudates obtained by injecting suspensions of aleuronat into the pleural cavities of dogs and rabbits were subjected to autolysis. The Kjeldahl method was used to determine the nitrogen of coagulable proteids converted by digestion into soluble form. Inflammatory exudates removed one or two days after injection of the irritant undergo very little change, while those removed three or more days after the onset of inflammation exhibit appreciable though slight autolysis. There is no relation between the amount of digestion and the number of cells which are present. If the cells all separated by centrifugalization from the serum and suspended in normal salt solution well marked autolysis is demonstrable. By recombining cells and serum it can be shown that the serum inhibits this autolysis. When this inhibitory action is prevented by heating the serum to 100° C leucocytes acting upon the coagulated serum cause very active digestion. In the following summary nitrogen of uncoagulable substances is represented by cubic centimeters of 1-10N. sulphuric acid; 5 cc. suspension of cells at 37° C., 5 days 9.3° cc.; control, 3.60; 5 cc. serum, 7.25; 5 cc. cells +5 cc. serum at 37° C., 5 days, 10.95; control, 10.85; 5 cc. cells+5 cc. coagulated serum at 37° C., 5 days, 23.1; control, 10.85.

The anti-enzymotic action of the serum is unaffected by a temperature of 65° C., but is destroyed at 75° C. The proteolytic ferments of the leucocytes act both in an acid and in an alkaline medium, but are most efficient in the latter. The anti-enzymotic action of the serum is favored by an alkaline reaction, but is completely lost in an acid medium. The serum of the exudate contains a proteolytic ferment which is active only in an acid medium. These facts are illustrated by the following summary of an experiment in which 5 cc. of a suspension of cells with serum, cells with heated serum and serum alone were kept at 37° C. for a period of five days.

The anti-enzymotic power exhibited by the serum of the inflammatory exudate is possessed by the serum of the blood, from which it doubtless passes into the exudate. In the later stages of inflammation produced by aleuronat, and in exudates caused by bacteria, there is some diminution of the anti-enzymotic action.

Shallow Well Waters of Brooklyn.—By James P. Atkinson. Many streets of Brooklyn are without a public water supply and a sewage system. The residents of these streets are therefore dependent upon wells for their water supply, and upon privy vaults and cesspools to receive the sewage and waste water of their homes. The soil is uniformly sandy and water may be had by driving a pipe or digging a few feet below the surface. The water so obtained is to a certain extent surface water. The underground water is necessarily influenced by the sea water. This influence is very marked in some instances, as is shown by the high chlorin content, accompanied by the low contents of other constituents which could indicate sewage contamination. The following tables present average analytic data regarding condemned shallow wells, also regarding wells considered to be of a suspicious quality and wells which are passed as being of fair quality. Very few of the latter class were considered to be of good quality, and some might have possibly been classed as suspicious upon their high nitrate contents considered with the proximity of the sources of contamination.

The highest and lowest figures which enter into the averages are also given. These figures do not represent any particular analyses, but are selected from the different analyses from which the averages are made. Table D gives the average data for deep wells that supply water for manufacturing purposes, and they may be used as a standard in judging the purity of wells whose waters are used for domestic purposes.

Tables giving averages and high and low figures of analyses of 438 shallow wells in Brooklyn, N. Y., which are used for domestic purposes, and a table of deep wells used for manufacturing purposes. The figures represent parts in 100,000.

A—82 CONTAMINATED WELL WATERS.

	Cl.	NO_2	NO_3	Free NH_3	Alb. NH_3	Distance from source of contamination.
A	4.64	.0018	.70	.0236	.0045	47 ft
L	.70	.0001	.30	Trace	.0004	10 "

H	12.10	.0003	3.600	.0190	.0270	100 "

D—14 UNCONTAMINATED DEEP WELL WATERS FOR BREWERY AND FACTORY USE.

A	5.60	Trace	.300	.0010	.0020	....
L	.80	None	.040	Trace	Trace	....
H	17.00	.0002	.400	.0065	.0030	....

A = Average figure. L = Lowest figure used in average. H = Highest figure used in average.

67.9 per cent. were considered to be of good quality. 13.4 per cent. were found to be of suspicious quality. 18.7 per cent were considered to be contaminated and unfit for domestic purposes.

It was found impossible, as a rule, to use the figures for chlorin and ammonia contents of these Brooklyn waters in judging their purity. The nitrates might give some clue to the condition, but it was mainly upon the nitrites that one had to depend. There was in each case of condemnation ample chance of pollution through privy or cesspool, and in many cases other sources such as stables for horses and cows, pig sties, chicken yards, etc. When the nitrites were as high as .0010 parts per 100,000 the water was condemned. When the nitrites ranged between .0003 and .0010 parts per 100,000 the water was considered to be of suspicious quality, and warning was given to boil before using for domestic purposes. In Brooklyn and Queens there are waters of known purity which show nitrites as high as .0003 parts per 100,000. Therefore, when nitrites amounting to .0003 parts per 100,000 were found, with other constituents of the water suitably low, such waters were passed as fit for domestic purposes.

It will be noticed in comparing the average figures of tables A, B and C that nitrite decreases with ammonia, and that the figures for nitrate are about the same in each table. The average chlorin in table C is much lower than in tables A and B, while the average depth of the wells and their average distance from the sources of contamination are about the

same. The nitrogen averages of table C approach those of table D. If one takes the nitrogen figures of the deep wells as a standard, the conclusion may be drawn (a) that the sandy soil of Brooklyn cannot be relied upon as a safe filter; (b) that Brooklyn soil, so far as the author's evidence goes, seems to be nearing the saturation point with sewage; and (c) that, consequently, these shallow wells are in growing danger of pollution.

The Influence of the External Temperature upon the Viscosity of the Blood.—By Russell Burton-Opitz. It was proved by a series of determinations that the viscosity of the "living" blood can be greatly influenced by changing the temperature of the surrounding medium. The viscosity was markedly increased if the dogs, used in the experiments, were immersed in water at 25° C. Warm water baths (42° to 45° C.) produced a corresponding decrease in the viscosity. The specific gravity of the blood was changed in a corresponding manner.

The Changes in the Viscosity of the Blood During Narcosis.—By Russell Burton-Opitz. Determinations of the viscosity of the "living" blood were made during deep and light ether and chloroform narcosis. It was found that the viscosity is increased by deep and lessened during light narcosis. The specific gravity of the blood also shows regular variations. It is increased by deep and lessened by light ether narcosis. Chloroform, on the other hand, produces a slight decrease during deep and an increase during light narcosis. Hence, the specific gravity cannot be regarded as an accurate index of the viscosity.

Studies of the Effects of Radium on Plants and Animals, with Demonstrations.—Communicated by William J. Gies. The various studies of radium included in this communication and which are still in progress were carried out at the writer's suggestion and under his general direction. They were made possible by the generosity of Mr. Hugo Lieber, who gave the writer an abundant supply of radium preparations for each series of experiments. Professor William Hallock also encouraged the work by permitting the use of some of his valuable preparations. Dr. G. B. Pegram has given advice freely on physical matters connected with radio-activty. The studies included in this plan were the following:*

Preliminary Notes on the Effects of Radium Rays on Plants.— By C. Stuart Gager, of the New York Botanical Garden. The radium has been employed in several forms and degrees of activity from 10,000 to 1,500,000. Experiments, so far, indicate that the effect is the same in kind, whether the plants are stimulated with gamma rays only, or with alpha and beta rays as well. When all three kinds of rays are employed, the effect, within the same time, seems to be increased. The results already obtained justify the following statements:

The rays of radium act as a stimulus to plants. For this stimulus there are minimum, optimum and maximum points, depending upon the proximity of the radium to the plant, the strength, quantity and condition of the radium salt, the time of exposure, and the nature and condition of the tissue.

The early stages of seed germination are accelerated, if stimulation ranges between the minimum and optimum points; otherwise they are retarded. Seeds are less sensitive to the rays when dry than when soaked. When seeds are stimulated *during* germination, subsequent growth is retarded; but radium rays acting through soil in which plants are growing accelerate both germination and subsequent growth of the shoot.

The growth of plants is retarded in an atmosphere of decaying radium emanations, such as may be drawn from tubes lined with Lieber's "radium coating."[1] Development of leguminous tubercles is retarded when a glass tube of radium bromide (10,000 activity) is in the soil. Experiments to obtain radiotropic response have so far given negative results. Alcoholic fermentation is accelerated by radium rays.

Chloroplasts, under the influence of the rays, change their position in the cell, as when exposed to too intense sunlight. Plastids are soon overstimulated, and their activity completely inhibited, causing etiolation and other attendant effects. Gemmæ of *Lunularia*, exposed for six days, failed to develop thalli. Meristem (embryonic tissue) of the hypocotyl is destroyed by prolonged exposure to the rays.

The Action of Radium Rays on Amœba Proteus and upon Other Microorganisms.—By Louis Hussak, of the Laboratory of Zoology, Columbia University, and the American Museum of Natural History. These experiments were intended primarily to show the influence, if any, of radium rays on the protoplasm of *Amœba proteus*. Other microorganisms (*Vorticella, Paramœcium*, etc.) were also subjects of experiment. Radium bromid preparations of 600, 1,000 10,000, and 1,500,000 activity (in thin glass tubes) were used and several celluloid rods covered with Lieber's "radium coatings" of 10,000 to 25,000 activity were also employed. The radium contained was held in the water within from 1 to 3 mm. of the organism under observation. Under these conditions no visible effects were produced, by even the strongest radium preparations, during periods of observation of about an hour. The water surrounding the animal may have prevented radiant effects.

The Effects of Intravenous Injections of Radium Bromid.—By Russell Burton-Opitz and G. M. Meyer, of the Physiological Laboratory, Columbia University. These experiments, dealing principally with the effects of radium bromid upon the circulation and respiration, were performed upon dogs weighing from four to five kilograms. Light ether-narcosis was employed. The solutions injected contained 1.8 mg. of radium bromid per cubic centimeter of distilled water. Preparations of radium bromid of 240, 1,000 and 10,000 activity were used. The facial vein was selected for the injections. The results were of a very uniform character, whether radium bromid of a high or low activity was employed. The injection was always followed, after a latent period of about five seconds, by a gradual and well-marked increase in blood pressure, this rise evidently being caused by general vaso-constriction. Soon, however, a marked decrease in the frequency of the heart, accompanied by a pronounced irregularity, causes a fall in pressure. Contractions in which the diastolic phase is extremely conspicuous interchange with a series of forcible preeminently systolic beats. It need hardly be mentioned that under these conditions the variations in blood pressure are extreme. These effects of radium occur also after both vagi have been divided. These

* Each of the collaborators has written the report of his own share of the investigation.

1 Proceedings of this society, December 21, 1904.

circulatory changes are accompanied by a gradual decrease in the frequency of respiration, terminating finally in complete respiratory paralysis. This effect precedes the total inhibition of the heart.

Much more rapid and precise effects were obtained with radium bromid of high activity (10,000) than with that of lower activity. In general, 0.5 mg. of the 10,000 activity (per kilo of body weight) sufficed to produce as decided an effect as 5.0 mgs. of the 240 activity (per kilo of body weight).

Practically all preparations of radium salts contain barium. In order to check the effects of such impurities, the authors carried out a number of comparative experiments with pure barium bromid. It was found that the effects of radium bromid preparations of low activity (240 and 1,000 activity) differ only quantitatively from those of barium bromid. Certain amounts of such radium preparations produce effects that can be obtained only by correspondingly larger amounts of barium bromid. The influence of barium in causing pronounced irregularity of the heart is not evidenced by the preparations of radium bromid of 10,000 activity; only a decided inhibition results, which is accompanied by a decided rise in blood pressure.

The Radio-activity of the Different Organs after Injections of Radium Bromid.—By Gustave M. Meyer, of the Laboratories of Physiological Chemistry and Physics, Columbia University. The radio-activity of the different organs of dogs experimented upon was determined by two methods. For an approximate estimation of the radio-activity, gold-leaf electroscope has been found very serviceable. In this case, it is only necessary to thoroughly dry the finely divided organ and note the rapidity with which the charged gold leaf descends. The use of the quadrant electrometer admits of a more exact valuation of the radio-activity. The organ is incinerated and the radio-activity of the ash determined. The determinations thus far made have been entirely upon the dogs used in the experiments of Opitz and Meyer[1]. The following parts have been examined: blood, liver, lungs, kidneys, spleen, pancreas, brain and muscle. Of these the blood showed the greatest activity, while the brain has so far given negative results.

The Influence of Radium Bromid on Metabolism in Dogs.—By William N. Berg and William H. Welker, of the Laboratory of Physiological Chemistry, Columbia University. The experiments are being carried out on dogs in nitrogenous equilibrium. Radium bromid preparations of 240, 1,000 and 10,000 activity have been employed. Thus far introduction has been by mouth only. One animal (6.6 kilos) has been fed 1.100 gram 240 activity, 0.250 gram 1,000 activity and 0.125 gram 10,000 activity in small amounts daily (during twelve days) without the appearance of any gross symptoms except diarrhea during the period of the administration of the preparation of 240 activity with its large content of barium. Proteid metabolism did not appear to be materially affected. Total sulphate (SO_4) in the urine was markedly increased, especially during the period following the administration of the preparation of highest activity, and when diarrhea as well as constipation was entirely absent.

In control experiments with barium bromid, much larger quantities per os (as much as 0.5 gram daily to a dog weighing only 4.5 kilos) were without any gross symptoms whatever. In the case of barium, also, proteid metabolism was practically unaffected by the quantities used. The quantity of total sulphate in the urine, unlike the result with radium, appeared to be practically unaffected by the barium bromid.

Other determinations are being made and injection experiments are in progress.

2 Injections as well as feeding experiments are in progress.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held June 14, 1905.

The President, James M. Anders, M.D., in the Chair.

Exhibition of Cases of Goiter; Suprapubic Cystotomy for Calculus; Entero-Anastomosis for Cancer of the Cecum; Perforated Gastric Ulcer; Posterior Gastro-Enterostomy for Ulcer; Gastro-Enterostomy for Carcinoma.—Dr. William L. Rodman presented these cases. The first was that of a young woman, aged twenty-two years, who had suffered for a few years from dyspnea, difficulty in swallowing and some evidence of congestion about the brain from pressure on the vessels of the neck of a large tumor. Operation was attended with but slight hemorrhage, and she left the hospital within a week. The second case was that of an elderly man in whom operation was successfully performed. The X-rays failed to reveal the stone. The patient in the third case made a perfect recovery. Numerous cancerous growths were present in the cecum. At the time of operation the symptoms of obstruction were complete, and the patient had vomited feces for a day. Radical operation was out of the question, and an entero-anastomosis of a distended ileum was made. The fourth case, a young man of twenty-two, had had ill-defined symptoms of dyspepsia for a year or two, but without the classical symptoms of ulcer. A few hours after seizure with profound colic and shock he was operated upon, and an ulcer was found on the anterior wall of the pylorus. An opening in the ulcer had been closed by omentum, and there had not been at the time a great amount of extravasation. Notwithstanding the development of a severe peritonitis, recovery ensued. The point of special interest was the absence of symptoms pointing to gastric ulcer, and the occurrence of rupture in connection with a latent ulcer.

In the fifth case diagnosis of gastric ulcer had been made some months previous, but operation was deferred until the condition of the kidneys was improved. Two old ulcers at the pylorus were found, one on the anterior and one on the posterior wall. An increase of from ten to fifteen pounds in weight, and the disappearance of all gastric symptoms, were the results of the operation. The sixth patient was a man aged fifty-five years, whose first dyspeptic symptoms appeared in September last. At that time he weighed 190 pounds. Six weeks ago his weight was 117 pounds. Opening of the abdomen revealed a large amount of carcinomatous material. Anastomosis was made by direct suture, eliminating the loop. There has been absolute relief of symptoms with a gain of 25 pounds in weight.

Fractures of the Head of the Radius; Report of Two Cases.—Dr. T. Turner Thomas contributed a very carefully prepared paper upon this subject, and exhibited numerous specimens, the result of his experimental study. He stated that vertical fracture of the head of the radius, chipping off a portion of the radial rim, is both atypical and

frequent fracture. Since it is always intracapsular, limitation of motion must always be expected during the healing process and for a variable period afterward. Non-union is rare, due to the admirable splinting effect of the orbicular ligament and the resulting close approximation of the fragments. For the same reason, Dr. Thomas believed that crepitus, deformity and mobility of the fragments on each other were usually absent, both fragments rotating together within the ligament. In the first case reported, the diagnosis was made by skiagraph; in the second, from the localized symptoms and the marked limitation of motion, especially of pronation and supination. In the first case, in which fracture occurred nearly two years ago, return of function was almost perfect, lacking only to a slight degree full extension. The second case, after about four months, lacks only in extension.

Dr. Thomas stated his belief that fractures of the neck of the radius were also much more common than has been supposed, and almost always associated with fracture of the head and impaction of the shaft into it. Both varieties of fracture, he thought, were almost always due to falls on the hand.

Dr. George E. Pfahler believed that the character of fracture under discussion was more frequent than generally suspected, and referred to ten cases he had seen in a series of 500 fractures. He did not think that an error need often be made in finding the fractures by radiodiagnosis.

Dr. M. K. Kassabian called attention to some lantern slides of the fracture. He has found less difficulty in taking skiagraphs of the fracture than intimated by Dr. Thomas. The technic has been so improved that there is shown not only the shadow of bone, but the structure, with any accompanying disturbance. Epiphyseal separation of the head of the radius, he stated, was often mistaken for fracture.

Dr. John B. Roberts considered Dr. Thomas' contribution of much interest, and asked that the experimental fractures be presented to the Mütter Museum.

Dr. L. J. Hammond suggested that experimental fractures would not take place under conditions present in the living subject. He did not regard fractures about the joints as serious as he had been taught to believe, and did not hesitate to leave a fracture of the elbow joint immobilized for three or four weeks, after that removing the dressing every day or two. With this method and the employment of passive motion, he has not seen loss of joint motion in simple fracture. The skiagraphs did not seem to him valuable as working principles to the surgeon inexperienced in X-ray work.

Dr. Thomas, in closing, referred to the liability of error in diagnosis by skiagraphy, but also recalled cases in which diagnosis of fracture of the head of the radius was only made by this method. He expressed his willingness to place the fractures in the Mütter Museum, and in regard to Dr. Hammond's suggestion, he pointed out that in experimental work the fracture occurred always at the same point, where the joint was weak, and that this was also true of the living subject.

Perineal Prostatectomy Performed with the Aid of Young's Tractor.—Dr. Moses Behrend, after a short review of the history of prostatectomy in general, reported the history of his case operated by the perineal route according to Young's method. The patient was seventy-five years of age, and made a good recovery. Age was considered not to be a contraindication of operation. He believed that the percentage of cures far exceeded the failures, that, though the prostatic urethra may be destroyed, the normal function returns. He concluded that sounds were not necessary, but advisable, and that the mortality was remarkably low when the type of case was considered.

Cervical Rib with Resulting Gangrene of the Fingers.—Dr. W. Wayne Babcock emphasized the importance of searching for a cervical rib in cases of paresthesia, anesthesia or persistent ischemia involving the hand, arm or shoulder, and reported a case in which circulatory changes first noticed at thirteen progressed until gangrene of the fingers resulted at the age of twenty. At the age of twenty-two the patient suffered pain of an unendurable character, which prompted him to seek operative relief for what was supposed to be severe frostbite. Excision of the rib was followed by a rapid amelioration of the pain and a more gradual return of the radial pulse.

BOOK REVIEWS.

OPERATIVE SURGERY. By JOSEPH D. BRYANT, M.D., Professor of the Principles and Practice of Surgery, Operative and Clinical Surgery, University and Bellevue Medical College; Visiting Surgeon to Bellevue and St. Vincent's Hospitals; Consulting Surgeon to the Hospital for Ruptured and Crippled, Woman's Hospital, and Manhattan State Hospital for the Insane; former Surgeon-General of N. G. N. Y.; etc. Fourth edition. D. Appleton & Company, New York and London.

IN the year 1886 the first edition of Bryant's Operative Surgery appeared, and immediately won universal recognition as a work of the highest authenticity and validity. Since that time it has run through many issues and has undergone three revisions, a fact which sufficiently speaks for its great popularity and wide distribution.

It is to be noted that the present fourth edition has been carefully gone over, numerous passages have been rewritten, much new matter has been added, new illustrations included and the old ones perfected, all of which goes to bring the work as completely abreast modern surgical attainment as is possible in a text book.

Dr. Bryant has the power of expression whereby he is able to set down facts in few words, and yet with such directness of thought that the reader comprehends the meaning clearly without strain or difficulty. Although his surgical training has been of the broadest, he is not content with presenting a book of personal experience alone, but incorporates in his work all the diverse opinions and procedures now in use.

The work as formerly embraces two volumes. The first volume is devoted to general surgical principles; operations upon the blood vessels, nerves, fibrous structures, muscles and bones; amputation; deformities; plastic surgery, and operations upon the mouth, pharynx, nose, oesophagus and neck.

It is difficult to detect from a volume of such uniform strength a section of paramount value, but all things considered the chapter on plastic surgery perhaps deserves this distinction. Certainly a more instructive and comprehensive statement of the subject can not be found; and this field, as is well recognized, is one which taxes most severely the ingenuity and proficiency of surgeons lest their efforts prove a deadly boomerang.

The second volume is almost entirely devoted to visceral surgery, which after all is chiefly considered by general surgeons. Here the highest authorities are fluently quoted and the final choice of operation, as generally indicated, is backed by the logical conclusions and experienced judgment of the author. This part of the work is unusually broad, even encyclopedic in its scope, but is at no time verbose.

Throughout the work the necessary surgical anatomy is copiously supplied, being largely incorporated in the general considerations, which tend to illuminate its natural dryness and show the practical application, thus stimulating a more ready memory.

A feature of the illustrative portion is the disclosure collectively of the generally employed instruments for the various types of operative technic.

A clear idea of this masterly contribution for the general advancement of surgical science can be derived only from a long and intimate acquaintance. It needs no further commendation than that in its present edition it will still maintain that position in the forefront of the most valued surgical literature which it has so long held.

The American Year-Book of Medicine and Surgery, 1903. Volume—Surgery. Edited by George M. Gould, M.D. W. B. Saunders & Company, Philadelphia and London.

The American Year-Book Surgery for 1905 follows closely the general characteristics of its predecessors in this series. The editors have attempted to present abstracts from all of the reported work of the past year, which, in their judgment, was either sufficiently meritorious or sufficiently interesting.

So much of the genuinely scientific and practical has been accomplished that it has been necessary to carry condensation to the extreme, a fact which at times conspicuously interferes with the clarity of the treatment of the subject. This is especially noticeable in the references to the ingenious work of McGraw and Maury relative to intestinal anastomosis by means of ligaturing.

The absolute futility of a perfect hand sterilization by means of the numerous methods now in use, and there are almost as many as there are surgeons, is shown by the conclusions derived from the exhaustive work of Ludham-Green. This should be read and thoroughly digested by all those who consider rubber gloves an unnecessary evil.

For general excellence of detail, symptomatology, operative indications, and post-operative managament, the chapter upon appendicitis is perhaps the most complete in the volume. Also, the chapter devoted to hernia is authoritative and deserves comment.

It is to be noted with pleasure that the true therapeutic availability of the Roentgen ray and of radium is thoroughly discussed. This article should assist to counteract the promiscuous, unintelligent and often unwarranted administration of these two very much overrated agencies to a trusting but uninformed public by whom they are largely regarded with something akin to superstitious awe.

Much interest will be manifested in the new field opened up through the study of syncytiolysis, by which a better knowledge relative to fetal nutrition has been gained, and which may give a clearer understanding of the etiology of eclampsia.

Throughout the book many new operative methods are described, which no doubt will prove of certain usefulness.

The general utility of the volume can not thus be fully shown. Suffice it to say that it presents the easiest, most ready and authentic means of keeping in touch with the rapid advances accomplished in the surgical field.

Chemical and Microscopical Diagnosis. By Dr. Francis Carter Wood. D. Appleton & Company, New York.

During the past few years developments from the study of clinical microscopy have gone forward with such rapidity that the medical profession at large has experienced difficulty in keeping abreast.

In this volume the author has presented his subject clearly and ably, emphasizing the laboratory methods which are of practical value, and of which every student of medicine should be cognizant. To those procedures the ultimate practicability and clinical merit of which yet remains to be proven he devotes sufficient space to delineate the facts according to the face value of our present day knowledge.

The arangement of the book is admirable. The first division has to do with the study of the blood, the text of which is enhanced by numerous and beautiful illustrative plates—especially to be noted are those showing the malarial cycle which have been stained by means of the author's modified chromatin stain. The chapter dealing with serum reactions is of especial interest. Following this, in order, are taken up the diagnostic features as presented by the study of the Gastric Contents, Feces, Animal Parasites, Sputum, Urine, Transudates and Exudates and Milk, to all of which sufficient space is devoted for an authoritative discussion. Finally, the author briefly reviews, in an appendix, the preparation of the various staining fluids.

One of the most commendable features of the book is the excellent halftone microphotographic reproductions which compose the majority of the many illustrations.

It may be said without reserve that this is one of the best works on diagnosis by an American author, and not only will be a valuable text-book for students but it will be welcomed as a library reference by every practitioner of medicine.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Des Grossesses Tubaires Meconnues. By Dr. Henri Bazalgette. 8vo, 191 pages. Vigot Frères, Paris.

Transactions of the American Pediatric Society. Sixteenth Session. Volume XVI. 8vo, 296 pages. Illustrated.

Diseases of Metabolism and Nutrition. By Dr. Carl von Noorden. 8vo, 86 pages. E. B. Treat & Co., New York.

The Crux of Pastoral Medicine. By Rev. Andrew Klarmannn. 12mo, 164 pages. Fr. Pustet & Co., New York and Cincinnati.

Progressive Medicine. Edited by H. A. Hare. Vol. II, June, 1905. 8vo, 346 pages. Lea Brothers & Co., Philadelphia and New York.

Clinical Diagnosis and Urinalysis. By Dr. J. R. Arneill. 8vo, 244 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

A Text-Book of Medical Practice. Edited by Dr. Wm. Bain. 8vo, 1,011 pages. Illustrations. Longmans, Green & Co., New York, London and Bombay.

A TEST OF CONDITION: PRELIMINARY REPORT.

BY C. WARD CRAMPTON, M.D.,

OF NEW YORK.

Introduction.—This report is given to the medical profession in its preliminary stage, after the work of a year and a half; so that it may become immediately available for use and perhaps the earlier subject to modification and improvement. The importance of the principle involved, however, cannot be overestimated.

Importance.—There does not exist to-day a reliable test of condition, although its need is felt in very many quarters. The physician would be glad to know accurately what the real condition or relative degree of health is in the patient who comes under his care for the first time. It is of the utmost importance for him to know to what extent the trouble complained of affects the general health and vitality. It would give him a real guide on which to base his advice to the overworked or run-down in prescribing a treatment of tonic, rest or exercise. It would give him a real method of determining the increase of health resulting from such treatment. "Feelings," cannot always be relied upon. To the prospective employer, military, civic or mercantile, the condition of the applicant, if accurately determined, would be of vital importance. To the psychologist an accurate test of this sort would serve as a basis for definite comparisons between mental and physical efficiency, at present almost an impossibility due to the meager information of physical condition obtainable by the tests now in use. To the educational expert it would give a basis for determining the effect of the various hygienic or unhygienic features of our modern school curriculum. To the physical trainer, the worker in practical hygiene, it would give a means of noting actual progress in the most important part of his work and of measuring his success in producing the condition of health. To the athletic instructor, the coach, the oarsman and the prize-fighter it would furnish what had long been sought, an indication of success of methods of training.

During the course of an investigation on the effects of muscular contraction on blood pressure the writer elaborated a test that promises to be useful in the way indicated. In brief, the test consists in the comparison of the systolic blood pressure and the heart rate of the recumbent position with those of the standing position. The physiology involved is as follows:

On assuming a standing position the voluminous splanchnic veins are constricted by the vasomotor action of the splanchnic nerves. If this contraction is effective against the increased pressure brought to bear through the gravity, the blood pressure in the upper body rises. If it is ineffective, it fails to rise or actually falls. This accounts for the great disparity of opinion on this point, some observers finding a regular rise of 10 to 15 mm., others finding no average change, others a fall, when the standing position is assumed after the recumbent. This is an indication therefore of the efficiency of the splanchnic vasomotor mechanism which is not only important but essential to life. Upon its successful working depends the blood pressure in the brain, on the maintenance of which depends not only consciousness but the working of every function of the body and even life itself.

This mechanism is the latest in the body to develop, appearing as it has only after man has taken to the erect position. It is very easily wearied by lack of sleep, by work and by any unhygienic proceedings in general; even the routine of our daily life exhausts it to a greater or less degree. The *total* abrogation of its functions leads to the accumulation of the blood in the abdomen, the exsanguination of the rest of the body, and death. It is a very fair presumption that the working of this most important function upon which depends blood pressure, the distribution of the blood, and the working of the brain will be an indication of the condition of the body as a whole and an index to its general efficiency.

Should this be so, we shall have arrived at the end of our investigation and it will only remain to observe the rise or fall of the systolic pressure to estimate the condition of the individual. Another factor, however, enters into consideration. When the blood pressure tends to fall, the heart rate is accelerated. This is associated with a rise in pressure which masks the inefficiency of the splanchnic contraction. This is apparently a conservative mechanism in the nature of a second defence against a fall of blood pressure. Clearly then we must take into account the amount of acceleration of the heart as well as the rise or fall of blood pressures when we estimate the amount of relative failure of the splanchnic contraction.

This state of affairs in our ideal "condition" would be, a maximal rise of blood pressure with no acceleration of the heart on standing, evidencing such a complete working of the splanchnic mechanism that the heart would not be called to help raise the blood pressure. When, however, we observe the same rise of pressure accompanied by the increase of heart rate we must infer a relative insufficiency of the splanchnic mechanism on account of the calling of the heart to help.

Hence a poorer condition. Similarily, we would not consider the splanchnic mechanism as failing so badly should the blood pressure fall alone as in case it should fall and the heart be considerably accelerated. The latter condition would demonstrate the falling of pressure in spite of the assistance of the heart, hence a greater degree of failure.

We may not perhaps with perfect accuracy be able to balance these two factors and determine how much a fall of 1 mm. in pressure signifies in terms of increase of heart beats a minute. We shall arrive approximately at the truth, however, if we assume that the respective limits of their total ranges coincide. We may then divide each total range into fractional parts each of equal significance and of balanced importance.

The total change of blood pressure in those who may be considered "in health," is from plus 10 to minus 10 mm. Hg. That of pulse rate is plus 5 to plus 35. We may divide our range into fifths and construct the following tentative scale, in which the letters constitute the index to the splanchnic efficiency:

	Blood-Pressure Increase:	+10	+5	0	—5	—10
Increase in Heart Rate:	5	A	B	C	D	E
	12	B	C	D	E	F
	20	C	D	E	F	G
	28	D	E	F	G	H
	35	E	F	G	H	I

Interpreting this scale, we would have with an increase of 10 mm., if occurring with only five increase of heart rate, the index A, the best possible condition if accompanied with an increase of 35, and index of E, etc.

By the term splanchnic circulation we should properly mean the arterial branches of the celiac axis, their branches and capillaries, with the radicles of the portal vein. This system is partly arterial and partly venous and it is to the venous portion that attention is to be called more particularly; the arterial portion and the capillaries present features very similar to like structures in other parts of the body whereas the venous portion presents features of extreme and novel importance. During the course of this work, however, when the splanchnic area is referred to, it will be understood that the portal vein and its radicles are meant particularly.

The Capacity of the Splanchnic Area.—The veins of the splanchnic area share with other veins of the body (which are not supported by rigid structures) the features of collapsibility. On this account the blood content of the total splanchnic area may therefore be very great or very small, in fact the veins alone may, under certain conditions, contain nearly all the blood of the body. Hill and Barnard[1] found in the dog, in the vertical, feet down, position that the cutting of the cervical cord causes the pressure in the aorta to fall to zero and practically the whole of the blood to be collected in the splanchnic area. Squeezing the abdomen brought back the aortic pressure to the normal. Hill worked with rabbits, suspending them without any operative interference in the vertical, feet down position; death invariably resulted in a short time. If the blood were kept from draining into the abdomen by a tight band, no inconvenience was suffered. If the rabbits were suspended in the head down position no bad result followed. These items serve to illustrate the great capacity of the splanchnic reservoir. The importance of this great capacity is demonstrated by the experiment of tying the aorta first below the celiac axis, and, secondly, above it, in an animal with the cervical cord cut. In the first instance practically no effect on aortic pressure is observed, in the second a very considerable rise is obtained.—Ludwig and Thiry.[7]

The Control of the Capacity of the Splanchnic Area.—Nervous.—(1) Splanchnic nerves, (2) vasomotor center, (3) reflex stimulation. Mechanical—(1) External pressure, (2) tone of abdominal walls, (3) aspiration of thorax, (4) respiration.

1. *Splanchnic Nerves.*—Mall[2] observed the direct influence of the splanchnics upon the portal vein. He obtained a contraction of the vein that could be easily noted by the eye. V. Besold and Gscheidlen[3] proved much earlier that the systemic veins had a vasomotor system and were controlled in a similar manner to the arteries. These investigations prove conclusively a somewhat neglected fact that the veins of the splanchic area have a tone as well as the arteries. That the splanchnic nerves are in the main vasoconstrictor in their function is shown by the dilatation of the splanchnic vessels on section of the nerves. This dilatation may be measured with some accuracy by the variations in the aortic pressure. The greater the room made for the blood in the splanchnic area, the lower the pressure will fall.

Hill has given the result of the action of the splanchnics in the experiment already quoted. Ludwig and Cyon[4] found that section of one nerve caused a fall of aortic pressure of 30 to 50 mm., the section of the other 8 to 10 mm. more. In every case the section was made by lumbar incision so that the opening of the thorax and abdomen were avoided. Asp[5] found that after section of both these nerves tone was partly regained in about two weeks, showing a taking up of the function by other branches of the sympathetic system.

Bayliss and Starling[6] have found that the third to the eleventh anterior thoracic roots contain the fibers which affect the splanchnic area. By excising these roots they caused (1) an abrupt but ephemeral rise of pressure in the portal vein due to the constriction of the mesenteric arteries, (2) a fall, due to this same constriction, (3) a rise, due to the constriction of the hepatic branches of the portal vein.

According to Bever and v. Besold[6] section of the cervical or the upper dorsal cord does not produce any further material lowering of blood pres-

sure after the splanchnics have been cut. V. Besold[8] found that by stimulation of the peripheral end of the cut cervical cord he was able to send up the blood pressure to seven times its normal height. Work by Hill and Barnard (*op. cit.*) would seem to indicate that since the splanchnic area was robbed of the support of the abdominal walls paralyzed by the section of the cord and not affected by the cutting of the splanchnics, we would expect therefore a greater filling of the veins and a greater decrease of pressure, after section of the cord than after section of the splanchnics alone. One of their experiments shows that with the splanchnics cut the blood pressure fell considerably when the abdomen was subsequently opened by a crucial incision.

2. *Vasomotor Center.*—The vasomotor center has been located in the medulla oblongata. It can be excited in two ways (1) by variations in the central blood pressure, (2) by reflex stimulation. A fall in cerebral blood pressure, *i.e.*, cerebral anemia, will cause a stimulation of the center, a consequent vasoconstriction and a rise in pressure. A rise in cerebral pressure will cause the reverse.

There are subsidiary vasomotor centers in the spinal cord and even local centers outside the central system; on this account we may have local conditions of vasotone entirely independent of the general condition.

3. *Reflex Stimulation of the Splanchnic Area Through the Vasomotor Center.*—Any nerve, save the depressor nerve, when cut and the central end stimulated, will effect a stimulation of the vasomotor center and cause a rise in pressure. Some nerves, under certain conditions, are proven to carry depressor fibers and their stimulation will result in a fall of pressure. (Howell [10] Reid Hunt.[11]) The depressor nerve when stimulated will cause a marked lowering of blood pressure and a decrease in heat rate, through its effect upon the medullary vasomotor center.

Mechanical Factors.—We have already noted that the mechanical squeezing of the abdomen will increase the blood pressure in rabbits and dogs, in the vertical feet-down position. The writer has called attention to the same effect obtaining in man in the sitting position when the knee is crossed and the abdomen compressed mechanically by the leaning over. It was found in a subject in poor condition that the blood pressure in the radial artery (held at the height of the ensiform) was greater when the abdomen was thus compressed than when the erect sitting attitude was assumed.[12]

Rowe[13] has noted quite empirically that long-continued study cannot be accomplished when "sitting up straight," and that the characteristic attitude of study—bending over at a desk or bending over with the knee supporting a book is conducive to the success of long-continued work. The effects of attitudes are discussed by Rowe and the blood pressures noted, and the results obtained would lead to the conclusion that the difference in mental ability noted by Rowe were due to blood pressure changes. Treves[14] has noted in enteroptosis that the symptoms often relieved by merely pressing upon the abdomen with the hands and that "many patients are unable to move about until they have adjusted their supports or bands." Bowen,[15] in a very complete work on the effect of exercise upon blood pressure, found that the pressure was raised during the whole of the exercise. Oliver[16] on the contrary found that while blood pressure was raised at first by exercise it fell rapidly if the exercise was continued. The difference in the results obtained by these two investigators is no doubt due to the difference in the exercise. In bicycling the position is somewhat flexed and the thighs press rhythmically upon the abdomen, by this means the splanchnic circulation is kept within bounds and the blood pressure is kept up. In walking, on the other hand, there is no such support and the blood drains rapidly into the splanchnic circulation. Oliver (*op. cit.*, p. 163) has proven conclusively the drain into the splanchnic area during continued exercise of this nature, namely, walking, and the fact that continued bicycling two hours and forty-five minutes does not allow of any drain. He found that after bicycling a pressure of twenty-two pounds distributed over the abdomen caused no rise in arterial blood pressure. After walking, on the contrary, one hour and thirty minutes, the same pressure caused a rise of 20 mm. The writer has verified these experiments. De Jager[21] finds that pressure on the abdomen has but little effect upon the abdominal arteries while it serves to express a large quantity of blood from the splanchnic veins.

The Effect of the Tone of the Abdominal Walls Upon the Capacity of the Splanchnic Area.—Hill and Barnard (*op. cit.*) have shown the value of the abdominal wall as a support to the circulation. In a dog suspended in the vertical, feet-down position, with the splanchnic nerves divided, the pressure fell markedly when the abdomen was opened. The slightest decrease in the tone of the abdominal walls will be followed by a decrease in intra-abdominal pressure. The cutting of the spinal cord for this reason causes a greater lowering of blood pressure than the mere cutting of the splanchnics, as has been already noted. Evidence is not wanting on this point. Treves (*op. cit.*) states that the greater part of the symptoms usually found with enteroptosis are due to the relaxation of the abdominal veins due to the decrease of intra-abdominal pressure caused by the loss of tone of the abdominal walls. Massage causes a direct emptying of the splanchnic vessels and an increase in blood pressure.[17] Quirin[18] finds that increase of intra-abdominal pressure brings up the pressure in the arteries merely by displacing the blood from the abdomen. Oliver (*op. cit.*) finds intra-abdominal tension decreased and associated with vasomotor

inability, in many forms of impoverished nutrition, chronic goutiness, anemia and neurasthenia.

The action of the abdominal muscles in maintaining intra-abdominal tension and the means of testing their efficiency have been well worked over by Harry Campbell.[19] Campbell lays particular stress upon the function of the transversalis as a constricting band shutting off the upper from the lower abdomen. The recti are described as separated in the infant and nominally close in the adult. In the male in good health the abdomen is flattened by their action; in the female this takes place, but the contour becomes rounded, due to the accumulation of subcutaneous fat.

The Effect of Respiration and Aspiration of the Thorax Upon the Capacity of the Splanchnic Area.—It is to be noted in Hill's experiment, previously cited, that opening of the thorax, after the splanchnic nerves had been cut, and the abdomen opened, caused a further fall of blood pressure; demonstrating the effect of the thoracic aspiration upon the return of blood from the abdominal veins. Leyden and Quincke[20] have found the negative pressure in the pleuræ to be as low as —42 mm. Campbell gives the following table of minus pressures in the pleural cavity:

At the end of an extraordinary expiration.— 0
At the end of an ordinary expiration....— 5 mm.
At the end of an ordinary inspiration....—10 mm.
At the end of an extraordinary inspiration.—30 mm.

Donders[21] gives the following results:

In position of ordinary quiet inspiration..—9 mm.
In position of ordinary quiet expiration.....—7.5
In position of deepest inspiration.....—30 to 40

This minus pressure is due to the elasticity of the lungs pulling against the comparatively rigid chest wall. This pull or suction has wide variations. In the infant it is practically nil, as the lungs fit the chest cavity with little or no tension of stretching. In old age the lung ordinarily becomes permanently stretched and fails to produce the suction evident in ordinary conditions. All organic diseases of the lungs—bronchitis, pleurisy and tuberculosis—diminish it, and in emphysema, it is reduced to a minimum. In fevers, as in typhoid and diphtheria, it is diminished. The bulging of the chest in pneumonia is due not ordinarily to a positive internal pressure, but to a diminution in the negative pressure.

This elasticity of the thorax is a factor in determining the amount of pulmonary suction actually efficient upon the circulation of the abdomen. The suction cannot be greater than the elastic resistance of the thoracic wall. In early youth this elasticity is greatest and the negative pressure lowest. It is at this time that any weakening of the thoracic wall from malnutition gives us the familiar result of a depressed sternum, and its exaggerated form, the "Trichterbrust." In adult life, however, the rigidity of the chest wall has become established, pulmonary suction is finally resisted, and becomes effective, as a potent factor not only in causing the upward flow of blood from the splanchnic area, but in causing the return of the lymph and the blood from the azygos and upper body veins.

It is evident that the variations in the negative pressure of the chest cannot fail to cause variations in the rate of inflow of blood to the thorax. We shall expect during inspiration an increased inflow, and during expiration a decreased inflow; also, owing to the same reason, we should have a decreased outflow during inspiration and an increased outflow during expiration. This should cause the chest to contain more blood at the end of inspiration than at any other time. Heger and Spehl found that the lungs contained 1-13 to 1-12 of the total blood in inspiration, and only 1-15 to 1-18 in expiration. Hill[24] concludes that "in natural breathing the air and the blood volume change together and in the same way."

From the foregoing facts it is evident that the respiratory mechanism is most potent in returning blood from the splanchnic veins.

The Effect of Variations in Splanchnic Capacity Upon Blood Pressure.—Arterial blood pressure depends primarily upon the force of the heart beat, the volume output per beat, the rate of beat, and the peripheral resistance. Turning to the cardiac conditions alone we should observe that, other things being equal, the greater the output per beat the greater will be the arterial pressure; also, the greater number of beats per minute the greater will be the pressure.

All combinations of these factors are possible. The stimulation of the vagus will cause a slower beat and a diminished output per beat. By stimulation of the accelerator nerves in the dog, Woolridge[25] obtained an increase of output per beat and a consequent rise in pressure without any acceleration. Munzel[26] and Roy and Adami[27] obtained an acceleration of the heart without any increase in blood pressure.

Roy and Adami (*op. cit.* and [28]); Howell and Donaldson (*op. cit.*); Tigerstedt[29] and others have found that the heart output depends largely upon the amount of blood available to the heart in the great veins. Anything increasing this amount of available blood causes a rise in pressure. Abdominal massage, abdominal constriction, muscular exercise, etc., all cause this result by constricting the splanchnic area.

Any factor causing a decrease in splanchnic tone, such as warm baths, fatigue, disease, exercise (second stage) will cause a lessoned venous inflow, a decreased output and a lowered blood pressure.

The importance of this mechanism in controlling the blood pressure has but recently been exploited, and has hardly reached the text-book stage. That the splanchnic mechanism is a most potent one, may be seen by the fact that excitation of the splanchnic nerves will produce a greater arterial pressure than the closure of the thoracic aorta with a clip[30], and also by the

fact that the complete failure of its vasoconstriction means the collection of practically all the blood of the body within its veins. Recent work by Romberg and Pässler,[31] and Pässler and Rolly,[32] goes to prove that death from diphtheria and pneumococcus septicemia is due not to cardiac failure, as hitherto believed, but to vasomotor paralysis, and that the heart at death is still able to contract. Patients may thus be treated with vasoconstricting elements, instead of cardiac stimulants.

The Method of Using the Test.—The patient is directed to lie down flat upon a couch with no head rest. The armlet of the blood pressure instrument is then placed around the upper arm. This should be arranged so that it bears the same relation to the heart lying as it will when the patient is standing, so that no hydrostatic error will be included. Absolute quiet is insisted upon, relaxation of the muscles is necessary, and all emotional disturbances should be guarded against. The pulse rate is then taken by quarter minutes for at least four successive quarters. These should be recorded until we arrive at a plateau in which the heart is steady, the indication of which may be taken to be the point where four records show no decrease. These four records forming a minute's record should be noted for comparison with the standing rate. Without releasing the grip on the radial artery, the systolic pressure should be taken.

This should be taken twice, and if any large difference is noted, a third time; and the average struck. If there is any considerable variation noted, it may be due to several disturbing factors, such as an uncomfortable position, emotional disturbances, nervous muscular contractions, holding the breath, etc., all of which should be eliminated. These items recorded, the patient is allowed to stand and the same records taken in the same way with the same precautions.

It is important that the pulse rate should be allowed to fall to its standing normal after rising, for it is accelerated by the muscular act of getting up. The blood pressure also rises considerably at first (though it may fall), but it strikes a balance as a rule a little before the pulse rate does. We may now compare our results and arrive at a conclusion as to the condition of the individual. The whole test takes less than five minutes.

It is advisable at first to repeat the test and corroborate the findings of the first examination; with a little practice, however, a repetition is unnecessary.

Range of Results.—In "normal" cases the heart rate increase varies from 0 to 43, the systolic pressure from plus 18 to minus 12, the diastolic, from 0 to plus 18. Various combinations of these have occurred. The usual combinations are "regular"—that is, the rise in systolic pressures is in inverse ratio to the rise in the pulse rate; both factors being equally significant, for good or for bad.

Case I.—A., aged eighteen years; football player; weight 185 pounds; very muscular: 10:30 A.M.:

	Pulse rate.	Systolic Pressure.
Lying	58	120 mm.
Standing	58	132 mm.
Difference	0	+12 mm.

Estimation as per scale A+.

This shows the least possible increase in pulse rate, viz.: Zero with nearly the greatest possible increase in systolic pressure.

Case II.—S., aged thirty-five years; a teacher, athletic, "in good shape," after the school day, 3 P.M.:

	Rate.	Pressure.
Lying	61	110 mm.
Standing	85	110 mm.
Difference	+24	+0

Estimation as per scale E.

This case shows a considerable rise in heart rate, 24, approximately, the middle of the scale and coupled with it no change in pressure; also a middle term.

Case III.—V., aged seventeen years; quarter-back football team, "in good shape," according to his own statement; weight 125 pounds. At the end of the football season, 11.20 A.M., twenty minutes after a recorded amount of exercise:

	Rate.	Pressure.
Lying	68	100 mm.
Standing	104	94 mm.
Difference	+36	—6 mm.

Estimation as per scale H.

This case shows very great increase in pulse rate and a considerable decrease of pressure. A "regular" variation, and a very poor record.

In these cases just cited, each factor is proportionately as "good" or "bad" in its significance as the other. If this were the invariable rule it would be necessary to record but one of these factors, for the other would be easily calculated as in inverse ratio to it. This, however, is not the case, as the following "irregular" cases show:

Case IV.—S., aged seventeen years; athlete, weight 140 pounds; 11 A.M., "not feeling very fit," coffee with breakfast: walked one and one-half miles to school and took two periods of hard school work, one standing in laboratory.

	Rate.	Pressure.
Lying	64	128
Standing	72	118
Difference	+8	—10

Scale E.

This shows a slight increase in pulse with a marked fall in pressure. A "good" pulse rate increase with a "bad" fall in pressure.

Case V.—B., aged sixteen years; athlete, weight 130 pounds; somewhat overtrained; 11 A.M., simple breakfast, no exercise, two periods of easy school work.

	Rate.	Pressure.
Lying	68	100
Standing	104	110
Difference	+36	+10

Showing a great increase in rate—a bad feature; coupled with a considerable increase in pressure—a good teature.

Validity of Results.—A test of this sort can only at present be proven by empirical methods, and to these we must resort. There is no other way known to the writer whereby the efficiency of the splanchnic mechanism may be determined by which a comparison of results and a proof might be established. We can, however, test the efficiency of the individual and observe how nearly he will follow out our predictions as regards his "condition" in his athletic and other work. Should a man work poorly after this test has shown him an "A," with splanchnic mechanism presumably in good order, we should have cause to doubt the validity of the test. Also should a man whose record places him an "E" or below show up well, in athletic events or other strenuous work, we should again have reason to doubt our test. Such is not the case. Without exception the athletes who have so been tested by this method have *invariably and fatally carried out predictions*, even though ignorant of the meaning of the test.

A second method more easily followed out is the testing of these individuals whose condition and general efficiency is approximately known. Here, though we may meet with some surprises, the following are several cases typical but in no way selected:

1. In V., already cited as Case III, whose record was taken four times during the course of the day, his index ran G, G, H and H—during the day, his pulse increased 28, 36, his pressure fell from —2 to —12 at different times. On being questioned it appeared that he had not been sleeping very well, though he was in "good shape." He begged off from his physical training work of the afternoon and was absent the next week, having "caught cold and a fever."

2. *Case VI.*—T., teacher, aged thirty-two years; weight 190 pounds; athlete. Had six hours' sleep, hurried breakfast, "fair shape"; one of the twenty best tennis players in the United States, gave a record of +27 rate, and +6 mm. pressure at 8:30 A.M.; +19 rate and —0 mm. pressure at 3 P.M., both equal to E index. Played tennis at 4:15 to 6:15 with a very much inferior player; won the first two sets at 6—0, 6—3, lost the next three 6—8, 3—6, 0—6, demonstrating very conclusively his lack of "staying qualities" on this particular occasion.

Case S., quoted at Case II.—Ran three blocks after a car one-half hour before test, and felt somewhat dizzy on standing. "In poor shape," though a "10 2-5 man" in the hundred yards dash five years ago. At 8:30 A.M., pulse rate increased +36, pressure —12 mm., passed a miserable day, not feeling well.

Case VII.—F., coach of track team; fair athlete; "in fine shape." Test at 10:30 A.M., and gave an index F, with increase of rate +20 and pressure —7. A few days afterward ran a 220-yard dash; this was followed by a mild case of collapse, with the usual unloading of the stomach afterward.

These and many other cases show decisively that the estimations of poor "condition" are accurate. On the other hand, estimations of good condition have proven equally accurate.

The condition A is a somewhat unusual one, only three cases were found in an investigation of 38. One was Case I, already cited, the fullback of a football team, whose work shown as particularly successful on a very successful team. He was practically untiring, was never "laid out," and was a remarkable player in every way. The second was an assistant director of physical training who kept in the best of condition and was remarkably "long winded" in continued work, as in wrestling and basketball.

The third was a young man, a student of good, though not unusual mental and physical ability, a member of the track team, whose work was principally on the long runs, where he showed not a great deal of speed, but a consistent ability "to keep at it," though he was apparently not very strong.

Aside from this method of proving the validity of the test we may seek to prove it by taking individuals of a known condition and observe the correspondence of the results. This has been used and has given much information concerning the accuracy of the test. In a few cases where the findings of the test disagreed with the condition as predetermined, the case was not made out clearly in favor of the empirical methods, whereby the first estimation of condition was made. In several of these particular cases subsequent observations on these patients demonstrated the accuracy of the test as against the other methods used.

An interesting and an important item of proof of the validity of the construction of the scale and the balancing of the two factors was brought to light in an investigation on the condition at different periods of the day. It was found that in most cases the condition gradually became worse during the day, but each of the two factors might show a wide variation. The following case is typical:

Case.—R., aged seventeen years; member of track team, one mile, not very good runner but able to "finish" well. (See table on next page.)

Medical Aspects of the Test.—By the use of this test we can estimate in a real way the progress made in our chronic cases and the value of the remedies applied. It is inapplicable to any but ambulant cases, for rest in bed interferes with it strongly. A moderate amount of rest

	Increase in Pulse Rate.	Increase in Systolic Pressure.	Index.	Remarks.
9:45 A.M.	0	+10	A+	Silent well, no exercise.
10:50 A.M.	0	+ 4	A—	After a lesson in physics.
11:45 A.M.	+ 8	+12	A—	After lesson in algebra.
12:20 A.M.	+ 5	+ 6	B	After lesson in French.
1 P.M.	+ 4	+15	A	After lunch and rest; no coffee.
2 P.M.	—14	+16	A—	After history lesson.
2:25 P.M.	+16	+ 8	B—	After one-half mile slow run.
2:30 P.M.	+18	+ 8	B—	Fifteen minutes hard exercise.
2:38 P.M.	+18	— 8	B—	After five minutes rest, feeling tired.

in the run-down will increase the efficiency of the vasomotor mechanism, but long-continued rest decreases its efficiency, from disuse, to a marked extent. The fall of cerebral pressure and consequent syncope caused by even the sitting up in bed of a patient long recumbent is familiar to all. Its chief use in future will no doubt be in diagnosis of the amount of damage to the general vitality any hidden disease or any course of life has produced in the patient under our observation for the first time and also in the estimation of the progress made under our management.

In the guidance of our therapeutics we may look for a field of usefulness. It is not enough to know how a drug affects the blood pressure, which is but vague information, we must know how it affects that most important function, the vasomotor control.

The writer has applied this test to a number of hard-worked business and professional men who have come under his care, with most satisfactory results. In every case it formed an accurate and reliable index to real improvement. It was very much more steady in its readings than would be expected from the apparent variations in observed condition, which were extremely variable, but it seemed to check real improvement much more positively than could be determined by observation.

In one case of neurasthenia, in which a relative degree of sexual impotence was a symptom, the index followed the regaining of this function very exactly, and marked a relapse as accurately.

INTUSSUSCEPTION.

BY W. E. DICKEN, M.D.,
OF OKLAHOMA CITY, O. T.;
LOCAL SURGEON FOR THE M. K. & T. R. R. CO.

NOTWITHSTANDING the large per cent. of intussusception in the young, I find men to-day that are blind to such symptoms and children dying from the want of prompt action on the part of the attending physician. For instance, invagination tumors have been mistaken for prolapse of the rectum, for polypi or for hemorrhoids, and have been excised. It is more the purpose of this paper to bring out discussions on this subject, and impress upon us the importance of a thorough knowledge of intussusception, than to present any new thought that in my feeble way I might offer. Intussusception consists in the invagination of one portion of the intestine into another. It occurs most frequently in infancy, being at this age the most common cause of acute intestinal obstruction. The accident is not common, but the life of the patent generally depends upon its prompt recognition. The condition is nearly always a descending one, in contradistinction to the post-mortem invaginations, which are often ascending ones. The following varieties have been found: The ileocecal, in which the ileocecal valve passes down into the colon; the ileocolic, in which a portion of the ileum passes through the valve; the ileol, affecting the ileum alone; the colic, in which the colon is alone involved, and the colicorectal, affecting the colon and rectum.

The cause of 34 per cent. of intussusception occurring in children under one year of age, is in all probability the weakened condition of the walls of the bowels and in all cases the etiology is supposed to be irregular peristalsis. In most cases the ileum enters the cecum or the colon; less frequently the ileum or the colon or cecum enters itself, or the colon enters the rectum.

The mechanism of one form of intussusception was demonstrated by R. T. Morris, of New York, to the Philadelphia Medical Society. He exposed the ileum of a rabbit and it was observed that when it was touched with sodium carbonate, contraction of the circular fibers of the bowel at the point touched would take place in from fifteen to thirty seconds. The longitudinal fibers of the bowel, still carrying on peristaltic movement (a reversed peristalsis by the way), would invaginate that portion of the bowel which was in a state of firm contraction. He did not know the exact value of this experiment, except that it showed the mechanism of one form of intussusception. It is known that certain ptomains produce muscular spasm, and it is fair to assume that some cases of intussusception are due to a poisoning of the muscular fibers of the bowel, as in the experiment. In post-mortem intussusception, as he had watched it, there had been paralysis of the circular fibers of the bowel, and an adjacent segment of bowel had dropped into the relaxed portion, almost the reverse of the mechanism demonstrated in this experiment. We do not, however, stop to think just what mechanism formed the intussusception we have under consideration, but are we sure that it is a case of intussusception, and just what methods we shall pursue to bring about the desired relief? In a large number of cases it is impossible to determine the exact cause of the intestinal obstruction without actual exploration of the abdominal cavity; but intussusception is capable of more certain diagnosis than any other form of acute internal strangulation.

If there is a sudden seizure of severe abdominal pain with vomiting, and the pain is noticed to come on in paroxysms, and there is a frequent passage of mucus, and perhaps blood, too, from the rectum, and on examination an elongated tumor is felt, hardening up under the finger during each paroxysm of pain and then softening if not disappearing again, it is evident that we have a case of intussusception in the acute form. In some cases the end of the intussusception can be felt per rectum. When vomiting sets in early, is frequently repeated and quickly becomes stercoraceous, and when the belly is uniformly and only moderately distended, and the excretion of urine is small, the obstruction is known to be seated in the small intestine, and the higher up the strangulation the more marked are these distinguishing features. When, on the other hand, the abdomen is greatly distended and the vomiting is less urgent and a longer interval elapses before it becomes stercoraceous, it indicates that the obstruction is in the large intestine. The hemorrhages constitute one of the most constant symptoms; they are absent in only 20 per cent. of acute cases; they vary in amount according to the site and extent of the invagination. As soon as the process becomes subacute, the hemorrhages may cease or temporarily disappear. On the other hand, large, gangrenous, putrid pieces of intestine may be passed per rectum. Lobstein mentions a peasant woman of about thirty who was suddenly seized with an attack of intussusception of the bowel, and was apparently in a moribund condition when she had a copious stool, in which she evacuated three feet of bowel with the mesentery attached. The woman recovered, but died five months later from a second attack of intussusception with ileum rupturing and peritonitis ensuing.

All of the above remarks have been relative to acute intussusception; but we have a form under the name of chronic intussusception which includes those cases of intussusception having a duration of one or more months. Their extreme importance is shown in the words of Dr. Treves, that no form of intestinal obstruction offers so many difficulties in the way of its recognition, and no form has been the subject of more error in diagnosis. This form appears most frequently in adult males. Its course is most irregular. The onset is sudden in only about one-third of the cases—a point, when present, of much value in the diagnosis of this from other forms of chronic obstruction. Pain, seldom severe, may be entirely absent for long intervals, these becoming shorter as the disease advances. Vomiting is marked in only about half the cases; it is feculent in only about 7 per cent. The action of the bowels varies greatly. As a rule they are irregular, more often with a tendency to diarrhea than toward constipation. In about 50 per cent. a bloody discharge from the anus may be expected. Distention of the abdomen is slight and may be absent save during attacks of temporary obstruction. A tumor is to be felt in about half the cases. The general condition is one of wasting and anemia, the patient not infrequently dying of marasmus.

None of the symptoms described above, however is pathognomonic, and only by careful consideration of the separate data can a mistake in diagnosis be avoided.

Now, having made our diagnosis by a careful study of the foregoing symptoms, the only thing in my mind to do, and to be done *at once* (anyhow within the first forty-eight hours of the trouble) is surgical interference. I say surgical interference because the great majority of cases come to that; and I deem it dangerous to waste time with other methods. The sooner the abdomen is invaded and the mechanical derangement relieved by mechanical means, the better for the patient. The old-time method of giving opium and belladonna and raising the pelvis and lower limbs of the child, and passing into the bowels the nozzle of a Lund's inflator, or a full-sized catheter well smeared with vaseline, attached by tubing to a bellows, and by this method filling the child full of wind, has long since been deemed too dangerous and abandoned. It is also risky to indulge very much in the clyster; on account of the weakened con-

dition of the walls of the bowels and the danger of perforation. It is impossible to give medicine by the mouth, on account of the incessant vomiting which is nearly always present. Hence there are only two things to be done—one, to place on the abdomen hot fomentations and await nature's good will and pleasure; or place the patient under anesthesia and enter the belly wall, relieving all abnormal conditions found therein.

I desire to describe a typical case which came under my care recently: Mrs. E. brought her three-year-old daughter to my office suffering intense pain at times in her abdomen and with incessant vomiting and great tenesmus. It was easy for me to make the diagnosis of intussusception. I sent her to the hospital, informing her of the gravity of the case, and prepared to operate. In about thirty-six hours from the commencement of the attack we had completed our operation. Before entering the abdomen, however, we could feel an elongated tumor along the course of the descending colon. We found with very little difficulty the intussusception, which consisted of about five inches of the descending colon swallowed up within itself. After breaking up with the fingers some slight adhesions, and with gentle traction, the gut was disengaged and the strangulation was relieved. Within the next six hours the bowels moved copiously *three times*, without any blood. There was no rise of temperature and my patient made an uneventful recovery. I will also state here that in all laparotomies in children, it is well to administer an anesthetic when the first dressing is made. There is nearly always fright, and the little patient will cry and strain, and you will likely have the stitches giving way and an abdominal rupture. I had one case like this, which made me very cautious with my first laparotomy dressings.

Fortunate indeed are we to find these typical cases. More often we grope around in the dark until the true light is seen only through an exploratory operation. But let me reiterate what has been said—in all cases of intussusception, I believe it far safer to operate than trust to any other method or methods of treatment. First be sure that you have intussusception, then operate, and nine chances out of ten you will be doing the right thing for your patient and yourself.

Chemistry of Nephritis.—The chemistry of the blood in nephritis has been studied exhaustively by F. Ereen (*Zeitsch. f. klin. Med.*, Vol. 57, Nos. 1 and 2) with the following results: In parenchymatous nephritis, the proportion of albumin to globulin in the blood is altered in that the latter is in excess. In the interstitial form the proportion is about normal. Other changes in the parenchymatous form are a decrease of lecithin and lime in the serum. There are other minor differences, but to determine whether these are constant or accidental will necessitate a larger number of analyses.

A CASE OF RETAINED INTUBATION TUBE TREATED BY GRADUAL DILATATION.[1]

BY FIELDING LEWIS TAYLOR, M.A., M.D.,
OF NEW YORK.

A. K., MALE, aged three years and two months, was first seen by me the latter part of November, 1903. He had then been ill with slight fever for four or five days, but had not shown any signs of croup until the evening of November 24. During the evening of November 25, Dr. J. I. Metzger saw the patient for the first time. He observed a separating necrotic membrane on the tonsils and administered antitoxin. There was at that time a moderate amount of laryngeal stridor. Marked dyspnea, however, developed rather acutely toward seven o'clock the following morning. When seen by me about eight o'clock, November 26, there was absolute cessation of breathing, and Dr. Metzger was endeavoring to perform artificial respiration. The child was unconscious, pulseless, limp and apparently moribund. Dr. Metzger stated that there had been no attempt at respiration for some minutes before my arrival.

I fortunately had a 6-7 (new scale) tube on the obturator, already threaded, which I had fixed for another and older patient. There was no time to lose, and I inserted this without difficulty. Then artificial respiration and precordial massage were resorted to with success. About forty-eight hours later this tube, being too large to be coughed out, became plugged with detached membrane. It was removed without difficulty and the next smaller size (4-5) introduced.

November 30, four days after the original intubation, this tube was removed, but reintubation was required after two hours. I now used the built-up O'Dwyer special tube 3, to change the points of pressure.

December 4, five days later, this was removed, but intubation became necessary again after eight hours, when an ordinary three-year tube was inserted.

December 12, eight days later, this tube was removed. The child recovered his voice after three days, and appeared to be progressing satisfactorily, when, December 21, nine days after the last extubation, I was urgently called by the attending physician, who said that dyspnea had been severe for several hours, and was unrelieved by ordinary measures. The family stated that there had been more or less difficulty in breathing for the previous three days, which had grown progressively worse. A three-year tube was inserted, which was removed four days later, on December 25.

January 3, nine days later, I was called to intubate and introduced tube 3. Some force was required to send it home. Just as before, for the previous three days there had been considerable dyspnea at times, particularly when the pa-

[1] Presented before the Section on Pediatrics, New York Academy of Medicine, May 11, 1905.

tient was disturbed. Nor had he been able to cough efficiently to expel accumulated mucus.

These two attacks of dyspnea, almost identical in that they began six days after extubation and grew gradually worse for three days until respiration became dangerously stridulous, led me to believe that I had a contracting cicatrix to deal with. (As the voice returned upon both occasions within a day or two and was nearly normal, it seems probable that the vocal cords were not involved.) I therefore decided to try gradual dilatation of the stricture, according to the method of Dr. John Rogers, so that after a week, tube 3 was removed and tube 5-7 (old scale) at once inserted and allowed to remain until February 17, when it was replaced by a Rogers 5-7 tube. This tube has the same maximum transverse diameter as the corresponding O'Dwyer tube, but its neck is only 3-32 of an inch narrower than the greatest breadth of its bulge.

This Rogers tube was coughed out one week later, February 24, and reinserted to be coughed out again in two days. Marked stridor followed after an hour, and reintubation was required.

Thinking that possibly this stridor was due to weakness of the abductor muscles from prolonged disuse, and hoping that sufficient dilatation had been obtained, I inserted tube 3 to allow the abductors to regain their tone. It seems that when under the same conditions, the laryngeal abductors show a greater tendency to atrophy than the adductors.

March 12, two weeks later, this little tube was removed and intubation was not required again until March 21, nine days later, when I inserted tube 4.

This first attempt to dilate the larynx gradually required sixty-eight days. I had failed the first time, but determined to begin again, and rapidly arrive at the use of larger tubes.

March 26, tube 4 was removed and a 6-7 Rogers tube inserted, to be coughed out in three days. It seemed that Rogers' thick neck tube was not as well retained as the usual one, so that I now used a 6-7 (new scale) O'Dwyer tube, which I left in place for fifty-six days, or until May 23, when I introduced tube 3 to allow the abductors to regain their tone. This tube was removed one week later, June 1, 1904, since which time the child has not experienced any trouble whatsoever. He recovered his voice at once, though for a time he was somewhat hoarse. A tube was worn, in all, 160 out of 187 days.

I think this was a case of subglottic stenosis, due to small cell infiltration and contraction of forming connective tissue, occasioned by the introduction of too large a tube, which the urgency of the case necessitated my using in the beginning.

The first reintubations after recovery from diphtheria were, I think, rendered necessary by edema of the injured mucous membrane within the cricoid, following removal of pressure. It seems reasonable, however, to suppose that the three attacks of dyspnea which occurred in each instance nine days after extubation were due to contraction of organizing exudate rather than to edema. Long continued dilatation probably caused softening and stretching of the newly forming scar tissue and absorption of a great part of the small cell infiltration.

173 West Seventy-third Street.

DERMOID CYSTS OF THE MEDIASTINUM.

BY ROGER S. MORRIS, A.B., M.D.,

OF ANN ARBOR, MICH.;

INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF MICHIGAN.

(Continued from Page 499.)

57. *Warthin.* In the Pathological Museum of the University of Michigan there is a specimen of malignant teratoma of the mediastinum, showing dermoid areas. Dr. Warthin will report this case in full.

In connection with dermoid cysts of the midiastinum the case of Atlas is of interest, though it cannot be included. Joël observed a teratoma on the pulmonary artery within the pericardium. The case of Villard, which is excluded by Pflanz and Ekehorn, is quoted for reasons which will appear later. Christian gives a case mentioned by Hare which is not included in the foregoing list. From the report given by Jones of his patient, it is not apparent that the tumor was a dermoid cyst, as Madelung implies. Fofanow's case possibly should not be given here; from the very brief account of it in the abstract, it seems, nevertheless, to belong in this series. Bird reports a dermoid cyst of the sternum in which a pedicle dipped down at the juncture of the manubrium and gladiolus sterni. The case of Roser, referred to by König, has probably been reported in another form, though careful search for it has been fruitless. Not included in previous reviews are the cases of Foà, Buyvid, König (?), Kraus (history and physical examination), Foucher, Sommer, Fofanow and Predtschenski. Although the number of cases could doubtless be enlarged, still it is believed that reference has been made to nearly all of those reported up to the present time.

Etiology.—The genesis of these growths will not be discussed at length. The subject is gone into in considerable detail by Pflanz, Ekehorn, Christian, Dangschat, and others. The most generally accepted view seems to be that which looks upon dermoids as the result of fetal inclusion. Wilms, in his comprehensive study, reaches the following conclusions: "Dermoid cysts of the head, thoracic cavity, and a part of the cysts in the retroperitoneal and retrorectal tissue arise through misplacement of fetal elements by the invagination of glandular structures, or by the closure of fetal clefts."

Dermoid cysts of the mediastinum are infrequent findings, whereas mediastinal tumors in general are not rarities. Riegel, in 1870, analyzed thirty-six cases which he had collected from the literature: of these five were dermoids. Of two hundred and eighty-eight cases of tumor of the mediastinum, given by Hare in 1889, only ten were dermoid cysts. Harris reports a series of forty-one cases of sarcoma and carcinoma of the mediastinum from St. Barthlomew's Hospital; in de la Camp's seventeen cases there is also none of dermoid. These few references suffice to indicate the infrequency with which dermoid cysts are encountered within the thoracic cavity.

Sex has no apparent influence. Of the fifty-seven cases, the sex is given in forty-eight, showing an equal division, twenty-four males and a like number of females. The age at which dermoid cysts of the mediastinum first begin to produce symptoms is of no little importance in a diagnostic way. On this point, figures are furnished in forty-six cases. Arranged according to decades, we find:

Between 1 and 10 years	4 cases.
Between 11 and 20 years	5 cases.
Between 21 and 30 years	24 cases.
Between 31 and 40 years	6 cases.
Between 41 and 50 years	2 cases.
Between 51 and 60 years	3 cases.
Between 61 and 70 years	1 case.

If we again subdivide the cases falling into the second decade, we find only one between the eleventh and seventeenth years, while the four remaining cases are between the ages of eighteen and twenty. Thus, of the forty-six cases, twenty-eight, or nearly 61 per cent., came to observation between the ages of eighteen and thirty. If we should reckon from the date of onset, a number of the cases which were first observed after thirty would be seen to have shown their first symptoms before this time. The youngest patient, a suckling, is that of Medoci, while Foà's is the oldest, being sixty-one.

Morbid Anatomy.—It may be well to emphasize here what is quite evident from a cursory glance at the cases abstracted above, *i.e.*, that the term "dermoid cyst" is not used in this paper in its strict etymological sense, but is made to include, in addition to simple dermoids, those cysts which are designated epidermoid, as well as the more complex tumors which are often classed with the teratomata; in the latter the *sine qua non* is a cyst having a lining similar to epidermis. In connection with the morbid anatomy of these growths the points which we shall consider are only those which may have direct bearing on the symptomatology, diagnosis, prognosis, complications, and treatment.

Mediastinal dermoids vary considerably in size; the smallest are about as large as a walnut, while frequently they attain dimensions exceeding those of a child's head. Though the majority of them are in the anterior mediastinum, this is by no means always the case; the larger cysts, probably usually originating here, soon pass beyond, or extend the confines of, this small space. The tumors are most often found beneath the upper one-half of the sternum, extending to one side, and in some cases to both sides, of this bone, but always further to one side than to the other, *i.e.*, they are placed asymmetrically. They may be found occupying the pleural sac, between the pericardium and adjacent lung, surrounded by lung tissue, resting between the diaphragm and pleura pulmonalis, or extending through the upper thoracic aperture and producing an external tumor in the lower part of the neck.

Adhesions between the cyst and the neighboring tissues are present practically without exception. The tumors adhere to the pleura most frequently, next to the pericardium, thoracic wall, great vessels, *et cetera*. The esophagus and trachea are seldom involved. The nature of the adhesions is not definitely given in many of the reports; they are not infrequently so firm, however, as to render total extirpation hazardous and, at times, impossible.

The thickness of the cyst wall is variable; in some cases it amounts to only a few millimeters, but it may be much thicker, usually as a result of old inflammation about the tumor. In the wall may be found pieces of bone and cartilage, and occasionally teeth. Bone was met with in thirteen cases (1, 3, 5, 6, 16, 22, 30, 37, 38, 42, 45, 47, 51); in four additional cases (8, 10, 17, 20) the walls were said to be calcified in places—possibly bone. In Gordon's specimen the bone was of considerable size and resembled the superior maxilla. Bits of cartilage were present with bone in eleven cases. Cartilage without bone was found five times. In eight instances teeth—one or more, up to seven—were discovered, bone and cartilage being found also in three cases and cartilage alone once.

In all carefully described specimens the inner lining of the cyst wall resembled skin. The majority presented finger-like or polypoid excrescences. On microscopical examination the correctness of the macroscopial impression is proven, since stratified pavement epithelium having a stratum corneum is found. Beneath this are usually seen hair follicles and sebaceous glands, and at times sweat glands, though always fewer in number than the sebaceous glands. In some cases—the epidermoid cysts—only stratified pavement epithelium is present, glands and hairs, either attached to the surface or free in the cyst contents, being absent. Hairs, when present, are usually more numerous on the polypoid masses.

The contents of the cyst are the result of desquamation of the epithelial cells alone—in the epidermoid cysts, in others (the larger group) there is found, in addition, the secretion of the sebaceous and sudoriferous glands and fallen hairs. Under the microscope, therefore, one may see cells resembling those of the stratum corneum of the epidermis, fat droplets, cholesterin crystals, and hairs. The latter are generally embedded in

the pultaceous contents and may be found singly or in balls or masses of different shape. There is frequently a fluid part in which there are more solid, friable, greasy masses or "coagula." In nearly a half of the cases the cyst has perforated into a bronchus, which is most common, into the lung, externally through the skin, into the pericardium (once), and into the aorta (once), allowing the contents to escape. As much as three liters may be contained in the cyst.

The tumor presents a single cavity most frequently, with a solid portion at times forming a part of it; in five cases the cyst was multilocular. The smaller cysts may be lined with cubical or ciliated epithelium. Sarcoma and carcinoma may develop in the cysts.

Symptomatology.—There is, in a great many cases, a fairly characteristic symptom-complex, as Ekehorn maintains; taken in conjunction with the results of objective examination, the symptomatology may be even more valuable.

Foucher describes a latent period during which the tumor gives no evidence of its existence. As a rule, this continues to the time of puberty, when there is a marked tendency for the first signs or symptoms, referable to a tumor of the mediastinum, to appear, owing to sudden, rapid development which the cyst seems to take on. Exceptions to this rule are seen in the cases of Sormani, von Török, Medoei, von Eiselberg (52), and Madelung (54), where the first symptoms came on in infancy or childhood. Again, there may be no signs of a growth in the mediastinum till long past the age of puberty, and, in women, even of the climateric, as is evidenced by Türk's patient. In fact, the latent stage may be the only one, and the dermoid may be an accidental finding at autopsy, the patient never having had symptoms suggesting this condition; such was the case with Sommer's patient, the symptoms finding a satisfactory explanation in the chronic pulmonary tuberculosis, from which the patient died.

In the great majority of the cases there is, however, an active stage. Its onset is by no means always characteristic; indeed, it is seldom that the condition has been correctly diagnosed early, and this is only possible under certain circumstances. Trauma, or pressure on the thorax, has been given by patients as the starting point of their symptoms occasionally. In Bergman's case the patient attributed his disease to pressure; Madelung's patient developed a pleural effusion following a blow on the chest wall, while in my own case the patient dates his trouble from trauma in the region of the heart. It is not inconceivable that a sharp blow may cause the rupture of a tense cyst. The pneumonia described by my patient was likely an effusion of the contents of the cyst into the pleura, as in Madelung's case. Generally, however, the onset cannot be ascribed to a definite cause. The earliest symptoms vary considerably, and, as stated, are usually those which may accompany many intrathoracic affections.

In thirty-three cases statements are given in regard to the onset. In nine (2, 3, 4, 24, 27, 40, 43, 49, 50) the earliest symptom was dyspnea, usually associated with pain in the chest, at times with cough or a feeling of pressure. The dyspnea is present only on exertion most commonly; it may develop acutely, and occasionally it is paroxysmal and vomiting may occur. Pleural effusion ushered in the disease five times (21, 23, 37, 38, 48), while in Godlee's patient an effusion followed shortly after the appearance of dyspnea and acute pain in the side. In another case (56) an effusion was possibly the first effect of the tumor. Pain has been the first thing noticed by the patient in four instances (13, 34, 35, 37), being referred to the shoulder twice, to the ear and side of the chest once each. In a fifth case cough has been associated with the pain (7). Three times hemoptysis (23—effusion followed, 36, 39) with cough has been the initial symptom. The patients had the symptoms of pulmonary phthisis twice (6, 16), leaving the mode of onset somewhat problematical. Asthma (5), pneumonia (17), abscess (42), and a tumor in the neck (55) have been noted. It is evident, therefore, that there is nothing typical in the mode of onset in dermoid cyst of the mediastinum.

As the disease progresses, the initial symptoms usually become aggravated and are accompanied by other manifestations of intrathoracic disease.

Dyspnea may be urgent at the onset; more commonly, as stated, it is noticed only on exertion, and in the remarkable case of Lebert this was practically the only evidence of the morbid process for more than forty years. It may be paroxysmal, associated with cough, hemotysis, cyanosis, and vomiting; or there may be periods, lasting months, during which the patient suffers from this symptom, followed by marked remissions, in which breathing is normal. In the later stages of the disease difficult breathing is more constant and severe, and it may become so extreme as to cause death.

Pain is a frequent symptom. It is usually acute, seldom dull and aching. In a certain proportion of the reported cases the pain has radiated to the shoulder (11, 12, 13, 24, 34, 35, 53, 56), to the ear (35) and back of the head (13), and down the arms. In one instance (11) paretic symptoms ensued in the affected arm. The arm may feel numb in the absence of pain (55). Often the pain is paroxysmal, and it may vary as the dyspnea does.

There is nothing typical in the cough. It may come on early and usually is not especially troublesome at first. Like the dyspnea, it is not infrequently paroxysmal. The expectoration, however, is of very great importance in some cases and should always be carefully and thoroughly examined. The quantity of the expectorated matter varies greatly; at first it is small in amount, later becoming more copious, so that 500 c.c. in twenty-four hours may be raised. In some

instances large quantities are raised suddenly after rupture of the cyst, such as is seen at times in empyema. The odor of the sputum is often foul; this may appear first after a hemorrhage. The sputum may have its origin from two sources, viz., the bronchial mucous membrane and the cyst. That arising from the former may lead to the suspicion of bronchiectasis, but differs in no way from the sputum which may be obtained from any case of mediastinal tumor; after there has been rupture of the cyst into a bronchus or an open lung cavity, the material which is expectorated becomes of great moment, and microscopical examination may now establish the diagnosis. The finding of epithelial cells resembling those of the horny layer of the skin, fat droplets and cholesterin crystals is highly suggestive of dermoid cyst, while the presence of hairs in the sputum is pathognomonic of this condition. Unfortunately the latter are not expectorated in all cases in which the cyst has perforated into the air passages, even when they are contained in the contents of the tumor. In at least twenty cases there has been a communication between the cyst and the bronchi; in ten instances (2, 6, 9, 13, 24, 27, 38, 45, 46, 56) hairs were expectorated in the sputum. This furnished the means of arriving at the correct diagnosis in seven cases (9, 24, 27, 38, 45, 46, 56). In Cloëtta's patient the attending physician looked upon the hairs as a deception. It is quite possible that in those cases where hairs have been lacking in the sputum, though present in the tumor cavity, their absence may be explained by the fact that they are frequently rolled up into ball-like masses too large to pass through the opening; Ekehorn's case (38), in which "concrements" made up largely of hair, were expectorated, would seem to bear directly on this possibility.

Not infrequently hemoptysis has been noted; it is more often a later occurrence, and may be so severe as to lead to exitus (7, 29, 36, 45, 51). In some cases, on the other hand, there has been a slow but somewhat constant bleeding, so that the sputum is bloody.

In the later stages the patients may have fever, usually remittent, and edema of the ankles with or without ascites; or a terminal infection may cause death.

The course of the disease is variable and has been divided by Dangschat into three main groups. Most frequently there is an insidious onset with gradual, constant increase in the intensity of the symptoms. Less often the onset is similar, followed later by sudden development of severe and often fatal symptoms; or the symptoms may come on suddenly and with great severity in the beginning, the further course of the disease being irregular, periods of remission alternating with exacerbations.

The condition lasts, as a rule, one or more years. Estimating the duration as accurately as possible from the histories, the following data are obtained:

Duration.	Number of Cases.
44 years	1 (4)
24 years	1 (27)
13 years	1 (24)
10+ years	1 (55)
10 years	2 (7, 54)
9 years	2 (53, 56)
6 years	1 (45)
5 years	3 (11, 36, 37)
4 years	3 (21, 31, 34)
3½ years	1 (32)
3 years	3 (16, 42, 43)
2 years	2 (13, 49)
1½ years	1 (1)
1 year	4 (38, 39, 50, 51)
11 months	1 (41)
9 months	1 (3)
2 to 3 months	1 (12)

The disease is, therefore, essentially chronic in its course. In Mandlebaum's case (41) the patient died of toxemia following pneumonia, which came on after operation. Virchow's patient (2-3 months) had malignant disease; in the somewhat similar case of Kraus and Jores (32) the history and duration suggest the possibility that the sarcomatous tissue found at autopsy developed late. Besides the cases tabulated above, the disease is reported to have lasted several years in three instances (22, 35, 40). A history of chronic pulmonary tuberculosis is given twice (6, 44).

Physical Signs.—The patient is usually well nourished and shows no signs of cachexia. The pupils are equal, the radial pulses alike and synchronous. There is an absence of edema of the arms and the superficial veins are not distended. The larynx is negative.

Inspection.—In a few cases a tumor, which may extend below the clavicles, has appeared in the neck (1, 11, 13, 35, 53, 55); fluctuation has been present, and at times a pulsation, never described as expansile. The tumor may be bilateral. More often there has been observed a fulness or bulging of one side of the chest, usually anteriorly. Such a condition has been found thirteen times (3, 21, 24, 32, 34, 41, 42, 43, 48, 49, 50, 51, 56). This is situated generally between the second and sixth ribs in front and may involve the sternum. The bulging may be found low down posteriorly, as in von Török's patient. The important thing in connection with the fulness or bulging, as shown by others, is its chronicity, its persistence for months or years. It remains, at times, after recovery from effusion into the pleural cavity. Inspection may also reveal diminished or absent expansion over the prominence.

Palpation.—The alteration in the expansion is confirmed by palpation. In addition, there has been a decrease or entire absence of tactile fremitus over the prominent or dull areas in the few instances (12, 32, 34, 37, 48, 49, 56) where it has been noted.

Percussion.—This shows an abnormal area of dulness on the thorax, corresponding to the ful-

ness or prominence, where such exists. Most commonly the dulness is absolute, due to the proximity of the tumor to the chest wall, with the consequent crowding out of the lung tissue. In nearly one-fourth of the cases, and the proportion is much greater if we reckon only those in which results of physical examination are given, the area of dulness suggests encapsulated pleuritic exudate, especially when the other signs obtained on palpation and auscultation are taken into account. The figures illustrate this point. The dulness begins high up in front, extending downward to the lower lung border. The upper border of the dull region, beginning above and in front, inclines outward, downward and backward, a fact alluded to by Dangschat, so that we obtain an area not unlike the usual one in pleurisy with effusion, except that it is reversed and has not a Damoiseau's curve. In one case (56) there was relative dulness over this region. Again a small area of dulness may be found anteriorly, or there may be a dull region in front separated from a similar one behind by resonance (49). In one instance (45) the dull area decreased in size after coughing, which led to the expectoration of a large amount of sputum. A point worthy of consideration is the fact that Traube's space may remain clear. In the case of a left-sided area of dulness, this speaks for an extrapleural cause.

Auscultation.—Over the dull area absence of all breath sounds is the rule. Where relative dulness exists, there may be weakened vesicular or bronchial breathing, the latter being the result of compression generally. Râles, moist and dry, are commonly found and are not necessarily confined to one side. In my case they were fairly well limited to a portion of the left upper lobe; since there was definite evidence of a communication between the cyst and the bronchial tree, the inference was natural that the râles might be attributable either to bronchitis resulting from irritation by the contents of the cyst or to the latter alone or to both. One should expect to find the ausculted spoken voice diminished and the whispered voice absent over the affected region of the chest. The possibility of obtaining signs of open cavity, due to emptying of a perforated cyst, should be kept in mind.

Roentgen-ray examination.—On examination with the fluroscope a diffuse shadow is cast by the tumor (56). Radiographs taken in one of Madelung's cases and in Türk's patient brought out nothing in addition to the findings obtained by the ordinary methods. In tumors containing bone and teeth it may be possible to demonstrate such structures in a good negative. The positive identification of teeth would lead one a long way toward the diagnosis; the finding of bone, while less typical, perhaps, would nevertheless be of no little diagnostic value.

Heart.—The apex may be dislocated as the result of pressure, and, in the case of a tumor occupying chiefly the left side, it has been found in the right nipple line. In the case of Cordes signs of pericardial effusion were due to the communication existing between the cyst and the pericardium. A systolic murmur may be present at the base, and one should look for accentuation of the second pulmonic sound.

The liver may be pushed downward when the tumor is on the right side, so that its lower edge may be felt one to three finger-breadths below the costal margin.

Complications and Intercurrent Infections.—Pneumonia, either croupous or lobular, has occurred eight times. It was met with early in the patients of Gordon and Marchand, and in Foà's case was the cause of death. Perforation of the cyst has already been referred to. Pulmonary tuberculosis was present in six instances. Malignant disease has developed in five cases, sarcoma being found in all, carcinoma with sarcoma in two (Virchow, Warthin).

Prognosis.—Without operation the outlook is extremely grave. The patients do not live more than a few years at the most after the condition is recognized, and, unfortunately, die frequently before the diagnosis has been made. With operative treatment the mortality has been reduced from 100 per cent. to about 30 per cent.

Diagnosis.—When expectoration of hairs occurs, the diagnosis offers no difficulties. Without this symptom, a positive diagnosis can still be made. The sputum may be characteristic, as shown above. More promising and more likely to yield valuable results is exploratory puncture. This has been carried out in a few instances. It is made into the dull area, a long needle of wide lumen being essential; a trocar, attached to a proper aspirating apparatus, would seem to be even better suited to the purpose. Repeated exploration may be necessary before puncturing the cyst or obtaining the contents. The brilliant results attained by this procedure are illustrated by the cases of Kückman and Türk. Where a fluctuating tumor exists, aneurism having been excluded, here, too, exploratory puncture is preferable, because safer. The radiograph may be of very great service. The entire picture of the disease must, of course, be taken into account. Of scientific interest, but possessing little real value from a diagnostic or therapeutic standpoint, would be the examination of the cyst contents obtained by aspiration for the "Cetylalkohol" of Sotnitschewsky and von Zeyneck, the "Acetonkörper" of Linser.

Malignant tumor of the mediastinum may offer considerable difficulty in differentiation. Dermoid cyst of the mediastinum usually appears under thirty years, malignant disease after this age. The duration of the latter is two to eleven months, usually six months, according to Feldman and others. Cachexia is rare with dermoid cyst. Pressure signs, such as edema, cyanosis, distention of superficial veins, inequality of the pupils, and laryngeal changes, which are so common in sarcoma and carcinoma, are not found in connection with mediastinal dermoid. That the signs

enumerated may occur with dermoid cyst is shown by the patients of Virchow, Pinders, Kraus and Jores, and Fofanow (?), but their significance is lost when we realize that sarcomatous or carcinomatous changes or both had occurred in each of these cases. The finding of secondary growths is, of course, of importance.

Aneurism usually occurs later in life than dermoid cyst. Etiological factors are of value. There is an absence of expansile pulsation. Pressure signs are wanting. The presence of a diastolic shock with accentuated second sound over an abnormal area of dulness makes the probability of aneurism strong, as Osler remarks. In Büchner's case aneurism could not be excluded.

Hydatid disease, especially when situated in the pleura, may parallel the symptoms and physical signs of certain cases of dermoid of the mediastinum very closely. If the sputum is negative, aspiration is the only certain way of arriving at a diagnosis, as the fluid in each disease is characteristic. More rarely hydatid cyst is found in the mediastinum; the resemblance to dermoid cyst may be considerable, as in Rose's patient.

The differential diagnosis between abscess of the mediastinum and dermoid cyst is seldom difficult. As Wilson pointed out, one of the most important distinguishing features may be the febrile reaction of the former. Some of the commoner etiological factors in abscess have also been present in mediastinal dermoid. The duration in abscess is generally shorter. Exploratory puncture is again the surest procedure. Where abscess and dermoid cyst coexist, as in von Török's case, operation alone may reveal the latter.

Other benign tumors, such as lipomata and fibromata, may best be differentiated from dermoid cyst by X-ray examination, exploratory puncture and sputum examination, together with the points to be obtained from the history.

In cases where pulmonary tuberculosis is found with a small dermoid cyst, the presence of the latter may never be suspected. Hemothorax should be easily differentiated, as a rule. Pulsating gangrene of the lung, a case of which has recently been reported by Steven, should cause no difficulty.

Encapsulated pleurisy with effusion, for which dermoid cyst has frequently been mistaken, can be excluded in many instances only by examination of the aspirated fluid. The same holds good in the case of empyema.

In a radiograph, lung calculi might suggest the possibility of bone, leading to a suspicion of dermoid. The occurrence of cough, dyspnea and hemoptysis, as in Stern's cases, may make the condition still more misleading. However, characteristic pulmonary calculi have not been found in connection with dermoid cysts, and there is the absence of suggestive findings on objective examination; no circumscribed mass is found, as a rule, in the Roentgen ray examination. The latter point would also help to exclude the rare condition described by Förster, Luschka, Pollack and others, in which bone is found in the lung; the shape of the bone, if large enough to be seen in a radiograph, with the negative history and physical signs, would rule out dermoid.

"Flimmercysten," resulting from the original communication between the esophagus and trachea, are rare findings at autopsy (Westenryk) and need not be considered here.

Treatment.—The only hope of recovery lies in operative treatment. In twenty of the cases given above (11, 13, 18, 24, 29, 31, 34, 35, 39, 40, 41, 42, 43, 48, 49, 50, 51, 53, 54, 55) operation has been performed; of these fourteen, or 70 per cent, survived the operation and were either entirely cured or making satisfactory recoveries. In view of the fact that death is practically certain to follow in a few years, at the most, after the disease has progressed sufficiently to render the diagnosis possible, the indication for operative intervention is clear.

In case there is an external tumor in the neck which communicates with, or is a part of, the cyst, operation may be safe and effective. Pöhn's case is the first of this kind operated upon; in Kückman's patient permanent cure resulted. Where the tumor is adherent to the chest wall, the danger from the operation is also small. It is in those patients where pneumothorax must be produced that the greatest difficulties may arise; these may be overcome in part, at least, by the use of the Sauerbruch cabinet or some similar device.

In most instances the treatment has consisted in evacuation and drainage of the cyst, after resection of part of one or more ribs. It has seldom been possible to make a total extirpation of the tumor, chiefly on account of the adhesions; in some cases the external skin has been sutured to that lining the cyst. A marked contraction of the cyst usually follows in the course of a few months, leaving only a small fistula.

In view of the constant and prolonged bronchitis which is present in many cases of dermoid cyst of the mediastinum, chloroform would seem to be preferable to ether, other things being equal, if resort be had to general anesthesia, as has usually been the case.

THE DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF INCIPIENT PULMONARY TUBERCULOSIS.[1]

BY HENRY FARNUM STOLL, M.D.,
OF HARTFORD, CONN.

It is largely due to the perfection of our diagnostic acumen that the science of medicine occupies its present exalted position. Thousands of lives are saved to-day that would have been lost but a few years ago, because more attention is now paid to the observation of the symptoms that beset the early hours of disease. The day is past for waiting for the development of the so-called "typical pictures" before we hazard a diagnosis. Frequent operations for appendicitis have demonstrated how vague and few the symptoms may be at times, and yet how serious the pathological condition present. A physician is scarcely more justified in waiting until his patient has become greatly emaciated and has evidences of beginning softening in his lungs before diagnosing tuberculosis, than he would be in waiting until a huge tumor formed over McBurney's point, or a general peritonitis had ensued, before diagnosing appendicitis.

What then is the minimum of probability upon which a diagnosis of tuberculosis can be made? One cannot condemn too strongly the remark made not infrequently by physicians as well as laymen, that so-and-so "doesn't look as if he had tuberculosis." I doubt not that tuberculosis is frequently excluded, solely because the patient does not have the facies described by Aretæus the Cappadocian, 50 B.C.: "Voice hoarse, neck slightly bent . . . nose sharp and slender . . . cheek bones prominent and red; eyes hollow, brilliant and glittering; swollen, pale or livid in the countenance . . . the slender part of the jaws rest on the teeth as if smiling; otherwise a cadaverous aspect."

Inasmuch as the diagnosis has to be made at times from the clinical history alone, it is of the utmost importance that this history be very complete. Unless questioned with care, the patient will forget much valuable data, and events of importance will not be mentioned because deemed of no moment by the patient. For instance, it is not enough to learn that some member of the family had tuberculosis, for our patient may not have been home for years, but if we ascertain that he was with the sick one and administered to his wants, then the probability is stronger that he contracted the disease.

Your patient rarely consults you because he thinks he has tuberculosis. As a matter of fact nothing is further from his mind. He may have a cough that has persisted in spite of medication, or he may have been losing weight and ambition; possibly he seeks relief from a disordered stomach. At another time a sudden hemorrhage will be the exciting cause for medical council. Again, a pleurisy will be complained of, or he may have an ischiorectal abscess. One or more of the above symptoms should suggest the possibility of tuberculosis, especially if occurring in one who has recently made a decided change in his manner of life, as occurs when one leaves the high school or college, where much time is spent out of doors, and engages in a confining business. Such a change may be sufficient to lower his natural resistance so that an active process may light up from organisms that have been dormant for a considerable period of time.

When a cough is present it is usually more marked in the morning and at the time at least, may be accompanied by some expectoration. The coughing spells are often of such severity that a considerable degree of nausea is caused and not infrequently they are followed by vomiting. *Paroxysms of coughing that are followed by vomiting are pretty apt to be either whooping-cough or pulmonary tuberculosis.* The considerate patient will many times quiet any misgivings you may have, by telling you that it is a "stomach cough," or a "bronchial catarrh," and that the expectorated material does not come from the lungs but from the back of the nose. Likewise we are assured that, though he may have had a few "hemorrhages from the throat," he has never had any from the lungs. Often the hemorrhage

[1] Read before the Medical Section of the Hartford Medical Society, April 10, 1905.

will come on during sleep or while perfectly quiet. Some afternoon temperature, a rapid pulse and night-sweats complete the usual picture. In one extreme class of cases we have the general symptoms slight and the local signs absent or very few. I recall a young woman who complained of pain in her right shoulder. Questioning developed that she had been "running down," as she expressed it, for some time and had a slight morning cough. Chief, however, was the shoulder pain which she attributed to sweeping, as it was worse at that time. Her right apex showed signs of involvement and her sputum contained tubercle bacilli.

The second rare type is to have the local signs marked and the constitutional symptoms few. This class is most common in big, strong men who eat and sleep well and have no symptoms aside from an occasional hemorrhage. The common type has both local signs and general symptoms. The earliest signs commonly met with are slight dulness, the absence of the normal vesicular murmur—a prolonged expiration—with or without râles.

The dulness may not be demonstrable except as the clavicles are percussed directly, and it is often not appreciated until one percusses at the end of a deep inspiration. Concerning the character of the respiratory murmur in the early stage there is not an absolute uniformity of opinion, though I believe the majority of observers consider that the harsh, wavy respirations precede the period of diminution of breath sounds. As the tactile fremitus and voice conduction are normally more marked on the right, we examine the left apex with great care if we find them equal on both sides, and when they are more marked at the left apex the presumption is stronger that the apex is involved.

The most common râle in the early stage is the crepitant, usually present at the end of a deep inspiration, though often not heard until the patient coughs; at other times a mucous click occurring at or near the end of inspiration is the first sign. Inasmuch as the most common site for the tuberculous deposit is from an inch to an inch and a half below the apex and slightly nearer the posterior than the anterior surface, we must examine the supraspinous fossæ with care, as the first signs are frequently observed there. If the hair on the chest and back is thick and long it will be necessary to shave the parts before the examination can be satisfactory. When examining a patient recumbent in bed one should always observe the signs present when lying on the right and left sides respectively, for not only will the note on percussion be found to vary with the change of position, but friction râles heard on the side nearest the bed will often disappear when that side is uppermost.

It is high up in the axilla, a part of the chest difficult of examination and often neglected, that one may detect the first abnormality. With the elbow but slightly abducted from the side this region can be satisfactorily auscultated with a Bowles' stethoscope. As an afternoon rise of temperature and a persistently rapid pulse may precede the signs in the lungs by a considerable period of time, we should be on the alert to detect them, especially in those whose family or business relation necessitate intimate relationship with the tuberculous.

The excursion of the diaphragm is diminished on the side of the lesion and may be demonstrated by Litten's sign, or by means of fluoroscope. Loomis has found the estimation of the corpulence, the thoracic perimeter, and the vital capacity to be of value in obscure cases. The corpulence is determined by dividing the weight in pounds by the height in inches, twenty-six being the normal for man and twenty-three for woman. The thoracic perimeter is the average of the inspiratory and expiratory chest measurements and should not be less than one-half the height. The vital capacity, determined by the spirometer, when normal, will be three cubic inches of air for each inch in height in the male and two cubic inches for the female. A departure from the normal in two or all of the above is quite suggestive of tuberculosis.

Differential Diagnosis.—In considering the differential diagnosis one first thinks of *malaria,* that haven where the ship of diagnostic doubt so often seeks refuge. In the first place malaria is an uncommon disease with us. I can recall only three or four cases that were admitted to the Hartford Hospital during the two years I was on the house staff. In the second place it has a definite symptomatology, can be diagnosed by finding the plasmodium in the blood, and promptly cured by quinine. Everything from flatfoot to otitis media has been called malaria, but I think that those who suffer most are the cases of incipient tuberculosis.

Nor should we overlook the fact that both diseases may be present at the same time. I should like to mention a case that came to the tuberculosis clinic the other day. The patient was fifteen years old and his mother said that several years ago he had had "typhoid malaria" and at that time had a high fever in the afternoon and a cough. I am not quite sure just what the nature of this particular disease is, but that it is a dire malady I am sure, as he has failed steadily since then, his cough has increased and at present the whole of the right lung is consolidated with beginning cavitation in the lower lobe.

Chlorosis.—Labbé[2] does not consider chlorosis as a disease *per se,* but as one manifestation of some other affection, more commonly tuberculosis, nephritis, syphilis, or some gastric disturbance. When no other cause can be determined he finds it is almost invariably the first manifestation of latent tuberculosis. Klebs, Jr., obtained a tuberculin reaction in a number of cases of chlorosis and Knopf mentions this fact as demonstrating the unreliability of tuberculin.

Haplin, on the other hand, reported a few years ago forty cases of true chlorosis occurring in tuberculous families, only two of which developed tuberculosis.

Notwithstanding the above, it is pretty generally believed the world over that chlorosis is a disease of itself, and that though at times associated with tuberculosis, even as Hodgkin's disease may be, it is nevertheless no more dependent upon the tubercle bacillus than is lymphadenoma.

In chlorosis the skin and mucous membranes are usually distinctly pale, but it should be remembered that persons may look pale with a normal condition of the blood, and may look of good color, although they are really anemic. It is for this reason that the actual estimation of the hemoglobin is of so much consequence. Many cases of tuberculosis look much more anemic than they really are. So similar is the symptomatology of these two diseases that we cannot make a positive diagnosis from that alone. If our patient has been losing weight and has a misshapen chest with poor expansion, it is very suggestive of tuberculosis. A blood examination and the prompt improvement in all symptoms following the ingestion of liberal amounts of iron, will, as a rule, stamp the case as chlorosis. When still in doubt, the tuberculin test, of which I will speak later, may be used.

Uncompensated Mitral Lesions, particularly stenosis, are sometimes mistaken for tuberculosis. The history of cough with occasional blood-streaked sputum, dyspnea on exertion, and the detection of a harsh respiratory murmur and moist râles may easily confuse one, especially as the murmur of mitral stenosis is faint or absent when compensation is broken. Yet the sharp ringing character of the first sound at the apex, the accentuation of the pulmonic second, the enlargement of the right ventricle, and the appearance of the murmur and improvement in symptoms following treatment will, as a rule, enable one to distinguish between the two.

Bronchitis.—In taking the histories of tuberculous cases one cannot be other than much impressed by the number who assert that their illness dates from a hard cold or an attack of grip. Thus, in thirty-four histories, I took at the Cedar Mountain Sanatorium, eighteen so described the onset. As bronchitis is such a common disease it behooves us to determine, if possible which cases are tuberculous and which are not. We should regard with suspicion all cases which do not recover after a few weeks, especially if there be associated with the cough, some loss of weight, sweats or other symptoms common to consumption; and in adults, a unilateral bronchitis is regularly tuberculous. Only frequent, careful examinations will enable us to appreciate the true condition. And I might say that one can no more make a thorough examination unless the body is nude from the waist up, than he can deliver a woman under a sheet. In view of the fact that a bronchitis often marks the invasion of a tuberculous process, we should never lose sight of our cases until the bronchitis has subsided.

Pleurisy.—All pleurisies, save those accompanying an acute pneumonia, are regarded by many as being tuberculous. While this is perhaps too radical a view, yet one is impressed with the frequency with which he encounters this symptom as having occurred during the early days of the disease. I can remember Dr. Delafield saying, "Whenever a patient has the ordinary symptoms of a dry pleurisy, and after ten days, with a clear tongue, a fair appetite and no great feeling of illness, there is a regular rise of temperature every afternoon, it is probable that the pleurisy marks the invasion of a miliary tuberculosis of the lungs."

At any rate, I think, we should state fairly to our patients the possibility of its being tuberculous, and see to it that their physical condition is kept as near perfection as is possible.

Recently a very simple method has been devised for ascertaining the etiology of serous effusions in the pleural cavities. Without going into the history of cytodiagnosis I will briefly state the conclusions: Effusions accompanying an acute pneumonia have a high specific gravity, a large amount of albumin and a high percentage of polynuclear leucocytes. Transudates occurring in heart and kidney disease, have a low specific gravity, a small amount of albumin and fibrin and a high precentage of lymphocytes.

Tuberculous effusions have a relatively high gravity, a large amount of albumin—boiling solid usually—considerable fibrin and a predominance of lymphocytes. As, however, the acuteness or chronicity of the inflammatory process appears to determine the predominance of the polynuclear leucocytes or the lymphocytes respectively, we may find that the polynuclears are in excess during the first few days, if the pleurisy be a very acute one.

Opportunity was afforded me to verify the above while resident house physician at the Hartford Hospital. In all, sixteen examinations were made, and of that number six were transudates occurring as the result of cardionephritic disease, and the remainder were considered tuberculous. These cases will be reported in detail later.

Acute tuberculous pneumonia, having, as it does, an onset identical with the pneumococcus pneumonia, is rarely diagnosed at first. During the early days the patient is apt to cough up considerable blood and very often, on about the third or fourth day, the sputum will become bright green in color. There is an absence of crisis, the pulse is more rapid, the sweating more marked and the emaciation more extreme than in the pneumococcus infection. If now the sputum be examined, elastic tissue and tubercle bacilli may be found. "Even then," Dr. Osler[3] says, "if you are old-fashioned enough you may say, 'Oh,

well! pneumonia sometimes does end that way.'" To add to our confusion, we will find that the acute tuberculous pneumonias often have a high leucocyte count, one of Osler's cases having 74,000 (*op. cit.*).

Another important and valuable aid to the diagnosis of obscure cases is tuberculin, which is now quite universally used by the phthisiotherapists in this country and Europe. I have employed it in a number of cases at the Hartford Hospital and found it valuable in demonstrating the tuberculous origin of suspected cases of "idiopathic pleurisy" and "unresolving pneumonia." In no case was there any indication of the slightest harm, and in two cases a note was made a few days later that the signs in the lung showing improvement.

A letter I received recently from Dr. V. Y. Bowditch expresses so well the views of a conservative yet progressive man that I will quote part of it: "When its use diagnostically was advocated so freely I hesitated for a long time before I could overcome the repugnance, foolish, perhaps, to its use. Yielding to the opinion of men in whose judgment I felt implicit trust, I began cautiously to use it in very obscure cases, feeling that by not doing so I was holding too conservative a position, perhaps, and thereby not giving the patients the benefit of a doubt that might exist. In the last two years I have used it in a considerable number of doubtful cases at both sanatoria, and although I do not consider it to be an infallible diagnostic agent, I do think it to be of service in certain cases, and I can honestly say that I have never seen the slightest harm come of it."

Dr. E. R. Baldwin, in a letter relative to its uses, said: "In short, tuberculin is not needed in most cases for diagnosis, but when needed is of the utmost value if a positive result from a small dose it obtained," and in a former article[4] he stated that "the latent tuberculosis in a person in apparent good health, that will not react to tuberculin, should cause no anxiety."

So firmly is the belief fixed in some lay minds, that consumption can only exist when the emaciation is extreme and the cough incessant, that nothing short of a tuberculin reaction will convince these "doubting Thomases" that tuberculosis is present.

In 1898 Ambler likened the diagnostic use of tuberculin to "hunting for a gas leak with a lighted candle." He now says, "I do not hesitate to use tuberculin at present; we have learned how to make our lamp a safety lamp." Moreover Trudeau, Ambler, Bowditch and others are not only using tuberculin for diagnosis but therapeutically as well.

You have doubtless observed that thus far I have made but scant mention of sputum examination. I am firmly convinced that there is a tendency to-day for the clinician to shift the responsibility of a diagnosis from his shoulders to that of the bacteriologist and the pathologist. Moreover, I believe there are a large number of physicians who will exclude tuberculosis because of two, or possibly three, negative examinations of the sputum, even though the clinical evidence is in favor of it. In the earliest stage the formula of miliary tubercles is the predominating feature and during that period the bacilli will be absent from the sputum, or very few in number. Again, in some chronic cases, the germs may be absent for considerable periods of time. In one of Osler's series of acute pneumonia tuberculosis, the tubercle bacilli were not found until the twentieth examination, made on the thirtieth day of the disease. The search for the organisms should be made on several successive days, at frequent intervals, but a negative examination should not outweigh a positive clinical picture.

And what would happen if we made a mistake and told a patient that he probably had tuberculosis if he really did not have it? The treatment to-day for tuberculosis is unfortunately not a specific one. The best we can do is to improve the general condition in every possible way and experience has demonstrated that fresh air, rest, and good food will best accomplish this end.

Now, the patient whose disease is incorrectly diagnosed as tuberculosis, is at least tired out and run down, and I know of no better way for him to regain his health than by rest, fresh air and good food. He may be able to accomplish this at home; well and good. If you send him to a well-managed sanitarium where incipient cases of tuberculosis are treated, even better; for not only will he receive the benefits that accrue from the regular life and constant medical supervision, but he will be less liable to contract tuberculosis there than he would be on any of our business streets on a windy day, or when the ever-faithful street cleaner is scattering the dry dust to the four winds.

Laymen can build hospitals for the treatment of consumption, laymen can educate the masses by distribution of literature, and laymen can improve the sanitary conditions of our poor. But it is the general practitioner who must recognize the disease when it is just beginning. Many hopes and ambitions are blighted, and many lives sacrificed each year because the disease is masquerading under another name during those precious moments when a cure is possible. We must be continually on the *qui vive*, and strive to recognize the disease from its approaching shadow.

By familiarizing ourselves with nature's first signals of distress, we can ofttimes turn to a happy ending what would otherwise have been a sad catastrophe.

ROD AUSCULTATION.

BY ED. REICHMANN, M.D.,
OF BERLIN, GERMANY;
PHYSICIAN-IN-CHIEF, INTERNAL DEPARTMENT, ST. MARIEN KRANKENHAUS.

The *Post-Graduate*, in its number of February, 1904, contained a report on my method of "Rod Auscultation" which now, after it has been more extensively tried, I desire to supplement with some additional data, since acquired.

As is well known, to practise the method a small rod (as is here shown) is applied firmly to

the surface of the body, vertically to the latter, and the top of the middle finger passed with moderate force over the rod while the latter is steadied with the thumb and index finger. This friction produces, in the rod, vibrations, sound waves, which, in accordance with well-known physical laws, are transmitted in every direction. Hence they pass also upon the surface of the body, and, if sufficiently strong, into the subjacent organs from which they are again transmitted in every direction. If then a stethoscope be placed near the rod we can, with the ear applied thereto, hear these sound waves, and we note a sound of a peculiarly grating character, resembling somewhat the noise produced when a finger is passed over silk or similar material. If the skin is soft and not tense, the sound waves can pass through the same for only a very short distance, and likewise they cannot go very far in the loose subcutaneous tissue. If they encounter an underlying contracted muscle, or, for instance, a rib, they will naturally be transmitted into the same, and, according to its course, continue in it, becoming audible nearly over the full extent of this muscle or of this rib, provided that both stethoscope and rod are placed over the same structure; an internal organ will, therefore, under these conditions, not be able to influence the audibility of the sound waves. But the conditions are different if a muscle or a rib does not intervene between the internal organ and the stethoscope and rod, or if either the stethoscope or the rod is applied so as to avoid a muscle or a rib. In this case then it is impossible for the sound waves to be transmitted through the latter from the rod to the stethoscope, and the examination of the internal organ is no longer disturbed thereby. We shall then, since the sound waves are transmitted in every direction in this internal organ, hear the sound produced by them as long as stethoscope and rod are over this organ, and cease to hear them when one or the other has left the organ; this for the reason that the waves being reflected at the boundary of the organ, at the serous covering, are thus prevented, or nearly so, from passing to an adjacent organ; hence, the sound that is heard becomes more dull and now resembles the noise produced by a finger passing over rubber or similar substances. (The difference in the sound is due principally to the absence of the high upper notes, which, as is well known, produce the above-mentioned grating noise and which are reflected most at the boundary of the organ.) To make still more certain it is best, every time we believe that we have found the boundary of the organ, to make a second examination by applying the stethoscope at another point, the rod, as before, being moved toward the boundary and the above described change of the sound listened for. If with both examinations the boundary is found to be at the same point, the result is bound to be correct.

The details as to the physical proof, etc., may be found in my previous articles on this subject.[1]

The density of the examined organ, the amount of air contained in the same, etc., cannot materially affect the examination, since the latter depends merely upon the transmission of the sound waves through a single organ; on the other hand, organs containing the same amount of air, and which therefore cannot be differentiated by ordinary percussion, can positively be distinguished from each other by rod examination, as explained by me in former papers.

Small organs are but little suited for rod auscultation, as transmission through the skin and the surface of the body is most likely to interfere with the examination. The heart also cannot, in most instances, be delimited with sufficient exactness by this method. This is more especially true of the right and left boundaries of the heart because transmission through the ribs too often plays a disturbing part and vitiates the findings. The upper and the lower boundaries are more readily determined.

It is much easier to examine the lungs, and I succeeded especially, as I have shown in the *Berliner Klinik*, Heft 181, in determining the position and extent of the apices with an accuracy impossible with any other method (except the Roentgen rays). I was enabled by this method to show that the statements of the textbooks on Internal Medicine with reference to the extent of the pulmonary apices are incorrect, that they are situated much more inward and do not by any means extend as far upward as has always been assumed by clinicians. I found the results of my examination to agree with the statements of the works on Anatomy and with my own investigations at autopsies.

By means of rod auscultation it is possible also to differentiate the individual lobes of the lungs provided they do not coalesce with one another.

It is equally possible to determine the boundaries of the liver readily and accurately if the abdominal muscles are not tense, and especially when that organ is somewhat hard—hard and

1 Zur Grössenbestimmung innerer Organe. Deutsch. med. Wochenschrift, No. 46, 1901; Weitere Mittheilungen über die Grössenbestimmung innerer Organe durch die Stäbchenauskultation. *Ibid.*, No. 20, 1902. Berliner Klinik, No. 181.

firm organs being better conductors than flaccid and soft ones.

The method is of special value in cases where the diagnosis is somewhat in doubt and where it becomes a matter of importance to clear this up, as, for instance, whether an abdominal tumor that has been definitely made out has its origin in the liver or is merely situated in its vicinity—a point that cannot always be determned by palpation and percussion. The change of the friction sound in this case is bound to occur very distinctly between liver and tumor if the tumor does not coalesce with the liver; the change will not take place if it does so coalesce, the sound waves in the latter instance encountering no obstacle from which they are reflected.

If the above described physical principles of rod auscultation are always borne in mind, if the above-named causes of error are taken into consideraton, and if, on the other hand, no more is expected of this method than it is able to accomplish, then, I am certain, it will be welcomed as a further and important complement to our present methods of examination.

MEDICAL PROGRESS.

SURGERY.

Laparotomy in Peritoneal Tuberculosis.—That laparotomy often cures tuberculosis of the peritoneum is undoubted, but the experience of D. GOESCHEL (*Deutsch. Arch. f. klin. Med.*, Vol. 84, Nos. 1 to 4) is not as favorable as that of most other authors, for in a series of 19 cases, only 16 per cent. were perfectly cured after three years. Not all cases are suitable for operation or require it. Thus, in children, as high as 33 per cent. recover spontaneously. The best results are always seen in the exudative type, while the adhesive type and the form running with tumor-formation are benefited only slightly. Where suppuration and ulceration accompany the disease, a laparotomy will often do more harm than good. The same applies to cases where other foci are already present in the body. Tuberculosis of the intestinal mucous membrane is a particularly severe complication. In very early cases, which run an acute course with rapidly increasing ascites, the sooner the operation is performed, the better. Simple puncture is rarely sufficient, since the fluid will rapidly reaccumulate. The author never employed iodoform and never resected tuberculous structures, except occasionally the appendix. The wound was generally closed entirely, except where pus was found, when a small strip of gauze was regularly introduced into the lower angle. During the after-treatment, the patients were kept in the open air if the weather permitted.

Report of Operations Performed at the Public Clinic for Students at the German Hospital During the Session of 1904 and 1905.— J. B. DEAVER (*N. Y. Med. Jour. and Phila. Med. Jour.*, July, 1905) reports the series of operations performed at the clinic for students at the German Hospital during the session 1904-1905; 23 clinics were given, during which 182 operations were performed with a mortality of five deaths. The deaths were from acute appendicitis, 1; cholelithiasis, 1; biliary cirrhosis, 1; strangulated inguinal hernia, 1; removal of prostate, 1. The author lays great stress upon the proper teaching of pathological anatomy at the operating table, so far as is possible, rather than at the post-mortem table.

Popliteal Aneurism, its Surgical Treatment.—H. M. TAYLOR (*N. Y. Med. Jour. and Phila. Med. Jour.*, July, 1905), in a consideration on this subject emphasizes two points which he considers very weighty. They are: (*a*) In traumatic and in sacculated aneurisms we can and should preserve the lumen of the parent artery. (*b*) In fusiform aneurisms we should arrest the circulation through the sac, and obliterate its cavity without disturbing the outside adhesion of the sac. In both innovations we lessen the danger of calling upon the collateral circulation too suddenly. In the treatment of sacculated aneurism the statistics of Dr. Ramshoff show the advantages of the revived Antyllus operation. They are mortality-proximal ligation 18 per cent., extirpation 11 per cent.; gangrene-proximal ligation 8 per cent., extirpation 3 per cent.

Fractures and Dislocations of the Ulna.—J. SHERMAN WIGHT (*Am. Med.*, July 8 and 15, 1905) treats this subject in a systematic manner. There are (1) fracture of the styloid process; (2) fracture of the shaft of the ulna; (3) fracture of the olecranon; (4) fracture of the coronoid process. The dynamic relations are fully treated and the mechanism of the injuries explained in detail. The results are explained in the clinical reports illustrating the different fractures. Thus the author gives a basis from which to determine the nature of an old fracture to the ulna. The patient suffers pain in the joint; this is sometimes severe. The power of flexion is generally lost, although in some instances there is good command over the motions of the forearm, mostly for the reason that some of the fibers of the tendon of the triceps remain attached to the upper end of the lower fragment. The patient has a sense of insecurity in his injured limb, which may be best explained by saying that the coordinate action of the elbow-joint has been impaired or lost. This impairment is different in different persons. It would appear as if the coordinate circle of the joint function had been more or less broken into; this circle is made up of bone, nerve and muscle. Therefore there should be no difficulty in understanding the disability which follows the break in the correlated bone. It would seem to be nearly impossible for the ulna to be dislocated by the application of violence to its lower end, unless we take into account those cases in which there has been a fracture of the external condyle; in such a case the ulna is dislocated backward, and is accompanied by the head of the radius and the broken off external condyle.

Antitetanic Serum in Gunshot Wounds.—The results obtained in the treatment of gunshot wounds by the prophylactic use of antitetanic serum combined with early surgical measures is recorded by H. J. SCHERCK (*St. Louis Med. Review*, July 29, 1905). The cases occurred as a result of the Fourth-of-July celebration in St. Louis, Mo. Seventy-eight cases in all were treated, and none developed tetanus. The method of treatment was as follows: The wound was freely incised, all foreign particles thoroughly removed, and the wound cauterized with 25 per cent. carbolic acid and loosely packed with gauze saturated in a 5 per cent. solution of carbolic acid. An immunizing dose (10 c.c.) of antitetanic serum was then injected into the cellular tissues of the abdominal wall. The cases were then carefully watched until all danger of tetanus had passed.

Gall-Stones in the Common Duct.—W. D. HAGGARD (*Journal A. M. A.*, August 12, 1905) holds that

there should be a more general early recognition of gall-stone disease before complications and common-duct obstruction occur. In the invasion of the common duct by stone two dangers are to be considered—obstruction to the flow of bile and infection. Unless the stone is tightly impacted there is still likely to be some flow, and this tends to wash away the infection. Even an impacted stone may be irregular in shape and allow some flow around it, or a round stone completely plugging the lumen may be floated back temporarily in a distended duct, thus causing the intermittent ball-valve obstruction of Fenger. During an intermission or if no infection or jaundice is present, the mortality of operation with a competent surgeon is slight, but unfortunately, as Mayo observes, "the majority of common-duct patients have either never had an intermission or have passed beyond it, and operation is no longer an election as to time, but a necessity, and, no matter how desperate, must be undertaken to save life." The complications of stone in the common duct, such as suppurative cholangitis, liver abscess, pancreas infection, cancer from prolonged irritation, etc., are noted by Haggard. The typical symptoms are very characteristic; they are, in the order of their incidence, pain, chill, temperature, sweating, hypersensitiveness and jaundice. The pain may be dull and constant, but is usually paroxysmal and cramplike. The chill, fever and sweating have a resemblance to malaria and, if jaundice be absent, may cause error in diagnosis. The gall-bladder is rarely dilated, having usually been thickened by previous infection. This is a valuable sign in discriminating the condition from about the only other one with which it is liable to be confused—obstruction of the common duct with jaundice from other causes, principally cancer at the head of the pancreas. With distention of the gall-bladder, a deep persistent jaundice generally indicates quite certainly a non-calculous origin. Jaundice itself is not an infallible sign, and should not be confidently looked for in the majority of gall-stone cases. The diagnosis can and should be made in most instances before the complications that cause jaundice occur. Obstruction being a mechanical condition, it requires mechanical treatment—operative removal. The statistics of surgery are increasingly favorable with prompt diagnosis and resort to operation. Surgery gives opportunity for the relief of the other element of danger—infection—by drainage, and drainage, Haggard says, is the secret of success in the treatment of inflammations of the gall tracts.

Gastro-enterostomy.—The various operations for securing gastric drainage as a correct treatment for certain morbid conditions of the stomach are discussed by W. H. WATHEN (*The Journal A. M. A.*, June 17), and he gives not only his own views and his own special technic of posterior gastro-enterostomy, but also the opinions, obtained through correspondence, of prominent surgeons, including Mayo Robson, Moynihan, Czerny, von Mikulicz, Kocher, Murphy, Mayo, Ochsner, Park and Deaver. His conclusions from a consideration of all the facts are, in substance, as follows: (1) Some cases of acute and subacute gastric and duodenal ulcer, and many cases of chronic and duodenal ulcer, should be treated by efficient stomach drainage into the duodenum or jejunum. (2) Pyloric divulsion and pyloroplasty for this purpose have failed and are now obsolete. (3) Gastroduodenostomy as modified by Kocher and Finney, may do in many cases, but it should be limited to such as can not be operated on by a posterior retrocolic gastro-enterostomy with the anastomosis near the duodeno-jejunal flexure. (4) Anterior anticolic gastro-enterostomy should not be the operation of election, but only of expediency and necessity, to give temporary relief, or to meet abnormal conditions contraindicating the posterior attachment. (5) The ideal operation of election is the posterior retrocolic attachment near the beginning of the jejunum, and at the bottom of the stomach in the pyloric end, thus eliminating the loop. (6) This affords the best drainage, prevents vicious circle and regurgitant vomiting, leaves stomach and intestine in nearly normal relation, and gives better immediate and ultimate results. (7) The intestinal incision should be longitudinal and not less than two inches long, and the stomach incision of corresponding length, preferably in the oblique direction. An elliptical strip of mucosa should be excised from both incisions. (8) The anastomosis is best made by continuous suture Pagenstecher or silk), using a full curved round-pointed needle. It should be applied in double layers, the inner to include all the visceral layers and unite the cut edges of the opening; the outer, one-fifth inch away, to include the serous and subserous layers. (9) Entero-enterostomy, or closure or resection of the proximal jejunum or pylorus, is needless. It causes traumatism and leaves a deformity that may cause immediate or subsequent bad results.

Etiology of Appendicitis.—After considering the various theories advanced by well-known authorities, SHURLY (*Buffalo Med. Jour.*, July, 1905) considers that the consensus of opinion seems to be that the important cause is the accession and activity of various bacteria, and specifically the colon bacillus through abrasion of the lining membrane; but to assign to these bacteria any more than a secondary or exciting rôle in the causation of the disease would seem irrational, when we consider the wide distribution of the colon bacilli throughout the intestinal tract. The formerly supposed causation of appendicitis by foreign bodies, concretions, etc., is disposed of by the many appendices which harbor such things without being diseased. The same may be said of anatomical variations. The author advances the theory, that if through mechanical action, or otherwise, an abrasion or atrium is formed by which these micro-organisms, especially the colon bacillus, secure an entrance into the connective tissue and lymph vessels, and thereby set up infection, and that probably concretions are the principal agents in producing such abrasions by mechanical action.

A Case of Congenital Urethral Stricture Associated with Hematuria and Symptoms Suggesting Renal Disease.—J. W. CHURCHMAN (*Johns Hopkins Hosp. Bull.*, July, 1905), after reporting in detail a case of congenital urethral stricture, summarizes the interesting features presented as follows: (1) This patient presented a urethral stricture in which a positive diagnosis of its congenital nature could be made. Such a diagnosis was warranted by: (*a*) The history, from which all record of urethral traumatism or of venereal infection was absent; (*b*) the association of an obvious congenital stricture at the meatus; (*c*) the complete cure of the clinical manifestations by proper treatment of the stricture; (*d*) the presence of clear urine and the absence of symptoms after the actual stricture had been dilated. (2) The second point of interest was offered by the clinical symptoms presented. These were nausea and vomiting, hematuria and pain over the left ureter. They suggested renal or urethral disease, and obscured the diagnosis which really only cleared up by the therapeutic test. (3) In the third place, this case suggests that another item must be added to our already long list of causes for hematuria, and that congenital stricture may be associated with

blood in the urine, the source of which may probably be an hypertrophied veru montanum.

Knee Injuries and How to Manage Them.—DE FOREST WILLARD (*Am. Med.*, June 17, 1905) says sprains of the knee are often followed by long continued results from the fact that ligamentous, tendinous or fascial structures are torn. Permanent disability and weakness are common. An early diagnosis of the existence of such tear, or of fracture, or of dislocation of cartilages or of loose bodies, is essential. The Roentgen ray may assist. Rest, complete or partial, is the initial element of treatment. Heat and cold are the most powerful abortives of synovial inflammation. Partial fixation by adhesive plaster strapping, or fixation by plaster-of-Paris or other solid splint, with the use of crutches, is helpful. The limitation of the period of rest is, however, most important. As soon as the inflammatory signs have subsided, massage and voluntary movements are important lest chronic tenderness of the joint be induced. Serous effusion is to be removed by compression, tapping or incision. Blood clots should be removed. Displaced semilunar cartilages should be replaced by manipulating and recurrence avoided by an apparatus limiting motion. Upon recurrence of the injury, the cartilage should be stitched in place or removed. Loose bodies in the joint should be removed, when discovered. Sensitive or hysteric joints are induced by too long continuance of rest. These can only be cured by involuntary and voluntary movements, which should usually be preceded by anesthesia. Fibrous anchylosis can be overcome by forcible and cautious movements, with persistent massage, dry heat, manipulations, etc.

MEDICINE.

Improvement of the Sahli Test-Meal.—Several years ago, Sahli recommended a test-meal, the chief ingredient of which was a soup made of flour roasted in butter. Owing to the fact that the fat was held in fine emulsion by the flour, a good idea of the motor function of the stomach could be obtained if a butyrometric test was made of the expressed soup. Since the latter test required a special centrifuge the method has not become popular though excellent in other respects. H. SAHLI (*Münch. med Woch.*, July 11, 1905) now recommends the following modification: Instead of centrifuging, the mixture of test-meal suphuric acid and omyl alcohol is placed in the water bath for ten to fiftcen minues when all the fat will separate on the surface of the mixture as perfectly as with the centrifuge. The Sahli test-meal is also an excellent method for determining the bacterial flora of the stomach. With the Ewald or Boss test-meal a large number of bacteria are quite regularly introduced into the stomach, but the Sahli emulsion is virtually sterile when taken, since it has been boiled shortly before use.

Intestinal Stones.—An interesting case of intestinal concretion is related by R. NAUNYN (*Deutsch. Archiv f. klin. Med.*, Vol. 84, Nos. 1 to 4). The patient suffered from alternating constipation and diarrhea and the diagnosis presented many difficulties until many hard, light-colored masses were passed. A chemical examination showed that these were made almost entirely of a resinous matter. The patient's history then disclosed that he had been in the habit of taking resinous tinctures for a long period for a painful gingivitis. The resin was precipitated in contact with saliva and had then formed compact masses in the lower intestines.

Diagnosis and Treatment of Gastric Ulcer.—After a careful review of the symptoms of gastric ulcer, in which are defined the typical and a typical symptoms, C. E. NAMMACK (*N. Y. Med. Jour. and Phila. Med. Jour.*, July 15, 1905), states that before a definite diagnosis of gastric ulcer can be made, the following conditions must be excluded: hyperchlorhydria, acute catarrhal gastritis, gastralgia, cholelithiasis, cancer of the stomach, intercostal neuralgia accompanying digestive disorders, gastric crisis in locomotor ataxia and other diseases of the spinal cord, and duodenal ulcer. The points of differential diagnoses are considered. The three leading indications for treatment are to improve general nutrition, to diminish the excessive acidity of the gastric juice, and to put the ulcer at rest. The author considers that the great majority of acute cases will heal under appropriate medical treatment, while surgery promises more in the treatment of chronic cases. Besides the chronic cases surgery is always indicated in hemorhage and perforation.

The Ethics of Consultation—B. D. BOSWORTH (*Journal A. M. A.*, July 8, 1905) calls consultation the highest function in medical practice and protests against the unreasonable neglect into which it has fallen. It is a duty, he thinks, of the young practitioner to avail himself of the counsel of the more experienced men with whom he has begun to compete. He also believes in exclusiveness in consultation, no matter how far the bars may have been let down, and is thankful that there is no law to prevent the exercise of individual judgment and discretion as to whom we shall meet in consultation. It is better that the medical attendant should first propose the calling of counsel, but the choice of the patient s family should be respected. He gives the mode of proceeding in an ideal consultation, and the need of conciseness and brevity, both for the sake of the patient and his friends, is insisted on, and he makes a special point that, unless it is demanded by the family physician himself and for good and sufficient reasons, no one who has been called as a consultant is ever justified in taking charge of the case, or should ever intimate that any part of the treatment did not receive his assent. Ignorance, he thinks, is the invariable excuse for the flagrant violation of ethical principles in these matters. The members of the profession ought to give more careful study to the principles of ethics that have been promulgated by the Association.

Albuminuria in Relation to Diabetes.—There are three distinct groups of cases in which albuminuria is associated with diabetes, according to M. LANCEREAUX (*Bull. de L'Acad. de Med.*, July 31, 1905). They are as follows: (1) Albuminuria due to arteriosclerosis with secondary lesions in the heart and kidneys; (2) albuminuria of epithelial origin, due to an intercurrent disease, particularly tuberculosis; (3) albuminuria without renal manifestations, alternating with glycosuria, and, like the latter, of nervous origin. In the first class of cases are frequently seen fat diabetics who have become albuminuric at an age difficult to determine, on account of the insidious development of this condition and the carelessness of the patient in seeking medical advice. It may, however, be said that in these cases the albuminuria appears subsequently to the diabetes and at the same age, from forty-five to fifty-five years, at which it appears in arteriosclerosis. The clinical features are an abundant, pale urine of relatively low specific gravity (1.010 to 1.020), nocturnal polyuria, a moderate amount of albumin, without or with a slight edema. Death occurs from uremia rather than from glycosuria. In

the second class of cases tuberculosis is the most common cause of the albuminuria. Among other causes is suppuration of the bladder (relatively common in the diabetic women) owing to the introduction of micro-organisms from without. The third class of cases are found among private rather than hospital patients, and are discovered only by accident. In these the albuminuria and glycosuria may be considered as two syndromes of similar origin; the author characterizes this association as the "albuminurious diabetes." This association is found particularly in obese and gouty patients.

Sunshine and Shadow in Medical Endeavor. The address of J. D. Bryant (*Journal A. M. A.*, August 12, 1905), covers the subject of the recognized results of medical science in relieving human suffering as well as the numerous annoyances and drawbacks experienced by the profession in its beneficent work. He gives entertaining illustrations of some of these drawbacks, the wiles of quackery, the much misled credulity of the public, the misappreciation of the differences between thrifty commercialism and ethical proprieties, the tendency to fads in the profession itself and to the overdoing of certain methods, etc., and the risks of falling into ruts and superficial contentment. Against all these, however, he balances the great achievements of the profession, the triumphs of surgery, the great advances made in the knowledge and origin of diseases and in their treatment and the vast increase of knowledge within the last few years all tending to diminish human suffering and adding infinite possibilities of comfort and enjoyment in human existence.

Physical Signs of Air and Fluid in the Pleura. The auscultation and percussion of cases of hydropneumothorax generally enable a ready diagnosis. C. Bäumler (*Deutsch. Arch. f. klin. Med.*, Vol. 84, Nos. 1 to 4) points out that there may, however, be considerable difficulty when old adhesions of the lung or advanced changes in the lung, such as compression or cavity-formation, influence the position of air and fluid. In such cases there may be an area of exquisite tympanitic percussion within the area of flatness caused by the fluid. In some cases which came to autopsy, the author discovered a stand of compressed pulmonary tissue adherent to the chest-wall. In other instances small accumulations of air are percussed through thin layers of fluid or thickened lung-tissue or strands of fibrin have formed in the fluid. The signs often change when the patient alters his position.

Epidemic Cerebrospinal Meningitis. The diplococcus of Weichselbaum was found in all cases of epidemic cerebrospinal meningitis examined bacteriologically by H. Lenhartz (*Deutsch. Arch. f. klin. Med.*, Vol. 84, Nos. 1 to 4), but in four cases other bacteria were also present. The course extended over weeks and months, even where the disease ended fatally. The mortality was not so high as reported by other authors, since 23 out of 45 cases recovered. A pronounced difference between this form of meningitis and the form caused by the diplococcus of Fraenkel, is that the latter almost always ends fatally in a few days. Leucocytosis is a constant symptom and may reach very high degrees, particularly in the more favorable cases. The best treatment is repeated lumbar puncture; this will also prevent the subsequent development or hydrocephalus. Usually 25 to 40 c.c. of fluid are removed and the needle withdrawn as soon as the pressure sinks below 100. In one case as many as 15 punctures were made. Where lumbar puncture is not successful the ventricles may be punctured directly, though here there is always danger of setting up a hemorrhage. The most common after-effects were blindness and deafness, owing to degenerative changes in the corresponding nerves. In one case, the patient recovered from idiocy and was again able to see after the use of the seton and and inunctions with mercurial ointment.

Essential Albuminuria.—Based upon the observation of one case for 15 years, B. Neukirch (*Deutsch. Arch. f. klin. Med.*, Vol. 84, Nos. 1 to 4) comes to the conclusion that essential albuminuria is a disease *sui generis* and not related to nephritis. The albuminuria was first noticed directly after an attack of diphtheria; at times the amount rose to one to a thousand, while frequently several hours later not even a trace could be detected. Casts and other renal elements were always absent and, despite the fact that the condition persisted for many years, no hypertrophy of the heart or other visceral changes appeared. Vegetable diet and rest in bed did not make a lasting impression, but with the advent of puberty the condition disappeared spontaneously. Bland diet and high altitudes are recommended and the patients should carefully avoid exposure to cold and excesses of any kind. The prognosis is very favorable since the underlying cause is probably only a disturbance in the innervation of the kidneys.

Dr. Osler's Farewell Address.—"Unity, Peace and Concord" is the title chosen for his address by Dr. Osler (*Journal A. M. A.*, August 5, 1905). The medical profession is the only one, he says, that everywhere throughout the world has the same methods, ambitions and aims—it is the only worldwide profession In a little more than a century a united profession working in every land has done more for the race than any other body of men. Any great discovery in any part of the world is common property at once. In referring to the things needed to bring about perfect unity in the profession in this country, he laid special emphasis on the need of reciprocity in the medical practice laws in the various States and Territories, and the need for consolidation of medical schools and for the recognition of those homeopathic physicians who are ready to accept the facts of scientific medicine. Osler believes that mutual concessions only are needed, such as the abandonment of special designation, and the intelligent toleration of therapeutic vagaries that have always beset the profession, but are at worst only flies on the wheels of progress. He advocates peace, but by this he does not mean cessation of our professional conflict with ignorance, apathy and vice. This must be steadily carried on. There is, however, at times, he says, a lack of professional harmony that should exist, and this is to be lamented. He thinks that there are three chief causes of the quarrels of physicians. The first is lack of proper friendly intercourse, the second is uncharitableness, and the third is the wagging tongue of individuals, who are too often ready to make trouble between physicians. He says that a physician should never listen to a patient who tells tales derogatory of other physicians, and should not believe them, even if he thinks they may be true.

PATHOLOGY AND BACTERIOLOGY.

Transmission of Disease by Mosquitoes.—J. R. Taylor (*Jour. A. M. A.*, July 8, 1905), gives a good summary of the facts in regard to the transmission of disease by mosquitoes, so far as known. He does not consider any of the possible methods practicable for the complete extermination of malaria, but thinks that the disease can be greatly reduced in prevalence. As regards yellow fever, he believes the methods instituted by Gorgas in Cuba, if thoroughly carried out, would exterminate the disease. The same methods

will apply for the extermination, or at least the diminution, of filariasis. He believes in quarantine in all possible cases of transmission of disease by vessels, that is, a quarantine based on the natural history of the disease as we know it. The isolation of infected persons is essential. For the destruction of mosquitoes, sulphur fumigation is most effectual, but has its inconveniences. The powdered leaves of datura (jimson weed) mixed with saltpeter and burned, an ounce of the mixture to each two hundred cubic feet of space, is a cheap, safe and effective method of destroying hibernating mosquitoes. Pyrethrum and formaldehyde are said to be effective against hibernating insects, though the former only stupefies the mosquitoes, which should be swept up and burned after its use. To exterminate the stegomyia or yellow fever mosquito, all water receptacles should be treated with oil or made insect proof, and drainage and flushing of ditches, etc., should be practised. Drainage methods are even more necessary against the malarial bearing type, which breeds especially in swamps. Taylor views the general results of experiments by the New Jersey mosquito commission in regard to the merits of various larvicides, such as petroleum and the creosote preparations.

Leucocytes in Malignant Growths.—J. B. FARMER, J. E. S. MOORE and C. E. WALKER, note (*Lancet*, August 5, 1905) some observations relating to the behavior of leucocytes in very early carcinoma. Three cases were studied, and in all the phenomenon was identical, suggesting a cytologic change peculiar to the transmutation of normal cells into carcinomatous elements. It was found that there was a distinct zone of transition from the normal to the cancerous element round the periphery of the tumor. This led to the conclusion that the growth had not originated from a single cell, but was being involved by direct conversion from many functioning elements. Leucocytes which had invaded the cytoplasm of epithelial cells were obscured. In many instances the cell and its included leucocytes were both dividing mitotically. It is deduced that a mixture of the respective chromosomes occurs, a process analogous to fertilization.

An Experimental Contribution to the Treatment of Cholelithiasis.—WILLIAM BAIN reports (*Brit. Med Jour.*, August 5, 1905) a series of experiments to determine (1) the changes, if any, undergone by gallstones introduced into the normal gall-bladder, (2) the fate of such calculi when cholecystitis was artificially produced, and (3) results of medication. Sixteen dogs were used. In some of them, along with the calculi, cultures of the *Bacillus coli communis* were introduced. All of the dogs gained weight after operation except two. The experiments showed that the normal gall-bladder will dissolve moderately large calculi in about three weeks. When cholecystitis is present the stones do not disappear, though there was always a reduction in weight. Of the medicaments used, two of them, namely, a mixture of urotropin and iridin and Harrogate old sulphur water gave fairly positive results in promoting dissolution. Ichthoform calomel, cholelysin and olive oil had no appreciative effect.

Enzymes and Anti-Enzymes of Inflammatory Exudates.—The serum of an inflammatory exudate has the power of inhibiting the action of proteolytic ferments contained in the leucocytes, according to E. L. OPIE (*Jour. of Exper. Medicine*, June 10, 1905). This anti-enzymotic power is possessed by the blood-serum from which it doubtless passes into the exudate. In the later stages of inflammation there is some diminution of this anti-enzymotic power. The antibody contained in the serum is destroyed by a temperature of 75° C. The proteolytic ferments of the leucocytes act both in an acid and in an alkaline medium, but are most efficient in the latter. The anti-enzymotic action of the serum is favored by an alkaline reaction, but is completely lost in an acid medium.

The Bacteriology of Pertussis.—A study of the bacterial contents of sputum obtained from cases of pertussis at the New York Foundling Asylum was made by M. WOLLSTEIN (*Jour. of Exper. Med.*, July 15, 1905). She was able to isolate bacilli belonging to the influenza group, but differentiated from *Bacillus influenzæ* by means of agglutination reactions with the blood of patients and of immunized laboratory animals. The bacilli were found with the greatest ease early in the attack, *i.e.*, when the cough had persisted for about two weeks and the whoop was just established. They continued very numerous in the sputum throughout the paroxysmal stage. Agglutination was effected by the serum of the child in dilutions of 1:200 and occasionally in 1:500.

The Nature of Mallory's Bodies in Scarlet Fever and Measles.—A study of the protozoon-like bodies observed by Mallory in the epithelial cells and in the lymph spaces of the skin, in material from autopsies on scarlet-fever cases, was made by C. W. FIELD (*Jour. of Exper. Med.*, July 15, 1905), who paid particular attention to these bodies as obtained from blister-fluid. He believes that the bodies found in sections of skin from cases of measles and scarlet fever are part of the protoplasm of the epithelial cells which has been so changed in its chemical nature that its staining reaction differs from that of the surrounding protoplasm. The small, round extracellular bodies found in the living patients may arise from degenerating cells. In sections of control and normal skin, the nuclei of the epithelial cells were often indented by the cell protoplasm, giving them an appearance similar to those indented by Mallory's bodies. It would seem that if these bodies of Mallory's were protozoa they would have been found in the sections from both the living and the dead skin of scarlet fever and measles, as they were present in the blister-fluid. Their absence is certainly more suggestive of a degeneration than of a protozoon. This view is also borne out by the fact that they were not found immediately after death, but were present in another specimen from the same case removed twenty-four hours later. It would seem probable that the bodies found in the blister-fluid were the products of degeneration and cystolytic activity, because they were found in the antitoxin rashes as well as in the cases of scarlet fever and measles. The bodies present in blister-fluid resemble very closely these granular bodies found in blood under certain conditions, and seen in vaccine lymph and in emulsions of tissues and in exudates. The author thinks, therefore, that they are for the most part, if not wholly, products of degenerating tissue cells and of leucocytes, and within certain limits specific to scarlet fever and measles.

Some Conditions Determining Variations in the Energy of Tumor Growths.—LEO LOEB (*Am. Med.*, August 12, 1905) asserts the rate of tumor-growth is not only influenced by the species into which the tumor is transplanted, but also by variations which exist among individuals or families of the same species. Under certain conditions a state of active immunity can be experimentally produced. It can be accomplished more easily with some tumors than with others. The energy of tumor-growth can be experimentally

increased through successive transplantations up to a certain maximum. It is also possible to cause an experimental decrease in the energy of tumor-growth. These variations are caused by a direct stimulating or depressing effect upon the tumor cells. (Contact metastases may occur, and different tumors which are morphologically similar or identical behave differently in this respect. The greatest care ought to be exercised to prevent a tumor from touching the wound during extirpation. The fact that surgeons operating on tumors do not become infected agrees with the facts found in experimental tumor inoculations.) Tumor growth is primarily due to an increased energy of growth of those cells from which the tumor takes its origin; it cannot be due to a lowered resistance of the organism in which the cells carry on their apparently unlimited growth. If a tumor cannot be successfully inoculated into other animals, it is probably not due to the fact that other animals are more resistant toward the growth of inoculated tumor cells than the animal in which the tumor-growth developed originally, but to other causes still unknown.

Etiology of Croupous Pneumonia.—Formerly it was believed that the diplococcus of Fraenkel was the sole cause of true lobar pneumonia, but the importance of the diplo-bacillus of Friedländer was soon recognized. Now H. Schottmüller (*Münch. med. Woch.*, July 25, 1905) states that the *Streptococcus mucosus* is also an etiological factor, since he has it in pure culture in the lungs of five cases. The clinical symptoms were onset with chills, high fever, delirium, and stupor and albuminuria. Frequent complications were empyema and pericarditis. The defervescence was more often by lysis, and the sputum was generally very tenacious and hemorrhagic or orange-colored. The microscopical appearance of the diseased lung did not differ from that of pneumococcus pneumonia, but the exudate was marked by being very thick and tenacious. In a few cases the germ could also be cultivated from the blood during life. The percentage of positive blood-cultures obtained by the author in pneumonia in general was 23 per cent., but not all of these cases died. Conversely, the disease may be fatal, even if germs cannot be obtained from the blood during life. The importance of the *Streptococcus mucosus* as a cause of pneumonia is evident if the advances of serum therapy in pneumonia are noted.

Mixed Infection of the Blood with Proteus and Streptococcus.—Bacilli of the proteus group very often give rise to local infections in combination with other germs, particularly in endometritis, peritonitis, gangrene of the lung and in phlegmons. Such processes are generally characterized by their bad odor. General infection, on the other hand, is very rare, so that the case of G. JOCHMANN (*Zeitsch. f. klin. Med.*, Vol. 57, Nos. 1 and 2) deserves to be put on record. The patient was suffering from mastoiditis with sinus-thrombosis, but did not recover from a radical operation. The clinical symptoms did not differ from those of other cases of otogenous sepsis, and cultures made from the blood shortly before death showed very many colonies of proteus and few of streptococcus. Agglutination tests were made, and it was found that the serum of the patient reacted with proteus in a dilution of 1-640 and with typhoid bacilli in a dilution of 1-160. The serum of rabbits inoculated with the proteus obtained from the blood also agglutinated to some extent the typhoid bacillus.

The Etiology and Pathogenesis of Pernicious Anemia.—C. H. BUNTING (*Bull. Johns Hopkins Hosp.*, June, 1905), after reviewing the general etiological causes of pernicious anemia as presented by various authors, states that it does not seem necessary to assume any specific predisposition to anemia, at least not a predisposition with a pathological condition of the marrow as a basis. He considers there is a disproportion between the resisting power of the individual and the strength of the pathological agent producing the anæmic state—a disproportion shown by an inability of the bone marrow to generate a sufficient number of red-blood cells to supply the deficiency. This disproportion is especially marked in the so-called "aplastic" cases, in which after death the marrow is found to be fatty and with practically no sign of regeneration. Whether this variability in reaction depends entirely upon a variation in the intensity of the toxic agent or in part to the condition of the individual is the same problem as is presented in many diseases, as, for example, the valuable resistance offered to invasion by the tubercle bacillus, or to the toxic agents producing a nephritis or a cirrhosis of the liver. It would seem to depend more on a general lack of resistance on the part of the individual than to any special predisposition or weakness of the bone marrow. It is obvious that an anemia may be produced in several ways: First, by insufficient or defective blood formation; second, by excessive loss of red blood cells from the circulation; third, by excessive destruction of red cells; or, fourth, by a combination of the preceding factors or any two of them. The author considers that the theory of Lazarus, that the megaloblastic transformation of the marrow is due to the presence of some toxic substance, approaches most closely the true solution of the question of pathogenesis. The absorption of this toxic substance is probably of intestinal origin, which acts on the circulatory blood-producing hemolysis and through the circulation also on the marrow, resulting in a faulty hyperplasia. The author concludes by stating that a toxin is present which destroys the red cells both in the circulation and in the marrow, that it reduces the erythrogenetic groups more or less to the megaloblastic centers, diminishing greatly the regenerating power of the marrow and resulting in a discharge of megaloblastic cells in the hasty effort to supply the circulation. Thus, the regular orderly development of the groups of the marrow cells is interfered with and a short cut is taken from the megaloblast to the macrocyte, an imperfect, immature cell, as shown by its polychromatophilia and granular basophilia.

Preservation of Milk with Peroxide of Hydrogen.—Most methods of rendering milk sterile are objectionable since they either add substances injurious to health or else render the milk less digestible. An ideal disinfectant has, however, been found by E. BAUMANN (*Münch. med. Woch.*, June 6, 1905) in peroxide of hydrogen. If added in amounts of 0.35 pro mille, the milk will keep for many days and the number of germs present will actually decrease to a very low number. When pathogenic germs, such as typhoid, cholera, dysentery or tuberculosis, were added to the milk, they could not again be detected after the most searching bacteriological examination. It is always best to heat the milk up to 50° C. after the addition of the peroxide, since a certain amount of free oxygen will be formed, which is strongly bactericidal. In order to avoid any dilution of the milk it is best to use the new preparation of peroxide, perhydrol, which contains 30 per cent. The taste is in nowise altered, and numerous experiments showed that the digestibility is the same as before.

Germ of Syphilis.—Evidence is becoming more and more conclusive that the *Spirochæta pallida*, first described by Schaudinn and Hoffmann, really is the much-sought micro-organism of syphilis. Thus, C FRAENKEL (*Münch. med. Woch.*, June 13, 1905), has examined a large number of primary lesions and manifestations of the earliest stage of syphilis, and reports positive in almost every case. In lesions undoubtedly not syphilitic similar structures could never be found. Great patience and high magnifying power are necessary since the organisms are very small and not evenly distributed: thus it may happen that twenty or thirty may be seen in one field and none in a large number of fields examined later. The technic is very simple: the cover-slips are immersed for ten minutes in alcohol, dried and placed for sixteen to eighteen hours in the azur solution recommended by Giemsa. The number of convolutions shown by the spirilla vary: some possess four to six and others as many as fourteen to sixteen. The author believes that they undoubtedly stand in etiological relation to syphilis, but cannot understand why they were not discovered before.

Beginning and Growth of Intestinal Cancer.—D. MARCKWALD (*Münch med. Woch.*, May 30, 1905), has been so fortunate as to observe two cases of intestinal carcinoma in their very earliest stages. In one the growth had started in the walls of the appendix and had attained the size of a pea, while the second was somewhat smaller and had been discovered accidentally at an autopsy. It is probable that the starting point in each case was a cell, or a number of cells, situated in the submucosa and most likely of fetal origin. No signs of inflammation or of trauma could be detected, so that the cause of the sudden growth of the cells remains unexplained. Owing to increase in size of the cell-nests, the surrounding tissues will be pushed apart so that the lymph-spaces dilate and give ready access to particles of the tumor. The walls of the arteries will thicken and the endothelial cells lining the intima hypertrophy and proliferate. The stroma of the surrounding tissues does not participate in the increased growth, but remains passive. The mucous membrane covering the most prominent parts soon becomes necrotic, since the supply of blood is more or less interfered with. Metastatic growths may be found in the immediate neighborhood of the original tumor, so that if the latter has attained a large size it may be absolutely impossible to say what is primary and what secondary.

Action of the Roentgen Rays.—It is very evident from the article of O. ROSENBACH (*Münch. med. Woch.*, May 30, 1905) that many problems relating to the action of the Roentgen rays upon the animal body are still unsettled and call for extensive experimentation. What is known is that the white cells, and probably to a less extent also the red cells, accumulate in the tissues of the skin. A loss of hemoglobin and a leucopenia will thus result quite constantly, but this is due in great part to an actual destruction of both kinds of cells in the blood-stream. If the spleen of an animal, treated for a long time with the rays, be examined, it will be regularly found very rich in iron. It is not known if the blood changes actually inhibit the production of new leucocytes in the bone marrow, and if this inhibition is temporary or permanent. Clinical experience seems to incline toward the former, since most cases of leucemia rapidly became worse when the treatment was discontinued.

The Urine in Chronic Diseases and in Collapse.—In the urine of heart disease, independent of the existence of edemas, C. KLIENEBERGER (*Münch. med. Woch.*, June 20, 1905) has almost always found a slight amount of albumin, together with an often enormous number of hyaline casts. The other elements are usually not increased excessively. The hyaline cylindruria lasts a variable length of time, and the prognosis is generally worse if it accompanies edema than in the presence of edema alone. Hyaline cylindruria, persisting for days or weeks, was observed only in cases which died soon, while if the condition lasted only a few days, the symptoms were unusually severe and often amounted to a real collapse. At autopsy, the chief changes were those of a renal congestion, and a nephritis was only rarely present. Concerning most chronic diseases the following statement may be put down: Shortly before death many hyaline casts make their appearance in the sediment. The amount of albumin varies, but is usually very slight. Here, again, a nephritis is usually absent, the condition of the urine being solely due to disturbances of circulation, such as precede death. In a large number of other diseases the same condition was found, and the author believes that a thorough examination of the urine will very often aid in differential diagnosis. If a pronounced hyaline cylindruria is present the condition of the patient is serious and recovery doubtful.

Streptococci in Variola and Varicella.—Since various protozoa are being found in the different infectious diseases of hitherto unknown etiology, H. DE WAELE and E. SUGG (*Münch. med. Woch.*, June 20, 1905) again draw attention to their former researches on smallpox and the allied diseases. In the lesions of smallpox cases, as well as in the blood, they encountered quite constantly a streptococcus which morphologically does not differ from other streptococci, but which is readily agglutinated by the serum of the patient as well as by the serum of vaccinated individuals. In the vesicles of cases of chickenpox another streptococcus was seen, toward which the serum of the patient behaved specifically. On the other hand, the smallpox serum did not affect the varicella streptococcus, and vice versa. In a large number of doubtful cases the authors could settle the diagnosis by means of the agglutination test, and the subsequent history always proved them to be correct, so that the method has great practical importance. Streptococci from other sources were never agglutinated by the serum of variola or varicella cases.

Cause of Death After Burns.—If a large portion of the skin of rabbits is treated with boiling water a small percentage of animals die very soon. Since these are generally the ones that have been imperfectly narcotized the probable cause here is shock. Even if these cases be excluded the time which elapses before death sets in varies considerably. During the first twenty-four hours, H. PFEIFFER (*Virchow's Archiv*, Vol. 180, No. 3), found considerable changes in the blood, manifesting themselves in the altered shape of the red cells and the hemoglobin contents. The urine is at first hemorrhagic, and later has an acid reaction and contains albumin. The cerebral symptoms amount to a primary stage of irritation, followed by apathy and somnolency, but sometimes there is a secondary increase of reflex irritability just before death. The pathological lesions include changes in the kidneys, ecchymoses and ulcers in the intestines and stomach, and degeneration of the heart and liver. The urine possesses distinctly toxic properties toward rabbits and other animals, which increase steadily up to the fifty-sixth hour. It could furthermore be shown that this toxicity is not due to the presence of blood-

coloring matter or to the acid reaction of the urine. The poison could be detected earlier in the urine than in the serum of the animals experimented upon; it possesses both a local necrotic and a general neurotoxic action. If injected into mice a period of irritation will first be noticed, followed by paralysis and cessation of respiration. With some urines the necrotic action is more pronounced, and rarely hemorrhages into the intestines and diarrhea will follow. The toxin is easily decomposed if exposed to daylight and also passes through bacterial filters. The principles causing necrosis are destroyed by short heating, while the neurotoxic agents are frequently unaffected or rendered more potent. It is not likely that these toxins are formed at the site of injury, but the proteid molecule is probably merely altered by the heat, and from this altered molecule the toxic molecules are then formed in the body. Hemolysis and agglutination of allied blood, by means of the blood of scalded rabbits, could never be observed to any marked degree, and the death of the latter can certainly not be attributed to blood changes. The intestinal ulcers so commonly seen are not caused by a direct action of the heat, since they are also frequent, if distant parts, such as the hind legs, are scalded. They are due to the toxin, toward which the intestinal mucosa is particularly intolerant.

Granules in Lymphocytes.—According to the original classification of Ehrlich, the lymphocytes and large mononuclear cells differ from the other white cells of the blood—in that they do not possess specific granulations. More recently, however, granulations have been discovered and D. Levaditi (*Virchow's Archiv*, Vol. 180, No. 3), now concludes that their occurrence is quite frequent, though inconstant. As far as histochemical and color-reactions are concerned, they are specific, hence the name X-granulation has been proposed.

Experimental Tricuspid Insufficiency.—Since tricuspid insufficiency is only rarely found as isolated valvular lesion, the opinions concerning the changes in the heart vary considerably. Theoretically, one would expect a dilatation and hypertrophy of the right ventricle and of the right auricle, with the possibility of perfect compensation. A tricuspid insufficiency could be brought about in rabbits by destroying the valves, and E. Stadler (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 1 and 2) found that the theoretical assumption was correct for the weight of the right ventricle, but more so that of the right auricle was much higher than under normal conditons. The weight of the entire heart was about normal since the left side had become atrophic. It follows that compensation was not perfect, for the left heart could not have thrown enough blood into the vessels; with lesions of a very slight degree, however, the left ventricle was nearly normal in size and the heart action probably also normal. If the greater part of the valves was destroyed, the animal died either at once or in a few hours or days; if the lesion was less severe, circulatory disturbances appeared, while with slight destruction the animal seemed perfectly well. Clinically, tricuspid insufficiency behaves like the mitral, but is more serious since there is no part of the heart which will aid in the compensation. The parenchymatous organs of the abdomen are prone to undergo serious changes, which may account for the severe cachexia.

Finer Structure of the Lymphocytes.—By means of a special method of treating blood-films, H. Schridde (*Münch. med. Woch.*, June 27, 1905), has been able to discover distinct granulations in almost all of the lymphocytes. Briefly, the film is hardened for twelve hours in a mixture of formaline and Müller's fluid, and then for twelve hours in plain Müller's fluid, and finally for thirty to sixty minutes in a 1 per cent. solution of osmic acid. A hot, 20 per cent. solution of acid-fuchsin in aniline water is employed for staining, after which the smear is differentiated in picric acid alcohol. In good specimens, all granulations except the basophile kind will appear stained, those of the lymphocytes appearing somewhat elongated, in close proximity to the nucleus and of a yellowish red hue. They are found in the normal blood as well as in leucemia and other conditions, and differ from lymphocytic granulations described by other observers.

The Toxin of Fatigue.—Further observations made by W. Weichardt (*Münch. med. Woch.*, June 27, 1905), proved that while his toxin may be obtained in large quantities from the muscle-juice of fatigued animals a simpler way would be to treat the muscle-juice of a normal animal with some reducing agent, such as sulphite of sodium. The toxin thus isolated is in every way identical with the original toxin and will be readily saturated by the antitoxin of the latter. A toxin may also be obtained with the aid of reducing agents from the albumin of placenta, brain, pollen and even eggs. The antitoxin neutralizes each one of these as readily as the muscle-toxin.

Spirochæta Pallida in Syphilis.—Reports on finding the *Spirochæta pallida* of Schaudinn in true syphilitic lesions are so numerous that even the most skeptical are beginning to believe that this organism has something to do with the development of the specific lesions. It is, however, clear from the article of B. Kiolemenoglou and F. v. Cube (*Münch. med. Woch.*, July 4, 1905), that non-specific lesions have not yet been searched sufficiently for similar organisms to enable a definite conclusion. Thus, the authors have found *Spirochæta* which could in no way be differentiated from the true *Spirochæta pallida* in the balanitic secretion of an inflamed phimosis, in simple balanitis, in the pus of a gonorrhoic, Bartholinian abscess and of scrofulodermatic abscesses, and also in broken-down carcinomata and in pointed condylomata. The *Spirochæta pallida* was never found alone, but always in company with the *Spirochæta refringens*.

Situs Transversus and Atresia of the Pylorus.—H. M. Little (*Johns Hopk. Hosp. Bull.*, July, 1905), reports a case of a newly-born child suffering with atresia of the pylorus. On account of the obstruction a gastro-enterostomy was performed on the sixth day, but the child died fourteen hours after the operation. The diagnosis of complete obstruction of the pylorus or upper portion of the duodenum was based on the following considerations: (1) The vomiting of a large amount of amniotic fluid shortly after birth; (2) recurrence of vomiting not regularly after the ingestion of small amounts of fluids, but as soon as approximately 20 to 30 c.c. has been given; (3) the presence in the stomach of entire amount of a feeding (15-20 c.c.) when the stomach was washed out two hours after its ingestion; (4) the absence of bile-staining of the vomitus or fluid obtained at lavage; (5) the presence and passing of meconium gradually showing more and more the appearance of bile; (6) the absence of any sign of digested milk in the stools as late as the seventh day; (7) the uniformly subnormal character of the temperature; (8) the persistent loss of weight; (9) the anuria; (10) the fact that the mother had hydramnios. At autopsy there was found complete transposition of the thoracic and abdominal

organs. The stomach showed that the pyloric end ended abruptly behind and to the left of the head of the pancreas.

PHYSIOLOGY.

The Specific Nature of Precipitins.—An investigation of the mooted question of the specific nature of the various precipitins was made by A. HUNTER (*Jour. of Physiol.*, July 13, 1905) with the following results: The albumin, euglobulin, and pseudoglobulin of ox-serum are each capable of leading to the formation of precipitins; and these precipitins are in a limited degree specific. They are mixtures of at least four distinct antibodies, of which albumin yields only one, while euglobin and pseudoglobulin each yield three. The production of precipitins follows a wave-like course, and is accompanied by an intermittent leucocytosis, the number of leucocytes at any moment bearing an inverse relation to the amount of precipitin.

The Action of Various Drugs on the Small Intestine.—It was possible for R. MAGNUS (*Pflüger's Archiv*, May 8, 1905) to prepare cat's small intestine in such a way as to get rid of every trace of Auerbach's plexus. Under the influence of stimulating poisons, such preparations react with a uniformly continuous contraction, while preparations containing the plexus react by means of rhythmic contractions. In small doses atropin acts upon Auerbach's plexus, stimulating the intestinal movements, while in large doses it paralyzes both nerves and muscles. Nicotine at first inhibits the intestinal movements through its action on the plexus, and later its action in this is to excite these movements. Even large doses do not cause paralysis. Combined doses of atropine and nicotine produce paralysis. Muscarin excites the centers of the plexus. Pilocarpine powerfully stimulates the movements. Physostigmin stimulates preparations that contain or do not contain the plexus. In the latter it produces rhythmical contractions.

Action of the Metallic Ferments on the Formed Elements of the Blood.—A study of the effects on the blood cells of subcutaneous injections of metallic ferments, particularly electrolytic solutions of gold, was made by A. ROBIN and M. P. EMILE-WEIL (*Bull. de l'Acad. de Med.*, July 24, 1905). In general, the injection is followed by a leucolysis, which in the normal individual is slight, but in conditions accompanied by a leucocytosis this destruction is frequently intense. It is succeeded either by a secondary leucocytosis or by a return to the equilibrium. The leucolysis affects principally the polynuclear neutrophiles. The red blood cells are not much affected, there being a tendency to a slight diminution in their number. It is worthy of note that diverse substances, such as pilocarpine, atropine, digitalis, salicylate of soda, quinine, etc., have a similar effect, namely, a short initial hypoleucocytosis, followed by a hyperleucocytosis. Ether and chloroform have the same action. M. Bize has found that the antidiphtheritic and antistreptococcus sera have also the same action on the leucocytes. The author suggests that this similarity between the metallic ferments and the antitoxins may not be a mere coincidence.

The Absorption of Chloroform in the Later Stages of Anesthesia.—The amounts of chloroform absorbed late in anesthesia are not great, and the breaking down of the drug, which is said to take place in the body, is at the best a small quantity, according to the researches of B. J. COLLINGWOOD (*Jour. of Physiol.*, May 9, 1905). It would also follow that when once anesthesia has been fully established, the dosage of the chloroform should be adjusted to prevent the blood giving up chloroform, rather than with the idea of pouring more of the drug into the organism. Previous observations show that the dosage of chloroform required to abolish the corneal reflex constantly decreases with the prolongation of anesthesia, sinking at the end of five hours to as low as .5 per cent. It would thus appear that when the organism is fully saturated with chloroform a very low percentage is sufficient to maintain anesthesia.

The Action of Adrenalin.—Apart from the general poisonous properties that are suggested by its chemical structure, adrenalin has one peculiar power, according to T. R. ELLIOTT (*Jour. of Physiol.*, July 13, 1905). Independent body cells, nerve-cells and their processes, skeletal muscles and visceral muscles in union only with sacral and cranial visceral nerves are influenced by it, as they are by any featureless poison. Its single characteristic is the aptness to stimulate plain muscle and gland cells that are or have been in functional union with sympathetic nerve fibers. In all vertebrates the reaction of any plain muscle to adrenalin is of a similar character to that following excitation of the sympathetic (thoracico-lumbar) visceral nerves supplying that muscle. The change may be either a contraction or a relaxation. In default of sympathetic innervation plain muscle is indifferent to adrenalin. Extent of reaction varies directly with the frequency of normal physiological impulses to rapid change of tension received by the muscle in life through the sympathetic nerves. A positive reaction to adrenalin is a trustworthy proof of the existence and nature of sympathetic nerves in any organ. Plain muscle, when denervated, shows increase of the capacity for irritation by adrenalin than it had previously possessed. Sympathetic nerve cells with their fibers, and the contractile muscle fibers, are not irritated by adrenalin. The stimulation takes place at the junction of muscle and fiber. The irritable substance at the myoneural junction depends for continuance of life on the nucleoplasm of the muscle cell, not of the nerve cell. Such peculiar irritability makes the profound biochemical distinction between all post ganglionic nerves of the thoracico-lumbar-visceral class, whether motor or inhibitor, on the one side, and all other efferent nerves with their respective junctions on the other.

The Changes in the Viscosity of the Blood during Narcosis.—The viscosity of the blood does not remain constant during narcosis, according to R. BURTON (*Jour. of Physiol.*, July 13, 1905). It is increased by deep and lessened during light narcosis. These differences cannot be considered of great importance, and the changes which result from the administration of moderate doses of morphine and ether or morphine and chloroform must at most be very slight. The changes in the specific gravity pursue a parallel course to those in the viscosity, in the case of light ether narcosis. During narcosis from chloroform the inverse relationship was found to exist.

The Action of Hyoscines, a Study of Optical Isomers.—It has been shown by A. R. CUSHNY (*Jour. of Physiol.*, July 13, 1905) that while levorotatory hyoscyamine has a powerful action on the salivary glands, heart and iris, the dextrorotatory artificial base is almost devoid of effect on these organs. The author has since studied the differences in the physiological action of the two isometric hyoscines. Levohyoscine (lately called scopolamine) acts twice as strongly as the racemic base (artificial or dextrorotatory hyoscine) on the terminations of the secretory nerves in the salivary glands and of the inhibitory nerves in the heart. It may be inferred that a similar ratio holds in other analogous terminations. Levohyoscine and racemic hyoscine have the same effect on the central

nervous system in man and mammals, and on the terminations of the motor nerves in frogs, in which they do not seem to affect the central nervous system. From this it would appear that, as in the case of the hyoscyamines, the dextrorotatory hyoscine is practically inactive in the terminations of the secretory and cardiac inhibitory nerves, while it acts equally strongly with the levorotatory base on the central nervous system in mammals and on the motor nerve ends in frogs. On the other hand dextrohyoscine differs from dextrohyoscyamine in not stimulating the spinal cord in the frog, but this may be due to its being very rapidly excreted. Hyoscyamine is practically devoid of hypnotic action in man, when given in doses which do not affect the peripheral organs.

The Functional Connection between Auricles and Ventricles.—In 1893, His described a bundle of muscle-fibers lying in the septum between the right and left sides of the heart, which he believed forms a connection between the auricles and ventricles. H. E. Hering (*Pflüger's Archiv*, May 31, 1905) proves that this bundle, which he terms His' transition-bundle, or connecting bundle, really does functionally unite auricles and ventricles. A very small cut in the septum between the ventricles is capable of destroying the functional connection between the auricles and ventricles, provided that this cut is in the region of the bundle described by His. This discovery was made in the dog, but since the connecting-bundle is also found in the hearts of other mammals, including man, there is no doubt that in these the connecting-bundle has the same function. According to Retzen, in adult man this bundle is 18 mm. long, 2.5 mm. broad, and 1.5 mm. thick. In a four-year-old child, the greatest diameter is 1 mm. Since the connecting-bundle, corresponding to its relatively small size, can hardly be supposed to possess any other function, the question arises: Why do muscle-fibers carry the cardiac excitation, instead of nerves which have this for their proper function? The answer is that the excitation is carried from auricle to ventricle by muscle-fibers because in mammalian hearts the conduction of the wave of cardiac activity is a muscular one.

The Force of Contraction of the Gall-Bladder and the Course of Its Motor and Inhibitory Nerve Fibers.—To show the force of contraction of the gall-bladder and the course of its motor and inhibitory nerve fibers, U. A. Chase (*Bull. Johns Hopk. Hos.*, June, 1905) performed a series of experiments on dogs. By means of special apparatus and after the skeletal muscles had been paralyzed by curare, the splanchnic nerves were stimulated. All possible error from direct or reflex stimulations of the skeletal muscles were entirely excluded. The author states that it appears from the results obtained that the bladder is capable of contracting against a resistance such as is offered by a column of Ringer's solution 214.5 to 313 mm. high. Moreover, the sudden maximum increase of pressure against which the bladder is working is about 200 mm. It seems evident from these figures that the musculature of the bladder is comparatively weak, and that its contractions are not at all comparable in force to those of the urinary bladder, which, according to Mosso, may contract in the dog with a force sufficient to support a column of water two meters high. Indeed, the maximum force of contraction of the bladder does not much exceed the maximum secretion pressure as determined by Haidenhain. After experiments to determine the course of the motor and inhibitory nerve fibers of the gall-bladder, the author arrives at the following conclusions: (1) The musculature of the gall-bladder is provided with motor (constrictor) and inhibitory (dilator) nerve fibers. These fibers are found in the splanchnic nerves; (2) both the motor and inhibitory fibers arise from the spinal cord in the roots of the sixth to the thirteenth dorsal nerves. The maximum outflow for the constrictor fibers is in the tenth, eleventh and twelfth dorsal nerves. The dilator fibers appear slightly higher up and are most in evidence from the eighth to the twelfth dorsal nerves, inclusive.

PRESCRIPTION HINTS.

Gastralgia.—

℞ Arseni trioxidi ..... gr. 1/24
Extr. gentianæ ..... gr. ii.

M. et fiat pil. Sig. one t. i. d. between meals. In severe cases employ counter-irritation over the epigastrium by means of the following:

℞ Ol. cajuputi ..... ʒ i
Tinct. capsici ether ..... ʒ iii
Lin. camphoræ ammon. ..... ʒ iv

M. et Sig. For external use. Rub in for 5 to 10 minutes once or twice daily.

In still severer cases use following externally:

℞ Pulv. ipecac. ..... ʒ ss
Lin. crotonis ..... ʒ ss
Adipis ..... ʒ i

M. ft. unguent. (Sawyer.)

Dropsy of Advanced Mitral Disease.—

℞ Pulv. digitalis ..... gr. i
Pulv. scillæ ..... gr. i
Pil. hydrarg. ..... gr. i
Conf. rosæ gallæ ..... q. s.

M. Fiat pil. Sig. One to be taken thrice daily between meals. (Sawyer.)

For Occasional Use in Constipation.—

℞ Magnes. pond ..... ʒ ss
Ol. ricini ..... ʒ ss
Mellis depurat ..... ʒ i

M. fiat confectiv. Sig. One teaspoonful at bedtime. (Sawyer.)

Backache of Loaded Colon.—

℞ Sodii et potassii tart. ..... ʒ iss
Sodii bicarb. ..... ʒ ss
Acid. tart. vel acid. citric ..... ʒ iiiss
Ol. limonis ..... ♏ iv

M. fiat pulvis. Sig. Two teaspoonfuls to be taken dissolved in a tumblerful of cold or warm water. (Sawyer.)

Eczema.—

℞ Lead oleate ..... 24 parts
Liquid paraffin (B. P.) ..... 14 parts

M. et Sig. Apply locally. (Sawyer.)

Traumatic or Irritative Dermatitis.—

℞ Zinci oxidi ..... ʒ iiss
Ol. amygd. dulcis ..... ʒ v
Lanolin ..... ʒ v

M. et Sig. Apply to part on a cloth. (Sabouraud.)

Hyperidrosis of the Feet.—

℞ Sodii salicyl. ..... ʒ ss
Potass. permanganat. ..... gr. xlv
Talc. pulv. ..... ʒ i
Bismuth. subnitrat. ..... ʒ iss

M. et Sig. For external use. (Brocq.)

Alopecia.—

℞ Acidi acetici crystal. ..... ʒ iiss
Chloroformis ..... ʒ iiss

M. et Sig. For external use. (E. Besnier.)

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 16, 1905.

NEW LIGHT ON THE PNEUMOCOCCUS.

It may seem almost Utopian to expect that some day it will be possible to interpret disease in terms of mathematics. Yet no less distinguished an investigator than Ferdinand Hueppe has expressed the belief that at no distant date it will be possible to apply the language of the differential calculus in the solution of the problems of pathology; for disease is a function of a number of variables, such as heredity, nutrition, climate, bacteria, etc. Translating this into the ordinary phraseology of medicine, it may be stated that in order to gain a clear conception of the nature of any morbid condition, it is necessary to consider the extremely variable character of its etiological factors.

This applies with peculiar force to pneumonia, a disease which has recently challenged the keen attention of the profession, by virtue of its gradually increasing virulence in urban communities during the past two decades. The organization of the Pneumonia Commission at the instance of the New York Board of Health was a laudable recognition of the need of probing into the variations in the causes of the disease, with the view of exercising a more effective control of the latter.

It is quite natural that the first point of attack in this investigation should be the pneumococcus, for this is the most tangible of all the etiological factors in the disease, and the one most susceptible to hygienic control. The first burdens of the Commission were therefore transferred to the shoulders of the bacteriologists, and during the six months that these have been attacking the unsolved problems of the pneumococcus, they have not only added a fund of valuable information to the meager knowledge we already possessed, but they have also given an earnest of far greater additions in the near future. The interesting results of these researches have just been published in the *Journal of Experimental Medicine*, August 25, 1905.

The investigations were carried out in New York, Philadelphia and Boston, and special lines of research were assigned to different bacteriologists. The main problems concerned the occurrence and the varying virulence of the pneumococci and its relatives found in the human mouth in health and disease, the occurrence of pneumococci in the hospital wards, the study of the buccal flora before and after outbreaks of pneumonia, the varying vitality of the pneumococcus, and the question of mouth disinfection. Some of these subjects had already been investigated, but the discovery of newer and more precise methods of identification of the pneumococcus made a repetition of this work indispensable. The pathological laboratory of the College of Physicians and Surgeons, New York, served as the central laboratory for the organization and direction of the work, under Professor Hiss.

Professor William H. Park and Dr. A. W. Williams, assisted by a large staff at the Research Laboratory of the New York Health Department, found that the throat of a large percentage of healthy persons, whether living in the city or in the country, harbors typical pneumococci. A larger percentage of atypical pneumococci, many of which seem to be closely related to the streptococci, are found in healthy persons than in those suffering from pneumonia. These normal throats also show a lower percentage of stains of pneumococci virulent for rabbits than the cultures obtained from cases of pneumonia. One very important series of experiments led to the following conclusion, to quote the language of the authors: "Since the virulence of pneumococci may be rapidly increased for a susceptible species of experimental animal by successive passage, and since pneumococci obtained from most pneumonias are more virulent for experimental animals than those obtained from healthy

individuals, therefore the virulence of pneumococci from cases of human infection is probably increased for human beings; hence cases of pneumonia should be considered, to a certain degree, contagious, and since the virulence of the pneumococcus may be quickly increased, and since the organism is very prevalent in normal sputum, all possible measures should be taken to restrict public expectoration."

In view of this important finding, it is certainly pertinent to ask whether the municipal authorities are doing everything in their power to prevent public expectoration. Large signs are prominently displayed on the subway platforms warning the passengers against the possible penalties to be meted out to the spitting offenders, yet, judging by the extreme frequency of this act, there seems to be a general idea that expectorating on the rough roadbed between the tracks is not only allowable but is also a praiseworthy diversion.

That in the course of time an efficient antitoxic serum will be available in the curative treatment of pneumonia, is a hope founded on tangible experimental results. Park and Williams, by means of inoculating sheep repeatedly with a pneumococcus strain, succeeded in producing a specific protective power of sheep's serum for mice against not only the homologous strain, but also against certain other strains. There is also developed an increased phagocytic power in the sheep.

A point that has an important bearing on the subject of the seasonal distribution of cases of pneumonia, is the discovery by Warfield T. Longcope and W. W. Fox that among the various cultures obtained from the saliva of normal individuals, the percentage of the true pneumococcus type is not very large in the month of November; in December it increases enormously, to fall gradually to a low level in March and April.

One very important feature of the industrious research conducted by Dr. Leo Buerger at the Pathological Laboratory of Mt. Sinai Hospital, was the evidence it afforded of the communicability of the pneumococcus from one person to another. Patients may acquire the pneumococcus during their stay in the hospital wards, and this germ may remain in the mouth for a long time afterward. It is also found for varying periods of time in the mouths of patients that have recovered from pneumonia. Persons in whose mouth the pneumococcus has been repeatedly found to be absent, may acquire the organism by association with pneumonia cases or with normal individuals in whom the pneumococcus is present. Living and virulent pneumococci are found in the handkerchiefs and dishes of pneumonia patients and "positive normal" cases, and on the lips of drinking cups and in the sputum floating on the surface of the so-called disinfectant liquid in the sputum cups. The author also found that seventy-nine per cent. of the pneumococci found in the mouths of normal persons are virulent. From this result one may reasonably conclude that the more general practice of a strict toilet of the buccal cavity will go far toward diminishing the prevalence of pneumonia.

The investigations of Professor Philip Hanson Hiss lead him to conclude as follows: "It seems more than probable that practically every individual, at least during the winter season, when exposed to environmental conditions such as those existing in New York City, acts as the host at some time or other, and probably at repeated intervals, of organisms of the true pneumococcus type." He also suggests that the pneumococci stand in etiological relation to some, at least, of the "common colds." A lesson of extremely practical import may be derived from these findings, namely, in view of the fact that the exciting bacterial sense of pneumonia is almost universally present in the normal mouth, the main hygienic precautions should be directed toward maintaining at par the general bodily health, thus minimizing the possibility of constitutional invasion. This, however, leads to the subject of the other etiological factors of pneumonia, with which it is hoped future researches will cope as ably as the present investigations have wrestled with the bacteriological aspect of the problem.

One of the important factors in the communicability of pneumonia is the dissemination of moist or dried sputum, either by means of the atmosphere or by means of articles of clothing. A careful study of the viability of the pneumococcus after drying was made by Professor F. C. Wood. He found that "in moist sputum kept in the dark at room temperatures the average life of the pneumococcus is eleven days, while in the same sputum kept at 0° C. the average life of the organism is thirty-five days. In dried sputum in the dark the pneumococcus lives on an average thirty-five days; in diffuse light, thirty days; and in sunlight, less than four hours. In powdered sputum even when kept in the dark

the death of the pneumococcus takes place in from one to four hours. When exposed to sunlight death occurs within an hour. Sprayed sputum particles remain in suspension for twenty-four hours. When sputum containing pneumococci is sprayed the organisms rarely survive for more than an hour, and often die in less time. The mucus of the sputum exerts a destructive action on the pneumococcus. Exposure of bacterial spray to sunlight while in suspension results in the destruction of the pneumococcus within half an hour." It is pointed out by Dr. Wood that inasmuch as moist sputum does not give off bacteria even when exposed to strong currents of air, it may be considered as innocuous except to persons handling clothes, bedding, etc., which have recently been contaminated. "The danger of infection from powdered sputum may be avoided by ample illumination and ventilation of the sick-room in order to destroy or dilute the bacteria, and by the avoidance of dry sweeping or dusting." It is also shown that the spray perish in from a few minutes to an hour pneumonia patient, may, if the ventilation of the room is good, be suspended in the air for a number of hours. The pneumococci present in the spray perish in from a few minutes to an hour and a half. "The risk of infection from the pneumococcus is largely confined to those in direct contact with the person whose excreta contain the organism."

We have quoted at length from the contribution of Professor Wood, for his results furnish a nice scientific demonstration of facts which have already been partly taken for granted. In contradistinction to the tubercle bacillus, it is to be noted that the process of drying diminishes the viability of the pneumococcus. The effects of sunlight and ample ventilation justify the modern recognition of these agents as valuable factors in the management of cases of pneumonia.

In surveying this valuable series of contributions to scientific medicine, it may be noted that while many of the facts revealed have already been suspected, a number of entirely new and unexpected phenomena have been discovered. Among these not the least important is the fact that the species pneumococcus includes a wide variety of organisms, each of which has a variable degree of virulence, and that bacteria which have hitherto been classified among the streptococci belong or are closely related to the pneumococci.

GILT-EDGED UNDERTAKING.

ONE of the most marked characteristics of the American mind is perhaps the narrowness of the line dividing pathos from bathos. The prompt ability to see the ludicrous element in any situation, no matter how gruesome or incongruous it may be, is all pervading.

With us it is but a short step from the sublime to the ridiculous and the professional humorist will readily extract more than sermons from the cold sepulchral stones while the reporter of hangings and lynchings is painfully apt to find good in everything. For the business and details of the undertaker's art have long been as fruitful a source of amusement to the American scribe of the higher class as the mother-in-law jest has been to the minor paragraphist who follows suit with the items of the advantage of flowers on the table and ice on the butter.

Of these writers Mark Twain has been perhaps the most prolific with his "Undertaker's Chat," "The Art of Inhumation" and the considerate undertaker with the rat in Huckleberry Finn. It was, however, Bret Harte who first struck the key-note, in 1879, of the advance in scientific undertaking, and foreshadowed the possibilites and results that were then only in their infancy. A prophecy that has not only been fulfilled, but which, according to M. Bertillon, of Paris, has been surpassed, for in Harte's time the "process" claimed no other merit than the ability to lighten the mourning heart and to cheer the drooping spirits of the bereaved. But we must remember that the telephone was long regarded as a toy, impossible of practical adaption, while the power of steam was considered as only of sufficient value to "raise the lid" of the kettle in the experimentor's brain.

The article in question was one of Harte's earlier publications and was entitled "Sleeping Car Experience." It consisted principally, as will be remembered, of a dialogue between two passengers, who, having boarded the train in the middle of the night, at a way-station, had taken seats in the one vacant section and were indulging in conversation in a languid, perfunctory sort of way. The remarks, which were evidently the continuation of what had been already said, were opened by the "One Man" with a feebly concealed yawn. "Yes! Well I reckon he was at one time as popular an undertaker as I knew."

The Other Man (feeling that it was incumbent upon him to say something), "But why was he popular as an undertaker?"

The One Man (lazily), "Well, he was kinder popular with widders and widdererers—sorter soothen 'em, a kinder keerless way: slung 'em suthin here and there, sometimes outer the Book, sometimes outer hisself, ez as a man of experience as hed hed sorrer."

The Other Man: "But how did he lose his popularity?"

The One Man: "Well that's the question. You see he interduced some things into undertaking that waz new. He had, for instance, a way, as he called it, of maniperlating the features of the deceased."

The Other Man (quietly): "How maniperlating?"

The One Man (struck with a bright, aggressive thought): "Look yer, did ye ever notiss how, generally speakin', onhandsome a corpse is?"

The Other Man had noticed this fact. "Yes, Sir," continued the One Man, "This yer undertaker, this Wilkins, had a way of correctin' all thet. And just by maniperlation. He worked over the face of the deceased ontil he perduced what the survivin' relatives called a look or resignation—you know a sort of smile like. When he wanted to put in any extrys he perduced what he called—having regular charges for this kind of work—a Christian's hope."

The Other Man: "I want to know?"

"Yes; well I admit at times it was a little startlin', but it wazn't thet which made him onpopular."

The Other Man: "Well, what *did* make him onpopular?"

The One Man: "Extrys, I think. When Mrs. Widdecombe lost her husband she put up a big funeral for the deceased. She had Wilkins, and that undertaker just laid hisself out; just spread hisself. Onfort'nally—perhaps fort'nally in the ways of Providence—one of Widdecombe's old friends, a doctor up thar in Chicago, comes down to the funeral. He goes up with his friends to look at the deceased, smilin' a peaceful sort o' heavinly smile, and this yer friend turns round, short and sudden, on the widder settin' in the pew and kinder enjoyin', as wimen will, all the compliments paid the corpse, and he says, says he: 'What did you say your husband dies of, Marm?' 'Consumption,' she says, wiping her eyes, poor critter, 'Consumption—gallopin' consumption.'

"'Consumption be d—d,' sez he, being' a profane kind of Chicago doctor, and not bein' ever under conviction. 'A Christian's resignation be blowed. Hell is full of that kind of resignation. It's pizon. Thet man died of strychnine. Look at that face: look at that contortion of them fashal muscles. Thet's strychnine. Thet's *Riser's Sardonikus*.'"

Now, while we frankly admit that this early attempt to soothe the dull cold ear of death was not a complete and glittering success, yet we do claim that it was unquestionably the acorn from which the Bertillon oak has grown. In fact the situation resembles that of Dr. Oliver Wendell Holmes' lectures on physiology, when the galvanized leg of the frog refused to respond. "Gentlemen," the dear old autocrat was wont to say, "the experiment failed, but the principle remains the same." Then too, this matter of cosmetic effect is one of the things that they do better in France. Gaston's fingers are more adapted to the niceties of the "laying out" business than are those of Buffalo Bill, and in these matters Tennessee's partner cannot compete with Alphonse.

The Gallic adaptation, however, is yielding more practical results, according to the *Bulletin générale de Thérapeutique*, which gives an account of M. Bertillon's plan, lately adopted in Paris, of facilitating the identification of bodies by a modification of the ordinary photographic process. "Before the picture is taken a few drops of glycerin are injected with a Pravaz' syringe into the eyes of the corpse. After this, it is stated, the lids open and expression is restored to some resemblance of life itself. The glitter of the eyes, however, is still wanting. This is secured by a further injection into the sclerotic. This illusion is completed by rubbing the lips with carmine, and the body thus prepared is said to yield a *living portrait*."

Alas, poor Yorick! A living portrait, with glistening eyes and carmined lips. A living portrait that only, perhaps, requires a further injection of glycerin into the abdominal muscles to yield on pressure the faint echo of "Papa" and "Mamma," and thus to complete the resurrection and the life.

MECHANICAL LAVAGE OF THE BLOOD.

While the pharmacologists and the students of immunity are trying to discover, from their individual points of view, the substances with which to combat the various bodily infections, a simple and at first sight ludicrous method of

treating a certain class of intoxications has suggested itself to an ingenious French clinician.

M. Charles Répin (*Comptes Rendus de l'Acad. des Sciences*, July 24, 1905) has actually proposed the startling procedure of removing the blood from the body, and then, after treating this in a simple manner so as to remove its noxious qualities, to return it to the blood-vessels. The novelty of this form of therapeusis is fully equaled by the daring of its conception. If this proposition were not founded on a series of successful animal experiments, one would be justified in dismissing it as the flippant product of a riotous imagination. In fact, the results of these experiments are such as to warrant a careful consideration of this method of blood-renovation.

One year ago the author invented an instrument by means of which he could rapidly separate the red blood cells from the plasma, and then replacing the latter by a saline or nutritive solution, be able to return the new mixture to the blood stream. The essential part of this device is a centrifuge. Simply stated, the mode of conducting his experiments was as follows: A canula was inserted into the external jugular vein of the mammal experimented upon, and a certain quantity of blood allowed to flow into the mechanical separator. The blood was then quickly centrifuged, the plasma drawn off and replaced by a quantity of normal salt solution, isotonic with the blood, or of a solution of glucose or saccharose. The mixture of red blood cells and artificial solution was then returned through the canula, which had been left in place, to the interior of the vein.

It has been found that this process does not injure the red blood cells, for after the experiment no hemoglobinuria is observed. Definite quantities of the artificial substitute for the blood-plasma must be used. The isotonic solutions of glucose or saccharose are rendered alkaline by phosphate of soda (3 to 1,000). The amount of the artificial plasma added varies from 8 to 20 times the amount of blood that has been removed. If the proportion of blood is only one volume to eight or ten volumes of the diluting agent, then 2 or 3 parts per 1,000 of citrate of soda are added to prevent the formation of thrombi in the blood-vessels.

It is possible to thus remove one-fifth of the entire volume of blood from an animal without the production of ill effects. If this limit be exceeded dyspnea will occur. If this is slight it will rapidly disappear if further removal of blood be stopped. If not, then the dyspnea increases and is followed by acute pulmonary edema. The cause of the latter is the diminished viscosity of the blood produced by the large amount of water injected. Watching the respiration it is possible to prevent these dangerous sequences by controlling the injection. Thus, in a goat the author was able to remove one-fourth of the plasma at one time. A few hours later the operation may be repeated without ill effects.

This unique procedure represents an up-to-date version or modification of the old-time practice of bleeding. There can be no doubt that in some cases this heroic remedy produced its good effects by diminishing the amount of toxins circulating in the body. In fact, venesection finds part of its modern justification in cases of gas poisoning, uremia, and other intoxications, in which it furnishes a ready means of removing a dangerous excess of toxic material from the blood. The chief danger, however, that results from bleeding is the reduction in the oxygen-carrying capacity of the blood, as shown by the air-hunger that follows induced or accidental hemorrhage. This disadvantage of venesection is obviated to a large degree by the return of the red blood cells uninjured to blood stream. The saline or nutritive solution serves not only to suspend the red blood cells, but also to maintain the normal fulness of the blood-vessels, and the normal osmotic relationships of the blood. The stimulant properties of the injected fluid must not be overlooked.

It is pointed out by M. Répin that "deplasmatation," which is the name given to this scientific development of venesection, has absolutely no value for infections in which the poisons are fixed to the cells. Since this is the case with the greater number of intoxications, one can predicate only a restricted field of usefulness for this interesting form of therapeutics. It would seem to be indicated in those diseases in which the poison circulates freely in the blood, such as eclampsia and uremia. It remains for some bold clinician to test the actual curative value of "deplasmatation."

Mobile Free of Fever.—Dr. Joseph Goldberger, of the Marine Hospital Service, who was sent to Mobile, Ala., by Surgeon-General Wyman to investigate the report that there was suspicious sickness there, has visited every house where a person is ill. He said on September 11 that there is not the slightest evidence of a case of suspicious fever.

ECHOES AND NEWS.

NEW YORK.

Manhattan State Hospital Sports.—An interesting and varied program of athletic sports, postponed from Labor Day, was given on September 9 by the patients and employees of Manhattan State Hospital, Ward's Island. It included baseball, swimming-race, foot-races of various kinds, tug-of-war, basket-ball, and a nail-driving contest. Music was furnished by the hospital orchestra, and refreshments were served.

Fire in Rockefeller Research Institute.—A recent fire in the laboratory of the Rockefeller Institute for Medical Research, which occupies a wing of the Nursery and Child's Hospital in Lexington Avenue, near Fiftieth Street, for a time seemed to imperil the lives of the mothers and babies in the hospital. Prompt action on the part of the firemen prevented serious damage. The fire was started by an oily concoction boiling over in the absence of a physician, who was reducing a mixture intended for use in the treatment of pneumonia.

Antityphoid Campaign.—Five hundred engineers from various parts of the country who are interested in water works gathered at the annual convention of the New England Water Works Association at the Murray Hill Hotel on Wednesday. The convention continued in session four days. A number of important papers on the use of copper sulphate to guard against typhoid fever epidemics, arising from unfiltered surface water supplies, were read. This new treatment of water supply has aroused much interest among water-works engineers. Dr. George T. Moore, of Washington, gave a general exposition of the problem. Then Prof. W. P. Mason, of Troy, described the uses of copper sulphate. The destruction of typhoid fever germs by copper sulphate was the theme of D. D. Jackson, of Brooklyn. Prof. Henry Kraemer, of Philadelphia, then gave his views on the germicidal properties of metallic copper. An erudite paper on how the sulphate behaves and what its uses are in purifying hard and turbid water was contributed by J. W. Ellms, of Cincinnati. G. A. Johnson, of Columbus, followed with some facts showing how the sulphate is applied. Other papers on the problem of vanquishing the typhoid fever germ by the use of copper were read, and a general discussion followed.

The American Tuberculosis Exhibition.—Arrangements are progressing favorably for the American Tuberculosis Exhibition, to be held in New York, November 27 to December 9. Sanatoria and anti-tuberculosis societies in all parts of the United States will cooperate to make the affair a success, and it is expected that a large part of the material from the French Exposition, to be held in Paris in October in connection with the International Congress of Tuberculosis, will be shipped to New York for the American exhibition. The committee of arrangements is also planning a series of conferences on special phases of the tuberculosis problem, which will be open to the public and will be of popular interest and value. Recent developments of note in the antituberculosis campaign are the organization of State associations to fight the disease in Iowa and Kentucky. The Iowa Association for the Study and Prevention of Tuberculosis was formed at a meeting called for the purpose at Des Moines, on July 27, and attended by representative physicians and laymen from all parts of the State. The new society is in the hands of a strong board of directors, with ex-Governor William Larrabee as president and Dr. E. Luther Stevens, Des Moines, as secretary. The Kentucky Antituberculosis Association, also recently organized, has its headquarters in Louisville, with W. C. Nones as president and George L. Sehon as secretary.

PHILADELPHIA.

Enteric Epidemic at Nanticoke.—Typhoid fever has made its appearance in the small mining town Nanticoke, near Wilkesbarre, Pa. In the space of a very short time more than one hundred cases occurred and so rapid has been its spread that the opening of the public schools has been postponed. The source of the water supply is from a mountain lake.

Typhoid Fever Not Yet Eradicated.—There were but five wards from which cases of enteric fever were not reported last week; each of these wards is supplied entirely with filtered water, a fact that lead the health authorities to believe that those cases reported from wards reciving filtered water are imported from summer resorts or elsewhere, and are not to be credited to the city water. Last week 125 cases were reported in contrast to 62 the preceding week.

Still on the Look-out for Yellow Fever.—Last Wednesday the American steamship Shawmut arrived at Reedy Island Quarantine Station, having on board a sick sailor whose condition aroused the suspicion of the authorities and caused the vessel to be detained. While the physicians were not inclined to diagnose the case as yellow fever they saw in it some evidences of that disease. The crew was placed in quarantine, the vessel fumigated and then sent to its destination.

Scopolamine as an Anesthetic.—Surgeons of this city have recently turned their attention to the study of scopolamine, but instead of using the drug to quiet patients suffering from delirium tremens or the delirium of the acute infectious diseases as reported by Liepolt (*Berlin. klin. Woch.*, No. 15, 1904) they have injected the drug hypodermatically for the relief of pain produced by operation. Dr. Orville Horwitz did a Bottini operation on a man seventy-three years old at the St. Agnes's Hospital after injecting 0.1 mg. of the drug with the addition of 25 mg. of morphine into the patient's arm. The man remained quiet for two hours and then awoke without nausea or vomiting. Dr. A. C. Wood has been making similar experiments at the Philadelphia Hospital.

School Teachers Must Obey the Health Law.—In order that this may be accomplished Dr. Dixon writes to the principals as follows: "Your attention is respectfully called to section 12 of the act of Assembly of June 18, 1895, which declares that 'all principals or other persons in charge of schools as aforesaid (namely, public, private, parochial, Sunday or other schools) are hereby required to refuse the admission of any child to the schools under their charge or supervision, except upon a certificate signed by a physician, setting forth that such child has been successfully vaccinated, or that it has previously had smallpox.' Section 21 of the same act provides that the penalty for failure, neglect or refusal to comply with or violation of this requirement shall, for every such offense, upon conviction thereof before any mayor, burgess, alderman, police magistrate or justice of the peace, pay a fine or penalty of not less than $5 or more than $100, and in de-

fault of payment thereof be imprisoned in the county jail for a period not exceeding sixty days. I beg you to observe that in this matter the principal or teacher is responsible, not to the school directors, but to the health authorities of the state or the municipality, and that no action of the school directors can supersede the requirements of the law. Any attempt to shift the responsibility onto the shoulders of the directors would therefore be attended by serious risk. I do not allow myself to doubt, however, that your own intelligent appreciation of the importance of the strict enforcement of this law, both for the protection of the health of the children under your care, as well as of that of the entire community, and for the avoidance of the serious interference with education which such an outbreak of smallpox in a community always involves, will make further reference to penalties entirely unnecessary."

To the secretaries of the Board of Health Dr. Dixon sent the following: "Allow me respectfully to call your attention to the fact that section 13 of the act of June 18, 1895, requires that 'the health authorities of all municipalities shall furnish to principals or other persons in charge of public, private, parochial, Sunday or other schools, and to physicians, the necessary certificates or blanks for the uses and purposes' as set forth as required in section 12 of said act, which section reads as follows: 'All principals or other persons in charge of schools as aforesaid are hereby required to refuse the admission of any child to the schools under their charge or supervision, except upon a certificate signed by a physician setting forth that such child has been successfully vaccinated, or that it has previously had smallpox.' Section 13 provides in addition that 'the registry of said schools shall exhibit the names and residences of all children or persons admitted or rejected for reasons set forth in this act, and said registry shall be open at all times to the inspection of the health authorities.' In view of the above-recited requirements, and the near approach of the opening of schools, I would suggest the importance of at once making inquiry in order to discover whether the principals or other persons in charge of all schools (public, private, parochial, Sunday or other schools), and all physicans within your jurisdiction, have been thus supplied with the necessary certificates, blanks or registries as required by law. It will be the duty of your board to supply any deficiencies in this respect. It will also be its duty to notify each principal or teacher, as the case may be, formally and in writng, at least one week before the opening of the schools, of the requirements of the law and the penalties for its neglect or violation."

CHICAGO.

Additional Ground for Illinois Infirmary.—The Illinois Charitable Eye and Ear Infirmary have acquired 100 feet additional frontage on Peoria Street, just north of Adams Street, for $20,000, on which to build a modern fireproof addition to its present building.

Guilty of Illegal Practice.—For practising medicine without a license, John Pattie, of Peoria, was recently found guilty and fined $100 and costs. Pattie has appealed from the decision of the court, and claims that he practised under the special direction of a licensed physician.

Washington Park Hospital.—The cornerstone of this hospital, located at 6010-6012 Vincennes Avenue, was laid September 4, and distinguished Swedish physicians took part in the ceremonies. The structure will be three stories high, 125 by 44 feet, and will have a capacity of 75 beds. The cost is to be $50,000. It will be ready for occupancy next January, and with the present buildings will have a total capacity of 105 beds.

New Hospital for Canton, Ill.—The Misses Graham, of Washington, D. C., who were formerly residents of Canton, propose to furnish the necessary grounds and to erect a public hospital building thereon at Canton, to cost $15,000, and containing about twenty rooms, under the condition that an endowment of $20,000 shall be provided, that the hospital shall be free to all schools of medicine, and that at least five rooms shall be available for charity patients.

Tuberculosis Death Rate Decreasing at Dunning.—The death rate among tuberculous patients at the Dunning institutions has decreased 15.31 per cent. since they have been removed to the new consumptive hospital. Superintendent Podstata, in a report submitted to the County Board, recently said this result was due to the surroundings at the new hospital, which is considered a model of its kind, with plenty of fresh air and light. During March, April, May, June, July and August of last year the death rate of tuberculous patients was 42.52 per cent. During the corresponding months this year the death rate is 27.21 per cent. Superintendent Podstata recommends that a small separate ward be constructed for the care of the patients who are helplessly afflicted with tuberculosis.

Notice to Illinois Embalmers.—Secretary Egan, of the Illinois State Board of Health, has issued a notice to Illinois embalmers to the effect that under the provisions of the act approved May 13, 1905, no person shall embalm, or prepare for transportation, any body dead of a contagious or infectious disease, or embalm any dead body, or hold himself out as practising the art of embalming, unless he holds a license from the State Board of Health authorizing him so to do. After September 1, 1905, no transportation company operating in the State of Illinois will accept a body dead of any contagious or infectious disease, unless it has been prepared by an embalmer holding a license issued by the State Board of Health. After January 1, 1906, any person who shall embalm, or prepare for transportation, any body dead of a contagious or infectious disease, or embalm any body, or hold himself out as practising the art of embalming without having obtained a license from the State Board of Health, shall be deemed guilty of a misdemeanor.

CANADA.

The Canadian Medical Association.—The thirty-eighth annual meeting of the Canadian Medical Association was held in Halifax, N. S., August 22 to 25, under the presidency of Dr. John Stewart, Halifax, the general secretary being Dr. George Elliott, Toronto. It was the third largest meeting in the history of the association so far as actual attendance from the Canadian profession was concerned, and more than quadrupled the attendance at the former meeting, held in that city in 1881. Among those who attended was the Hon. Dr. Parker, of Halifax, the second president of the association, and there were but two others present who had been in attendance in 1881. In that year the farthest point from which a member traveled was London, Ontario; this year there were some from British Columbia. The formal opening took place on August 22, when the Reverend President Forrest, of Dalhousie University, opened the proceedings with prayer. Following him His Honor, the Lieutenant-Governor of Nova Scotia, welcomed the visiting delegates in the

name of the Province Down by the Sea. Then the Mayor of Halifax extended a welcome on behalf of the corporation of that city, and following His Worship, the president of the Medical Society of Nova Scotia, Dr. H. A. March, of Bridgewater, read an address on behalf of that society, which acted as hosts.

Dr. John Stewart then read the annual presidential address, after which Dr. D. A. Campbell, of Halifax, read the Address in Medicine, taking for his subject the history of the medical profession in Nova Scotia. The Address in Surgery was delivered the following day by Mr. Francis Caird, of Edinburgh, and in the afternoon of the same day Dr. J. W. Stirling, of Montreal, read the Address in Ophthalmology. On the evening of the next day Dr. Howard A. Kelly, of Baltimore, read the Address in Gynecology, his subject being cystitis in women. Following that were two lantern demonstrations of much interest, the first conducted by Dr. J. M. Elder, of Montreal, in the absence of Dr. J. Alex. Hutchinson, Montreal, on fractures as shown by radiographs; the second by Professor J. J. McKenzie, of Toronto University, on recent studies on the elastic elements of the aortic wall in relation to arteriosclerosis. On the morning of the last day a general discussion took place on obstetrics, the particular subject being "The Management of the Puerperal State." This was opened by Dr. Thomas Walker, of St. John, N. B., continued by Dr. H. L. Reddy, Montreal, and participated in by Dr. Albert A. Macdonald, Toronto; Dr. F. R. Eccles, London, Ontario; Dr. M. A. Curry, Halifax; and Dr. D. McIntosh, Pugwash. This proved an interesting feature of the meeting.

Reorganization of the Association.—The most important item of business considered was that of reorganization of the association on the lines of the British Medical and American Medical Associations. This led to the appointment of a special committee, consisting of one member from each province, with Dr. Alexander McPhedran, of Toronto, as chairman. This committee made an interim report before the close of the meeting and was continued. In the intervening time before the next annual meeting suggestions will be asked from the members of the association in the various provinces. The Committee on Public Health, appointed two years ago, was discharged and a new and larger committee appointed in its stead. The convener of this committee is Dr. E. P. Lachapelle, of Montreal, an advanced sanitarian. It was decided to meet in Toronto in 1906 at the same time as the meeting of the British Medical Association.

Election of Officers.—The following were the officers elected for the ensuing year: President Dr. Alexander McPhedran, Toronto; vice-presidents—Prince Edward Island, Dr. H. D. Johnson, Charlottetown; Nova Scotia, Dr. G. Carleton Jones, Halifax; New Brunswick, Dr. Emery, St. John; Quebec, Dr. H. S. Birkett, Montreal; Ontario, Dr. J. D Courtenay, Ottawa; Manitoba, Dr. S. P. Prowse, Winnipeg; Northwest Territories, Dr. H. G. McKid, Calgary; British Columbia, Dr. R. E. McKechnie, Vancouver. Local secretaries: Prince Edward Island, Dr. Simpson, New Glasgow; Nova Scotia Dr. J. R. Corston, Halifax; New Brunswick, Dr. J. A Scammell, St. John; Quebec, Dr. Ridley McKenzie, Montreal; Ontario, Dr. Harold Parsons, Toronto; Manitoba, Dr. J. R. Davidson, Winnipeg; Northwest Territories, Dr. J. Hislop, Edmonton; British Columbia, Dr. W. H Sutherland, Revelstoke. General secretary, Dr. George Elliott, Toronto; treasurer, Dr. H. Beaumont Small, Ottawa; executive council, Drs. W. P. Caven, Albert A. Macdonald and F. LeM. Grasett, Toronto.

GENERAL.

No Plague Cases on the Isthmus.—There have been no further developments regarding the supposed presence of the bubonic plague on the Isthmus. The quarantine has been entirely raised. The sanitary conditions of the Isthmus are comparatively good. There is no yellow fever in the city of Panama.

Official Cholera Bulletin.—An official bulletin issued in Berlin on September 11, says, that 16 cholera cases and 6 deaths were reported from noon, September 9, to noon, September 10, and 15 cases and 6 deaths from noon, September 10, to noon September 11, making the totals 170 cases and 58 deaths.

Russia Not Responsible.—The Government at St. Petersburg reiterates, officially, that the outbreak of cholera did not originate in Russia, as the raftsmen among whom the disease was first discovered, although they came down the Vistula, had been in Germany a fortnight before they became sick, whereas ten days is the period of inception for cholera.

Bites at Night.—At the beginning of the campaign in New Orleans it was stated by the official fever fighters that the stegomyia was to be feared principally during the hours of daylight, biting seldom at night. Health Officer Khonke, however, made this important statement recently: "The stegomyia is a day mosquito, but it has been discovered that shortly after the twelve days' infection it also becomes a night mosquito and bites at night. We did not know this until very recently."

Canal Officials Return.—A number of Panama Canal officials on leave of absence recently arrived in New York on the steamship Mexico. Mr. Benson, auditor of the Canal Commission, said that malaria was more of a cause for worry on the Isthmus than yellow fever. When the Mexico left Colon on September 5 there were but four cases of the fever there. Ten passengers and seven of the crew were found to have abnormal temperatures, and were removed at Quarantine for observation.

Friction in Fever Fight.—Lack of faith on the part of some of the authorities in the mosquito as the only transmitter of yellow fever is given as one of the causes of the controversy which has resulted in Dr. Tichenor's withdrawal from Tallulah, La., whither he had been sent by the State Board of Health to take charge of the situation. Until Dr. Tichenor reached Tallulah no one had any idea of the extent of the disease there. Dr. Tichenor at the end of his investigation telegraphed that the whole town was infected, that the situation was exceedingly serious, and that help was needed. The new cases and deaths since have borne out his first telegrams. Dr. Tichenor immediately proceeded to apply the mosquito theory rigidly, but found that some of those in authority did not altogether believe in it, with the result that friction resulted, and he asked to be relieved. Efforts are being made now to send Dr. Ezdorf to Tallulah.

The Last Battle of a Hundred Years.—The Rev. Beverly Warner, of New Orleans, in a recent issue of *Charities*, writes: "We are not concerning ourselves much these days with questions as to how the fever came in, or trying to shift responsibilities. We are fighting what we believe to be the last battle of a hundred years' war. It is the profound conviction of the health authorities, federal and local, that New Orleans need never again fear an epidemic. When the last case has passed into history, we expect to have proved that the fever is no longer a mysterious enemy, coming from an unknown quarter, and striking in the dark—but an open and well-known foe, against whom we may

always be on guard, and with which we have a certain knowledge of being able to cope. Under the sane and experienced leadership of the Marine Hospital Service, we are fighting at our own cost and charges in men and money. And we expect to win." This expectation is being realized, for at present the fever is spreading only among smaller towns, where the enthusiasm and system of the New Orleans campaign is wanting.

The Progress of Cholera in Germany.—The latest reports from Germany are to the effect that cholera has scattered itself over 32,000 square miles. The district extends from the River Oder northwestward to the Russian border, about two hundred and fifty miles, and from Danzig to Grozisko, south of Posen 150 miles. All this shows not only how difficult it is to guard against the inroads of an infectious disease in more or less densely populated regions, where intercommunication is so varied and intricate, but how impossible it is to educate the people generally in the necessary means for their own safety. The local health authorities are, however, meeting the issues in a valiant and thorough manner.

OBITUARY.

DR. THOMAS MENEES, one of the best known physicians in the South, is dead at his home in Nashville, Tenn., at the age of eighty-three years. Dr. Menees was a member of the Confederate Congress and had been a professor in several Southern colleges.

DR. JAMES LAWS, for many years a surgeon in the navy and for a time fleet surgeon under Admiral Porter, died at Washington, D. C., September 13, aged seventy-eight years. He was born in Philadelphia, was graduated from Jefferson Medical College and entered the navy as a surgeon. He was chief surgeon of the Kane Arctic relief expedition, and received from Queen Victoria a decoration for his services. After the close of the Civil War he resumed the practice of his profession in Philadelphia until 1883, since when he had been an examining surgeon in the Pension Bureau at Washington.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held May 27, 1905.

The President, Charles G. Schram, M.D., in the Chair.

Tendon Transplantation for Deltoid Paralysis.—Dr. Royal Whitman presented a patient six years old who had been a sufferer from complete paralysis of the deltoid. As a consequence of this the humerus hung down out of the socket at the shoulder-joint, and the arm swung absolutely helpless and flail-like. The deformity was corrected by the transplantation of a portion of the trapezius muscle along the shaft of the humerus inserted into the deltoid. When the operation was done the arm was put in an elevated position, the muscle fibers being drawn taut and then was gradually brought downward at intervals afterward until it came to the side of the body. Now the little patient can swing her left arm and put it up above her head, and considers that she can use it as well as other people. As a matter of fact, however, there is very little power in it, but the child has learned to use other muscles in such a way as to help out whatever of power was gained by the transplantation of the trapezius.

Stimulation of Effort.—In these cases before operation as the result of the palsy, children cannot be brought to exercise any effort and so cannot be trained to use whatever little of muscular power they possess. After the transplantation it is necessary to bring training into effect, so as to encourage the use of all the muscles in the neighborhood. While this was impossible before, it is usually not difficult after operation. The palsy in this case was due to an anterior poliomyletis, which affected the child at the age of about two and a half years and left the deltoid completely paralytic. The fibers of the trapezius were fastened to the atrophied deltoid by strong silk sutures of braided silk, which were allowed to remain in place, and have given no difficulty, as they do not in cases where asepsis has been complete.

Echinococcus of Liver.—Dr. Henry C. Coe presented an echinococcus cyst of the liver which had been removed from a patient operated upon for the relief of symptoms pointing to the kidneys. There had been no suspicion of the presence of the cyst until after the opening of the abdominal cavity, and the exploration of the liver region.

Amenorrhea and General Diseases.—Dr. Coe read a paper on the association of amenorrhea with chronic disease. He called attention to the fact that while absence of menstruation, especially after it had once been established, is usually attributed to some affection of the genital organs, not infrequently it is really due to some chronic systemic disease. He has recently had under observation several cases of amenorrhea which ultimately proved to be acromegaly, a disease that is very difficult of diagnosis in early stages. These cases called his attention to the fact that not infrequently diseases of the ductless glands are associated with disturbances of menstruation and usually in the direction of lessening the amount of menstrual flow. The thyroid gland has been of interest to gynecologists for various reasons, but it is evident that the other ductless glands must also be considered because of their effect upon symptoms that come to the gynecologist for treatment.

Illustrative Cases.—One of the first cases was that of a young woman, aged twenty-five years, who suffered from amenorrhea for a considerable period, after having begun to take on flesh. She was married, and it was the sterility of the marriage that brought her to the physician. In this case some marked atrophic changes were found in the uterus, though there had been no hot flushes and no other symptoms of a precocious nature. The taking on of weight recalled somewhat the similar occurrence after castration. In this case thyroid extract was given, which at times proves helpful, though most of the cases are not relieved by it. Some of these patients continue in good health, after their amenorrhea has set in, but many of them decline in health or show symptoms of some constitutional disease.

Acromegaly.—A young woman who presented a marked tendency to adiposity, but with no previous menstrual signs and no local changes in the uterus, began to suffer from scanty and then absent menstruation. Thyroid extract was given, and the faradic current was applied to the thyroid glands, but without effect. In a careful examination made under an anesthesia no cause for the menstrual condition could be found. A year later the coarseness of features and the enlargement of the extremities so characteristic of acromegaly became manifest, and the patient suffered from the intense headache and some of the eye symptoms that indicated the

presence of brain tumor. There was no doubt that the original amenorrhea and tendency to accumulation of adipose tissue was a primary symptom of the affection of the hypophyseal gland.

Adiposity and Coarse Features.—A young girl, aged eighteen years, came under observation not long since, gave a history of having had no menstruation for nearly a year. During this time she had gained much weight, and now weighed two hundred pounds. She had always been stout, but there had been a marked increase in the tendency since the absence of menstruation asserted itself. She already presented the coarseness of features that were suggestive of beginning acromegaly. Besides, there was considerable mental sluggishness, though as yet no complaint of headache. A bimanual examination made per rectum showed the presence of a small uterus, but no pathological condition. The administration of thyroid extract did not help the patient, and the acromegalic tendencies have continued. The frequency with which such cases present themselves for treatment for sterility is rather remarkable, and it is evident that if patients' cases are to be properly understood, there must be a careful review of the history, with the idea of recognizing the possible presence of any affection of the ductless gland.

Curettement and Non-menstruation.—In certain patients the endometrium seems to have a much lessened activity as regards its reproductive powers than in others. In two cases Dr. Coe has seen complete failure of menstruation follow curettement. It is evident that careful precautions must be taken not to allow some of these general diseases that are already beginning to lessen the menstrual flow, to be an unrecognized factor in these cases. In patients in whom the cause for the amenorrhea seems without doubt to be due to some defect of the ductless glands, the administration of these substances does not always or indeed usually prove of much service. Dr. Coe has tried extracts of petuitary and submammary glands both without success. In Hodgkin's disease it is the usual rule for the patient to suffer from scanty menstruation and then, in the course of the disease, to have menstruation stop entirely. Usually any treatment that brings about any amelioration of the Hodgkin's disease will also restore the menstruation; but the outlook is very unfavorable.

Petuitary Therapeutics.—Dr. Howard Lilienthal said, in discussing Dr. Coe's paper, that the use of extract of the petuitary body could not be expected to do any good in acromegaly, since the disease was really due to an enlargement of the hypophyseal gland, and this enlargement was usually malignant. Too much of the specific substance is already finding its way into the circulation, and the addition of further material of the same kind from without would, if possible, only add to the symptoms. Dr. Lilienthal said that Kocher, of Berne, in studying the cases of myxedema consequent upon the ablation of the whole thyroid, which produced the so-called cachexia strumipriva, noticed that amenorrhea was among the first symptoms.

Antagonism of Thyroid and Ovary.—Dr. Coe said, in closing the discussion, there seems to be no doubt now in the minds of physiologists and gynecologists that there is a distinct antagonism between the thyroid and the ovary. By this, of course, is meant that the internal secretion of the ovary which undoubtedly exists, has some action opposite to that of the secretion produced by the thyroid. It is not an unusual thing to find an increase in size of the thyroid, during menstruation. An enlargement of this gland during pregnancy is almost the rule. In these cases of absent menstruation, the thyroid is sometimes diminished in size, but sometimes it is unaffected. Undoubtedly there is some close relationship between these structures, and yet extract of thyroid fails to be of service in many cases.

Gunshot Wound of the Abdomen.—Dr. George T. Chase reported a case of gunshot wound of the abdomen, with perforation of the stomach and intestines, treated by operation, and followed by cure. The patient was a woman of twenty-nine years, married, who during a drunken debauch shot herself with a revolver of small caliber at 3 A.M. She was taken at once to the Hood Wright Hospital, where Dr. Chase saw her about 5 A.M. She was suffering from moderate shock, and the wound of entrance of the bullet was on the left side, just below the costal cartilages, while the wound of exit was on the opposite side, somewhat posterially, so that the bullet has passed straight through the upper abdomen. There was no vomiting, and no urinal disturbance. It was deemed advisable, however, to operate, and the penetrating wounds of the hollow viscera, which were found, showed the propriety of this.

Injured Viscera.—The bullet had penetrated the stomach anteriorly and passed out posteriorly. It had penetrated the descending colon and also the right kidney. The wound in the kidney was through the substance of the organ and not the pelvis. Notwithstanding the presence of these wounds , the contents of the intestinal tract were not found in the peritoneal cavity. After the wounds had been tied up, the kidney wound was flushed out with saline solution, and drainage inserted in this neighborhood. Pneumonia developed on the seventh day, and yet the patient recovered from it. Urine flowed for some time from the posterior wound, but gradually this ceased, and now the patient seems entirely well. One of the important elements in the favorable termination of this case was undoubtedly the fact that the woman like all suicides, wanted very much to get well. The favorable points in the case besides this were the smallness of the projectile, which was probably not more than 22-caliber, the lack of delay before the operation was performed and the excellent physical condition of the patient apart from her drunkenness.

Size of Projectile.—Dr. Howard Lilienthal said that there are two things that make gunshot wounds especially favorable. If the projectile is small, little damage is done and even perforating wounds will sometimes not leak. The old-fashioned bulldog revolver with a smooth bore made a more ragged wound and was more likely to be folowed by septic conditions than the rifled arms of more modern days. If the colon is full then there is danger of perforation. Had the stomach been full on this occasion the patient would surely have run a greater risk. The absence of food in the stomach and intestines is what seems to account for the better results in abdominal wounds of colored patients than in white patients. Colored folks are not quarrelsome as a rule when they have had enough to eat. It is when starving that they are more likely to get into deadly quarrels.

The rule for operation in perforating wounds of the abdomen in civil life is that where circumstances are favorable, and the patient is seen not long after the accident, operation should be performed. In war, however, owing to the lack of facilities for aseptic operation, the opposite rule holds. The percentage

of recovery in war times is not so good in operated cases with the high power of explosive and small-caliber bullets.

Non-Operative Recovery.—Dr. Henry C. Coe said that during his first year of practice he was called to see a severe case of revolver wound of the abdomen, in which the ball had penetrated the abdominal cavity. The patient was a cousin, college graduate and athlete, who was disturbed by finding a burglar in the house. He got up and grappled with him and the burglar held a revolver of 45-caliber against his abdomen and fired. The shock was not enough to prostrate the patient at once, and he succeeded in preventing the burglar from firing again. The incident took place in the country and a country physician was called, had the good judgment not to probe the wound, but simply sealed the anterior wound and allowed the posterior to remain open. No peritonitis resulted and at no time was there any pain. There was some extravasion of urine through the posterior wound showing that, as in Dr. Chases' case, the kidney had been wounded. There was no rise of temperature, however, and the patient proceeded to make an uninterrupted recovery, evidently due to his strong and healthy constitution. The wound was inflicted in the early morning hours, when the viscera were empty, and this seems to have been the other favorable factor. For sometime subsequently he suffered from pyelitis, but was able to continue his athletic exercises though in cold weather there was discomfort in that kidney. Some years later he was able to pass a medical examination for insurance, and now there seems no doubt that he has entirely recovered from the effects of the wound.

Pushing Aside of Tissues.—The most interesting thing with regard to bullet wounds made by the larger projectiles is that occasionally when they are slow going, they push the hollow viscera aside or fail to wound veins or arteries because these yield and allow them to pass. Dr. Lilienthal recently saw a case in which a revolver wound was inflicted just below the eye, and the ball entering a very short distance below the orbit, passed out just behind the mastoid, and yet, in spite of all the important structures that lay in its path, it seemed to have been perfectly direct, not a single one of them was hurt.

Nephrolithiasis.—Dr. Howard Lilienthal read a paper describing some experiences with kidney calculi. The first case was that of a young man of thirty-two years, who had the usual characteristic symptoms of renal colic followed by profuse hematuria. He suffered for an hour before being seen and passed almost pure blood. After a hot bath and perfect rest for some hours, the pain quieted down and he was able to be about the next day. Large quantities of water were advised and a favorable prognosis was given. The patient was directed to take four quarts of water between meals. Over a year later a stone was passed and the patient has been perfectly well ever since. In this case some pyelonephritis developed, causing the presence of albumin in the urine. For a time this prevented the patient from taking out insurance, but subsequently the condition improved, and all the symptoms disappeared. This is now several years ago, and there has been no further complaint. A second case occurred in an older man of sixty-three years, who had his first attack at this age. He was treated just as was the first one, and after drinking plentifully of water for some months, passed a stone, since when there has been no further trouble. In the third case the patient was admitted to Mt. Sinai Hospital with the diagnosis, typhoid fever. There was a marked leucocytosis present, and no Widal reaction could be found. There was some local tenderness in the right iliac region, but all the urine contained red blood cells, and the right kidney was larger than normal. The X-rays were employed, but no stone could be found. After a time an abcess pointed in the flank and was opened with the evacuation of pure pus. For a time this was thought to be a subphrenic abscess from an old appendicitis, but after a time urine came from the wound, and it was evident that the kidney was involved. The wound healed after a time, but later there occurred exacerbations of symptoms, when the temperature rose to 105° F. This patient also was treated with large quantities of water and after a time the sinus closed.

Fallibility of X-Rays.—In a subsequent case a young man of thirty-one years, who had suffered from characteristic renal colic four times, each attack being more serious than the previous one, and each followed by blood in the urine. A careful X-ray examination failed to disclose any hint of the presence of stone. He too was placed on the water regime, and after a time he passed several stones. Phosphatic stones are easiest affected by the water treatment. In general it may be said when only one or two attacks of renal colic have occurred it is always well to give this method of treatment a thorough trial. When many stones are present Dr. Lilienthal considers that it is more advisable to remove the kidney entirely than to do a nephrotomy.

Reflex Anuria.—In a certain number of cases almost any manipulation of the urinary tract in certain sensitive individuals may lead to complete stoppage of the urine. In one case under Dr. Lilienthal's care, the patient was a bad subject because of cardiac and asthmatic complications. As the result of an examination by the uretoscope, complete anuria occurred, and lasted for forty-eight hours, after which the anuria disappeared and was followed by a free flow of urine. Unfortunately a pneumonia subsequently developed and the patient died. In another case where the patient complained of a dull pain in the right flank and there was a distinct tenderness in the right hypochondrium, many stones were removed from the right kidney, but for several hours afterward not a drop of urine was passed. This condition passed off after a time, however, and is evidently one of reflex anuria, though of course the thought that there might be no other kidney present proved a source of worry.

Indications for Operation.—When the stone is very large or when there have been repeated attacks of renal colic, operation is indicated. Otherwise water diuresis should be employed, a quart of water being taken at a sitting within fifteen minutes. This should be repeated four times a day. Whenever pyonephrosis is present operation is indicated. Reflex anuria has been denied and the symptoms attributed to it have been said to be uremic. There is no doubt however that complete anuria from nervous reflex can occur. There is no need of haste in the treatment of the condition, as such patients will live from seven to ten days, even though they are not passing a single drop of urine. Life endured for eight days in the patient from whom the solitary kidney was removed, and true uremia did not develop. After a time there was nausea, and the patient became edematous but there was no convulsions. Various

methods of treatment then may be tried before operation need be considered necessary.

Inversion of Patient.—Dr. Cabot stated that following Dr. Lilienthal's suggestion, he has found that if patients are advised to lie down as far as possible in an inverted posture the hips and legs being much higher than the body the attacks of renal colic may be brought to an end. Subsequently, under the water treatment, such stones may be passed absolutely without pain. In one case in Dr. Cabot's experience this was true, and the only warning the patient had of the passage of the stone was its dropping in the water-closet, whence it was recovered. Dr. Cabot has kept kidney calculi for a year in piperazine solution, but without effect. He considers that reflex anuria from manipulation of the bladder may readily occur and he has seen it last for many hours. The rule, however, is that it passes off without any special treatment.

Hysteric Renal Colic.—Dr. Coe said that it must not be forgotten that in certain highly neurotic women attacks closely resembling renal colic may develop. Some years ago he was called to see a young woman who seemed to be suffering from typical renal colic. Morphine did no good, and chloroform had to be employed for her attacks, several of which occurred. The urine was very scanty and it was considered that a calculus would surely be found. Two of the best surgeons in the city were called in consultation and the kidney was opened, but no trace of a stone could be discovered. There was a rather stormy convalescence, in which the pulse would frequently rise to 140 and the family usually in the night would be summoned to her bedside for a dying scene. Two weeks after the first operation there was a typical attack of renal colic apparently on the other side. Dr. Coe immediately used ether in order to overcome the pain and made the remark that this was what he should have to do every time the attack returned. There was no further occasion to resort to the etherization.

Dr. Coe said that X-ray pictures are apt to be misleading in some cases and always require to be done by an expert and all their features carefully analyzed. He knows of a case in which even a bullet was thought to be present in the X-ray photograph and yet proved not to be where located.

Dr. Lilienthal said that on several occasions in his experience the X-rays have suggested a false diagnosis. In one case there was a distinct shadow present which was thought to be a stone in the ureter. Later examination by an expert in the use of the X-rays led to the report that this apparent stone was really a sesamoid bone, in the obturator muscle. In a member of the house staff who was suffering from renal colic, having every day two attacks, there seemed to be at least three stones present. Later, however, this was demonstrated to be a mistake, and none was found.

Liver in Uremia.—In many cases of uremia the liver is affected as well as the kidneys. In fact, the modern explanations of uremia nearly always include a reference to degenerative conditions of the liver. In anuria it occurs after kidney operations. Not infrequently affections of the liver are found to be present and it is this rather than the operative intervention in the urinary tract that leads to the serious result. In the light of this close association of hepatic and renal lesions it becomes advisable to estimate the condition of the liver before operating upon the kidney.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Regular Meeting held April 17, 1905.

The meeting was devoted to comparative surgery, a report being made of the work done in the course in operative surgery on animals by the third-year class of the Johns Hopkins Medical School. Dr. Cushing, by way of introduction, emphasized the importance of building up a veterinary hospital in connection with surgical teaching—not only for the teaching purposes proper, but also by way of disarming the criticism, perhaps a just one, which was made against the reckless use of material involved in allowing students to operate on healthy animals. Operative surgery was usually taught by work on the cadaver; it was therefore confined to operations on the extremity and ligation of arteries. But the absolutely essential instinct to surgical cleanliness, the ability to handle living tissues, skill in controlling hemorrhage—these things could not be learned from a cadaver. Nor was it possible to teach or to learn visceral surgery in this way.

When the course in animal surgery at the medical school was started, operations were done for hypothetical lesions. The material was not then necessarily wasted, but could often be used in one of the laboratories; a gastrostonized dog, for instance, furnished the physiologist with gastric juice for study, and so forth. Nevertheless this method involved needless operation; and criticism of this feature only began to be disarmed when animals were brought in with lesions which needed treatment. For the future, then, the plan is to build up a veterinary hospital so that animals may receive necessary surgical attention and students may receive useful surgical instruction at the same time.

Hemorrhagic Cysts of the Thyroid.—Mr. Faris reported two cases of this condition occurring in dogs. The first was in an Irish setter. It had caused interference with respiration, and cure was effected by its removal. The second occurred in a hound, was associated with bad temper, muscular twitching, loss of hair, increase in weight and dryness of skin. No exophthalmos was present. The cyst was removed, but without much improvement in the dog's condition. Both tumors proved to be thick-walled cysts, containing dark red, grumous material made up of shadows of red blood cells and cholesterin. The pathology of the thyroid in dogs was said to be similar to that in man. Hemorrhagic cysts, while rare, were occasionally reported. There etiology was still undetermined. Trauma probably plays a part and changes in the vessel walls with rupture probably do the rest.

Uterovaginal Prolapse.—Mr. Thacher reported two cases. The first was an acute one complicating labor in a bitch. The vagina and cervix were prolapsed, the bladder was out of the pelvis, there was inability to urinate, and the animal was in bad condition. A uterus containing nine pups was removed and the prolapsus reduced. Death occurred in fifteen hours, hydronephrosis and localized peritonitis being present. In the second case an irreducible mass protruded from the vulva and two operations were required to correct the condition. Obstetrical complications were said to be common in animals, and death often occurred without delivery. Acute prolapse was most frequent in the herbiverous animals and the immediate cause was often a very full uterus.

Inguinal Hernia in the Dog.—These cases were reported by Mr. Beall. The first patient showed an irreducible inguinal hernia with cystocele, and the

radical hernia operation was done. Death occurred on the second day, the dog showing ulcers of the stomach and an atrophied right kidney. The second patient had a bilateral inguinal hernia. The two sides were operated on separately and complete cure resulted. In the third dog the hernia contained the omentum and the round ligament. Hernia in the dog is a very common condition, the commonest variety being the mid-ventral. The inguinal form occurs much more often in the female than in the male—due probably to the occurrence of pregnancy and to the fact that normally a bitch has practically a patent canal of Nuck. In the male, too, the tunica vaginalis retains its connection with the peritoneum, so that the anatomical facts alone do not explain the occurrence of inguinal hernia which is relatively rare in male dogs.

Canine Tumors.—This series was reported by Mr. Ortschild. The first was an adeno-carcinoma of the breast with glandular metastasis. The complete operation was done. Death occurred from cancrum oris. Mixed teratomata over the breast and thorax were found in the second case. These on section showed cartilage, adeno-carcinoma, carcinoma simplex and bone. In another dog a cyst adenoma of the breast was found and removed. This patient died from a phagedenic ulcer of the mouth. In a fourth case a mixed tumor of the breast, which had succeeded to a "milk-breast" following a bite, was removed. Cure resulted. An intracystic papilloma of the breast with metastases, a fibrolipoma of the vaginal wall and a hygroma of the right shoulder were also reported. The last tumor of the series was a pedunculated growth arising from the lower abdomen and just swinging clear of the ground when the dog walked. It was removed, and proved on section to be an adenoma. Tumors—particularly carcinomata of the skin and mammæ—are common in dogs. Fibrontat. enchondromata and sarcomata of the breast are also seen. Dr. Bloodgood showed the specimen of a melanosarcoma of the liver occurring in a horse.

Meeting held April 31, 1905.

Analysis of 221 Cases of Typhoid Fever.—This series was reported by Dr. Thompson, of Worcester, Mass. The epidemic had started among workmen in one of the suburbs of Boston, and was traced definitely to a privy infection. The cases were treated at the Boston City Hospital. The majority were males and ranged in age from eight to sixty-three years. Sixty-five per cent. were in the first three decades of life and 5 per cent. gave a history of previous attack. A motley array or symptoms was seen at the onset; deafness was initial in three cases. The febrile period varied from 7 to 86 days and relapses occurred in 21 cases. Rose spots were present in 69 per cent., sweats were a striking feature in two cases, and herpes was noted in one case; 23½ per cent. showed a subnormal leucocyte count. Myocarditis was marked in two cases, thrombosis was seen in seven, infarct of the lung in one and parotitis in two. Nausea and vomiting were troublesome in five. Hemorrhage occurred in 22 patients, distention was marked in 23 and in two cases fatal perforation occurred. The spleen was palpable in 69 per cent. of the cases noted. True catarrhal jaundice was present in one case. Four showed epistaxis, three pleurisy and seven bronchitis. The ear was most often affected of the organs of special sense. Retention of the urine occurred in six cases, acute nephritis in two. Cystitis was seen three times, hematuria twice. Two patients showed acute mastitis. One patient went to term normally during the disease and was delivered without event. Necrosis of the nasal septum was seen once. The Widal reaction was positive in 93 per cent. of the cases noted. The mortality of the series was 12 per cent. The features exhibited by the cases were the frequncy of a typical typhoid state, the notable implication of the central nervous system and the inefficiency of sponging as compared with treatment by tubs.

Painful Heels.—Dr. Baer reported five cases of this condition. The first was a man of eighteen who had had gonorrheal urethritis three months previously and whose discharge was still present on admission. Both heels were extremely painful, no flatfoot was present and the radiograph showed exostoses beneath the os calcis on both sides. They were both removed by operation and cure was complete. The second patient complained of pain in heels and ankles. There was history of an attack of gonorrhea nine months previously. The os calcis was found thickened, but the patient refused operation. In the third case there was pain in the heels and back. The patient had had three attacks of gonorrhea. There was a spot of extreme point tenderness at the attachment of the plantar fascia. The exostoses were removed by operation and, though cultures were negative, the sections showed diplococci which decolorized by Gram. The fourth patient denied gonorrhea but had had an inguinal bubo. Pain in the heels had been present for several months. There was tenderness on pressure over the heel and on stretching the plantar fascia. The radiograph showed exostoses. These were removed and a pure culture of the gonococcus grown from them. In the fifth patient exostoses were removed but were sterile on culture. Operation, however, gave complete relief.

The primary seat of the deposit in these cases seemed to be in the plantar fascia from which there was a downgrowth into the periosteum. The exostosis was always situated at the attachment of the plantar fascia, but in some of the cases there was also thickening of the sides of the os calcis. Motions were not limited, but there was a characteristic gait, the heels being used little or not at all. When the spine was affected the symptoms were those of an osteo-arthritis. In the two cases in this series in which the spine was affected as well as the heels, gonococci were found in the growths removed from the heels.

Atheromatous Cyst of the Scrotum.—This case was reported by Dr. Churchman. The patient was a colored man aged forty-one years. The tumor had been present since early boyhood. It lay in the raphe of the scrotum, was freely movable under the skin and was a little larger than the testicles, though resembling them in shape, it had no definite pedicle. There were no symptoms accompanying it. The tumor was removed under cocaine, and proved on section to be an epithelial-lined cyst containing cholesterin crystals and epithelial cells, but no true dermoid elements.

Bladder Calculus in an Infant.—The patient, reported by Dr. Churchman, was a male nineteen months of age. He was healthy and sturdy, but had had for four months hematuria with straining and pain at stool and on micturition. By means of a small sound search a stone was located in the bladder. The patient had not yet been subjected to operation. No case of stone in the bladder in so young a patient had occurred in the 80 cases seen at the Johns Hopkins Hospital.

Congenital Urethral Stricture.—This patient was a boy aged thirteen years who had come to the clinic complaining of hematuria and pain over the ureter, with nausea and vomiting. Previous genito-urinary trouble was denied. An X-ray picture and examina-

tion of the urine for tubercle bacilli were negative. Examination of the urethra showed a pin-point meatus and two narrowings—one in the bulbo-membranous portion and one just back of the meatus. Under gradual dilation all symptoms disappeared and the urine became absolutely clear.

Traumatic Atrophy of the Testicle.—The patient was aged nineteen years and had been normal in every way until eleven months before admission, when he had received a kick upon the scrotum followed by redness and swelling of the left testicle. The swelling soon went down and atrophy supervened, the testicle gradually shrinking until it reached the size of a hazelnut. It, with an accompanying varicocele, was removed under cocaine. Section of the testicle showed a good many normal tubules and a few atrophied ones. There was no connective-tissue increase. The vas and epididymis were patent and no good pathological explanation was found for the atrophy. The specimen also contained a curious gland-like structure which looked on cross-section much like the uterus. It was connected with the tunica albuginea by a tube lined by columnar ciliated epithelium which looked a good deal like the Fallopian tube. The structures were thought to be rests of the Müllerian duct.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-Urinary Diseases.

Stated Meeting, held May 17, 1905.

The President, Ramon Guiteras, M.D., in the Chair.

Multiple Vesical Calculi.—Dr. John Van der Poel reported a case illustrating the advisability of preliminary X-ray plates in cases of enlarged prostate, combined with visical calculi, when the perineal route for prostatectomy has been decided upon. In the case in question, two stones were detected with the searcher, whereas upon cystoscopic examination with the No. 1 Nitze cystoscope, but one was seen, the second evidently lying in the bas-fond of the bladder. After the prostate had been removed, the two stones were easily taken out through the perineal wound and dilated posterior, urethra, and the bladder explored with the finger as thoroughly as possible. The perineal wound healed up rapidly —(the inverted incision having been used)—and by the seventh day, all urine was passed per urethram, the patient having been up from the fourth day. A persistent cystitis, with pain at the glans penis and the anus, led to a further examination with the stone searcher, when another calculus was easily detected. As the patient had so recently been subjected to a rather thorough and severe perineal operation, litholapaxy was decided upon, in preference to a suprapubic operation. The crushing was done without anesthetic, with the assistance of Dr. Gardner. No pain was complained of except during the process of aspiration, when the parts in the region of the internal sphincter and from where the prostate had been removed, were sensitive, though not exquisitely so. After drainage for two days by a fixed urethral catheter, the patient was up on the third day and out of the hospital on the fourth.

A Case of Exstrophy of the Bladder.—Presented by the Chairman, Dr. Ramon Guiteras: The patient, a young man, was shown to illustrate the result of an operation for complete exstrophy of the bladder, the entire bladder having lain exposed on the abdominal wall. The Wood operation was done by Dr. Guiteras, taking a flap from above the bladder and one on either side from the groins, and bringing them together. The edges of the gaping urethra were then brought together, and healed without any trouble. A few skin grafts were applied about the edges of the wound. Two small sinuses remained, which healed in the course of a few days without treatment. The entire operation was done at one sitting. The result was very satisfactory, considering the nature and extent of the defect. The patient was now able to hold seven ounces of urine in his bladder, and was fairly comfortable, whereas before the operation there was a constant flow of urine.

Dr. Eugene Fuller said he had never before seen such a good result in so aggravated a case.

A New Genito-urinary Basin.—Dr. A. L. Wolbarst showed a basin especially designed to fit between the thighs. It was made with an anterior notch in which the penis rests. On account of its shape, it is much more convenient than the ordinary pus basin for the purpose of bladder irrigation or other manipulations about the bladder and scrotum.

Foreign Body Removed from the Bladder.—Dr. Van der Poel showed this specimen. It was a French nail, two and three-quarter inches long with a very sharp point, which he had removed from the bladder of a man forty-eight years old, who had introduced it into his urethra for the purpose, as he said, of relieving an itching of the parts. While he was engaged in this act, the door suddenly opened, and the nail slipped from his grasp. He consulted Dr. George E. Close, who, detected the nail in the urethra, and the patient was then referred to Dr. Van der Poel, who found that the nail had passed into the bladder. It was readily detected with the stone searcher, with the cystoscope and found to lie almost perpendicularly, with the point downward in the postprostatic pouch—(the nail having been introduced head first) —and the head in the vault of the bladder. On account of its size and its peculiar position, it was deemed advisable to remove it through a suprapubic incision, which was done, and the man made an uneventful recovery. The case is interesting first, from the fact that foreign bodies of over two, or two and one-half inches in length, always, or most always, assume a transverse or transverse-oblique position in the bladder, whereas this was almost parallel with the long axis of the body, and secondly from the fact that although it was very sharp, it gave rise to no pain, strangury, or hematuria.

Vesical Calculus Removed by Operative Cystoscope.—Specimen was shown by Dr. Van der Poel. The patient was a man sixty-four years old who had given symptoms of stone in the bladder. With the cystoscope, three calculi, about the size of the tip of the little finger, were detected in the postprostatic pouch. At first the patient refused operative interference, but after the use of diluents had proved unsuccessful, he again applied for relief. The first stone, weighing nineteen grains, was removed with comparative ease with Nitze's operative cystoscope, with the lithotrite attachment. The second stone, weighing thirty-one grains, proved more troublesome. After the cystoscope had been introduced into the bladder the lithotrite attachment opened and the stone seized, the lamp failed to approximate with the rest of the instrument, which could not be withdrawn farther than the bulb. A perineal section was rapidly done under cocaine, the lithotrite closed and withdrawn, and the calculus re-

moved. The patient still had the third stone in his bladder, which Dr. Van der Poel said he hoped to remove in the near future, as it was about of the same size as the others.

Three attempts were made to get a skiagraph of the vesical calculi in this case, but they all proved unsuccessful, owing probably to the thickness of the antero-posterior diameter of the body of the patient, for although not a stout man, he was very large from the pubis to the sacrum. The stones were not composed of pure uric acid, which on account of their composition would fail to show a radiographic shadow, but were apparently made up of phosphates, with carbonate of lime and urates, as no trouble had been found in radiographing them through the shoulder of the patient after their removal from the bladder, their formation being shown on the plate below, which was taken without any intervening substance and the calculi not having been cut.

Dr. Fuller recalled a case of prostatectomy, with stone, that came under his observation some time ago. The patient was about five feet, six inches tall, and weighed fully two hundred and forty pounds. On account of his size he had been unable to walk about for a long time, and his tissues had become so soft that it was difficult to distinguish between fat and muscle. He had an enlarged prostate, and twelve faceted stones in the postprostatic cul-de-sac. The bladder was extremely sacculent, and on account of its size it was considered wise to do the prostatectomy by the perineal route. After enucleating the prostate, five of the stones were removed with considerable difficulty. Ten days later, when the tube was removed, it was found that the enlarged bladder had contracted to such an extent that the remaining calculi could be scooped out with the greatest ease.

Different Conditions in Movable Kidney and Their Treatment.— Dr. Robert T. Morris said he would present the subject very briefly. In regard to nomenclature, he believed that the term "loose kidney" was better than "movable kidney," and it was both brief and expressive. In dealing with this condition, there were two chief classifications: First—The loose kidney occurring alone as a diagnostic entity; not associated with other loose viscera. Second—The loose kidney associated with other loose viscera. Going back to the first class, in which the loose kidney occurred alone, we could again make a division of the cases into those in which the condition of the kidney caused symptoms, and those in which it did not cause symptoms. In a certain proportion of cases of loose kidney, the patients complained very little of any disturbance. Dr. Morris said he had seen kidneys so loose that they could be carried pretty well down to the pelvic brim, and yet the disturbance was not great in degree, while in other cases a range of a few centimetres would provoke most distressing symptoms, even precipitating a psychosis. The causes for the symptoms depended upon three chief factors. When there is an angulation of the ureter it produces obstruction, at times transitory in character, spasm of the muscularis of the ureter, and symptoms similar to those attending the passage of a renal calculus. The second group, and by far the largest, was that in which there was interference with a portion of the large sympathetic nerve branches, which were so abundantly distributed in the kidney, and readily observed in operations on that organ. The dragging on these sympathetic branches, so near to the great solar plexus, provoked the largest number of symptoms. In the third class of cases, we had direct pressure effects; direct mechanical effects. The loose kidney might lie upon the pylorus. When it rested against the pylorus or the duodenum, it might cause obstruction and eventually lead to dilatation of the stomach or give rise to a chronic gastritis. Or pressure in that region might occasion acute attacks of gastrio-duodenitis. Then again, the loose kidney might rest on the superior mesenteric vein. Edebohls has called attention to that possibility, and his observation was apparently borne out in cases of congestion of the cecum and appendix. This congestion might persist for months or years, and some of those patients eventually came to the surgeon for relief. In one patient who came under the speaker's observation in whom the "sweet-oil treatment" had given temporary relief, the symptoms were permanently relieved by anchoring the loose kidney.

Dr. Morris said that in the class of cases in which the loose kidney was associated with other loose organs, we had really to deal with a diastasis of the rectus muscles of the abdomen. These muscles could be separated for a distance of several centimeters with the finger through the skin, and they often remained separated year after year, so that the lax peritoneal support of the viscera, associated with the diastasis, allowed the chain of events which were so frequently observed.

Treatment.—In cases in which there was angulation of the ureter as the chief symptom, any one of the common abdominal supports would often afford relief. In those cases in which there was direct pressure upon the pylorus or duodenum, or upon the superior mesenteric vein, one of the common abdominal supports would often relieve the symptoms, and the patients would frequently gain so rapidly in weight and feel so much better that they would refuse to consider operative interference. In the class of cases in which the loose kidney dragged upon the branches of the sympathetic nerve, there were usually many reflex symptoms, and these hypersensitive patients, as a rule, were not well relieved by any form of abdominal support, and for that reason the speaker said he advised operation pretty promptly. He advised operation in cases that were not easily

relieved by support, which was in the majority of this type of cases.

Choice of Operation.—Dr. Morris said he formerly employed Senn's method, packing the kidney with iodoform gauze until granulations had appeared; then removing the gauze and trusting to fibrous adhesions. This method worked very well, but left an open wound for a longer period than he liked, and required more time for healing. He then tried the Guyon method, simply suturing without splitting the capsule of the kidney. After that, for three or four years, he tried a method of his own, turning up a trap-door section of the capsule of the kidney and drawing it through the psoas muscle. Later he took up Edebohl's method and employed it in a series of cases with excellent results, and he regarded it as the best operation that had thus far been devised up to the time of the publication of Dr. A. H. Goelet's paper, about two years ago, in which he advised suspension of the kidney by means of a suture introduced in such a way that traction upon it carried the kidney up behind the ribs. This procedure was very simple, so that the operation could often be completed in fifteen minutes or even less and it answered every purpose of retaining the kidney in a normal position. In that class of cases in which there was a wide diastasis of the recti muscles, and in which the loose kidney was associated with other loose abdominal organs, Dr. Morris considered it important to repair the diastasis. To do this effectually, he excised the entire strip of bare fibrous tissue between the recti muscles, and then united the muscles, cutting through peritoneum and all. Sometimes this excised strip was five, six or seven inches long, and two or three inches wide. He then shortened the falciform ligament of the liver, and lessened the tension upon the gastrocolic ligament. After that had been done, the kidney itself could be treated in the manner described by Dr. Goelet.

The Different Conditions in Calculous Kidney and Their Treatment.—Dr. Eugene Fuller stated that in dealing with this condition it was necessary to determine whether the stone was encysted or non-encysted. The latter class gave rise to the most trouble, as the former never caused obstructive symptoms. In a case of encysted calculus without any infection, the patient might go on for years without knowing that he had a stone, but a loose stone in the kidney was very apt to give rise to trouble in a comparatively short time. When obstruction and infection had once occurred, disorganization of the kidney was likely to follow, with the formation of a renal or perirenal abscess.

Symptoms.—In a case of calculus of the kidney, all the classical symptoms of that condition might be present, or they might be entirely absent. There might be localized pain in the loin, or radiating to the neck of the bladder or the thigh and penis. The pain associated with this condition was often mistaken for an ordinary bowel colic. There might be frequency of urination, or retentive symptoms, or absolute anuria. Hematuria was not an infrequent symptom of the condition, especially in dealing with uric acid calculi. Among the more recent aids in the diagnosis of calculous conditions of the kidney, Dr. Fuller mentioned ureteral catheterization, the use of wax-tipped ureteral bougies, and skiagraphy.

Treatment.—The choice of treatment lay between the expectant or therapeutic, and the operative. Certain patients of advanced age, with marked evidences of arteriosclerosis, or other contra-indications to operation, might be treated expectantly. In cases of renal calculus followed by destructive pyelitis, the kidney might be found in such a disorganized condition that its removal was indicated, but entire removal should only be done when it was absolutely imperative, because in such cases the stone diathesis still existed, and the opposite kidney was likely to become similarly involved sooner or later. Nephrotomy or partial nephrectomy in connection with the removal of stones were recommended.

The Different Conditions in Tuberculous Kidney and Their Treatment.—By Dr. Charles Langdon Gibson. (To appear in a future issue of the Medical News.) Dr. J. A. Nydegger, of the Marine Hospital, Stapleton, Staten Island, referred to a case of tuberculosis of the kidney under his care at the present time. The patient was brought to the hospital last December, having come from the South, where he had been treated for cystitis. Tubercle bacilli were found in the urine, and subsequently the patient developed chills, followed by high temperature. A cystoscopic examination of the bladder revealed many ulcerations, which were treated locally with a solution of silver nitrate and an emulsion of iodoform. Later, a perineal section was done and the bladder drained, but as the patient failed to improve, it was decided to remove the affected left kidney. Upon cutting down on that side, the upper portion of the kidney was found to be occupied by a large abcess, while the lower section of the organ, as far as could be ascertained, had been entirely destroyed.

Dr. Van der Poel said he had been particularly interested in what Dr. Gibson said in regard to the possibility of doing a resection of the kidney in tuberculosis of that organ. If we could successfully resect a certain amount of diseased kidney tissue, it would certainly be a great advance in renal surgery. In the diagnosis of tuberculous kidney, there were some cases that gave rise to but few symptoms where a diagnosis was difficult. In cases in which there was marked acidity of the urine, with polyuria and pus, the diagnosis of tuberculosis of the kidney was fairly certain, even without the presence of tubercle in the urine, which were only found in about 50 per cent. of the cases, probably because but a single examination from a small specimen had been made. The speaker said he recently saw a patient in whom the symptoms were characteristic of stone, though in a moderate degree. There had been attacks of a dull pain over the kidney, which had persisted for a number of weeks at a time; there had been one or two attacks of hematuria, and pus had been intermittently continuous in the urine. The pain, however, was referred to the left loin, and all the symptoms were attributed to the corresponding kidney. Purely by accident, the right ureter was catheterized before the left, and pus was withdrawn. The patient was so sensitive that the opposite ureter was not catherterized. A radiograph was then taken, which showed a stone in the right kidney. The case was still under observation, and was a good illustration of the problems that were occasionally met with in dealing with lesions of the kidney. When the tubercle bacilli were found, the question becomes comparatively simple, and when we have to deal with occasional attacks of hematuria and pain, with pus in the urine, and with a negative skiagraph, it was sometimes impossible to assert whether we were dealing with tuberculosis or a stone in the kidney.

Dr. Robert T. Morris said the idea of removing the affected part of a tuberculous kidney and then depending on constitutional treatment was a new one to him. In selected cases, where the parenchyma only was involved, he thought the method could be resorted to advantageously. There could be no doubt of the fact that in certain cases of tuberculosis of the kidney the constitutional treatment was of the utmost importance.

Dr. Charles H. Chetwood said great advances had been made in kidney surgery during the past ten years, with a corresponding diminution in the operative mortality. The most important advance in connection with this class of diseases was the earlier and more accurate diagnosis. Cystoscopy, cyoscopy and the X-rays were valuable adjuncts to the older methods of diagnosis, and we could now determine not only whether a lesion of the kidney actually existed, but also ascertain the condition of the opposite kidney. By means of the X-rays, the presence or absence of renal calculi could be determined in cases where the diagnosis could not possibly have been established by other methods, and it was even claimed that tuberculosis of the kidney could be recognized by means of the rays. In dealing with a calculous kidney, the occurrence of infection would often be the determining factor in bringing the case to the attention of the surgeon, even when multiple stones were present. In operating for the relief of pyelonephrosis, with or without the presence of stone, it was often difficult to decide whether to remove the kidney or not. The general conservative opinion was to save as much of the kidney as possible. Even when nothing was left, apparently, but a mere fibrous sac, the organ might still possess some functionating power. The same conservatism was not advisable in dealing with a tuberculous kidney, according to the consensus of opinion among writers on that subject. The operation of resection of the kidney had thus far shown a high mortality, and where the integrity of the opposite kidney could be established, a complete nephrectomy would probably be preferable.

Dr. Chetwood said he did not believe we had to deal with primary tuberculosis of the bladder. Given a tuberculosis of the bladder, we might expect to find tuberculous lesions elsewhere, usually in the kidney.

Gonorrheal Infection of the Kidney.—Dr. Follen Cabot reported the case of a young man who had a stone in the bladder, which was finally removed. The patient enjoyed good health for about a year, when pus was found in his urine, and he was treated for a time for cystitis. He was subsequently examined with the cystoscope, and pus was observed coming from the kidney. A catheter was introduced into the pelvis of that kidney, and the pus that was withdrawn was found to contain many gonococci. The man had had a previous attack of gonorrhea, for which he claimed that he had received no local treatment whatever. The urine continued to show pus, and a subsequent nephrotomy revealed six calculi in the kidney, none of them loose. The kidney also contained about a pint of pus, from which unfortunately no cultures were made. A few days after the operation the attempt was made, but with negative results, perhaps owing to the fact of the presence of many kinds of micro-organisms. The pus drawn from the kidney pelvis by uretereal catheter showed typical gonococci by Gram's decolorization stain but no cultures were made at that time.

Dr. A. H. Goelet differed with Dr. Morris on the subject of nomenclature. He did not favor either the term movable kidney or loose kidney, because the normal kidney was movable. He employed instead the term prolapsed kidney, which described the condition more accurately than any other that had been suggested.

In speaking of the conditions caused by prolapsed kidney, Dr. Morris stated that it produced a congestion of the appendix and the adjacent bowel, but he did not call attention to the fact that it interfered with the function and nutrition of the kidney itself, producing a condition which might be only an irritation of the kidney at first, but which in many instances went on to a mild form of pyelonephritis. The occurrence of this condition he thought depended a good deal upon the actual position of the kidney, and the habits of dress of the patient. He had shown that pyelonephritis exists in the majority of these cases as demonstrated by microscopical examination of the urine. Another pathological condition produced by prolapse of the kidney was a chronic congestion of the pelvic organs in the female, owing to interference with the return circulation from the pelvis. Because women wore their clothing suspended from the waist distention of the bowels must take place below the waist line, and in this way the kidney which is attached to the colon and driven back against the ovarian vein, pinching it against the spine, and thus producing pelvic congestion. The question of the attachment of the kidney to the colon had not received sufficient attention, and was an important factor in these cases.

Operation Upon a Prolapsed Kidney.—In operating for prolapsed kidney, Dr. Goelet said he had returned to the method of packing gauze around the lower pole of the kidney, in addition to the sutures, the packing being inserted for the purpose of preventing reattachment of the kidney to the colon and to lessen the strain on the sustaining sutures. He emphasied the importance of completely detaching the kidney from the colon as one of the essentials of the technic of the operation. Dr. Goelet expressed his appreciation of Dr. Morris' commendation of his method of suturing the kidney, which unquestionably restores the organ to its normal position, and he believed restoration of the kidney to its normal position was essential in successfully overcoming the symptoms and conditions produced by displacement.

Dr. Guiteras said that in some cases where stone was present in one kidney with pain on the opposite side, the pain was not renorenal reflex, but an evidence of acute inflammation of the kidney on the painful side, while on the side, where no pain was complained of, there had been an inflammation that had left the kidney in a much worse condition than its fellow, in which pain was present. At the last meeting of the Section, Dr. Guiteras said, he had shown two kidneys from the same patient, one removed at operation, the other at autopsy. In that case the patient had complained only of pain on the right side, never on the left. Upon catheterization of the left ureter, there was an escape of two ounces of pus, while there was a very slight amount of pus from the right kidney. The left kidney was removed and was found to be in a condition of pyonephrosis—a pus sac with thin walls and the kidney tissue practically destroyed. The patient died two days after the operation, and at the autopsy the right kidney was found to be in a condition of acute suppurative

pyelonephritis. Dr. Guiteras said that the case reported by Dr. Cabot, in which gonococci were found in the kidney, was an extremely rare one. There were probably not over a dozen cases of gonorrheal infection of the kidney reported in literature.

Dr. Van der Poel remarked that the experiments with artificial tuberculosis in rabbits detailed by Dr. Morris were very interesting and instructive, as regards the natural repair of tissues affected with tuberculosis, although it was impossible to say how close the analogy was between human tuberculosis and the disease in rabbits.

General Enteroptosis.—Dr. A. Ernest Gallant makes use of the term "ectopic" as embracing the various forms of kidneys which are not found to occupy their normal relation in the loins and gives preference to the term "prolapsed" kidney to that variety which has descended behind the colon, and which is almost always associated with prolapse of the other abdominal viscera. The latter condition is frequently overlooked by those surgeons who deem every prolapsed kidney a subject for fixation, forgetting that the kidney mobility is only a part of the general enteroptosis, involving, not infrequently the stomach, colon, liver, spleen, etc. Occasionally, following inquiry, the kidney will be found prolapsed—traumatic movable kidney, but, if the surgeons who fail to examine the stomach, would send their patients to a stomach specialist and ask for his report on the position, size, shape and working capacity of that organ, many unnecessary operations on prolapsed kidneys would be avoided. Prolapsed kidney is, unfortunately, easy of palpation, so easily reached that it offers a tempting field for surgical reward. In dealing with a prolapsed but replacable kidney, Dr. Gallant said that he seldom finds it necessary to operate. A replacable kidney as well as other intra-abdominal viscera, with the exception of a floating spleen, can be kept in place by means of a properly fitted corset, such as he describes on a previous occasion. If, as has been conclusively shown, that ordinary palpation of the kidney does produce albumin in the urine, what must result when the kidney has been fixed and subjected to the constant irritation and pressure induced by the corsets and clothing usually worn? Dr. Gallant said that he could not agree with Dr. Morris' statement that a diastasis of the recti muscles is present in the majority of these patients, unless he would limit it to women who have borne children or had large abdominal tumors, and others who are very stout. In Dr. Gallant's experience in sixty per cent. of women with prolapsed kidney there was no history of childbearing or tumors, and the abdominal muscles were very tense. In cases where actual diastasis existed, instead of taking out a strip of fascia from between the recti, as suggested by Dr. Morris, Dr. Gallant prefers to reinforce and reduce the abdominal wall by overlapping the fascial layers, as suggested by Dr. J. A. Blake for the cure of ventral hernia.

Dr. Morris, in closing, said that the term loose kidney was briefer than prolapsed kidney, and more euphonious than ectopic kidney. While many patients were greatly relieved by a properly fitted corset, still, it did not relieve all. Furthermore, the fashions in corsets changed, and the women sometimes tired of the same style, and asked for operation and permanent relief.

Dr. Fuller, in closing, said he did not feel very hopeful regarding the outlook of partial nephrectomy in case of tuberculosis of the kidney. The disease was so diffuse in its nature that hygienic and climatic influences offered greater chances of a permanent cure than an operation of the kind described. Of course, in cases where there was an abcess of the kidney, operative interference was imperative.

BOOK REVIEWS.

Diseases of the Heart, a Clinical Text-book for the use of Students and Practitioners of Medicine. By Edmund Henry Colbeck, B.A., M.D., B.C.(Cantab); F.R.C.P.(London); D.P.H.(Cantab), Physician to Out-Patients at the City of London Hospital for Diseases of the Chest; Physician to the Metropolitan Dispensary, E.C.; Late House Physician at St. Mary's Hospital, etc., etc. With 43 illustrations. Second Edition, revised and enlarged. W. T. Keener & Co., Chicago.

This is an excellent monograph on the diseases of the heart. It is especially full in the matter of diagnosis, but no one who realises the difficulties of cardiac therapeutics will complain of lack of treatment in it. Over sixty pages of its 340 are devoted to diseases of the myocardium. This is as it should be, for as has been well said, it is not so much the valvular lesions that are serious in the heart, since these may be compensated for by the heart muscle, but when the muscle begins to fail, then the end is not far off. This is the second edition, and in these days, when monographs in medicine are no more popular than collections of short stories, in general literature it is interesting to note that it is called for only three years after the first. It contains an account of the mechanical strain of the heart and of the Stokes-Adams syndrome, which were not in the work as originally published. We can cordially recommend this little volume to those who are especially interested in the diseases of the heart.

The Ophthalmic Year-Book. A Digest of the Literature of Ophthalmology, with Index of Publications for the Year 1903. By Edward Jackson, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic; President of the American Academy of Ophthalmology and Oto-Laryngology; Ophthalmologist to the Denver County Hospital, St. Anthony's Hospital, and Mercy Hospital, Denver. The Herrick Book and Stationery Company, Denver, Colo.

From the mass of ophthalmological literature published, this author has weeded out that which appeals to him as of relative importance and has critically reproduced it in sufficient detail to make it available for practical application at such places as it is possible to convey more clearly the visual character of the topic under discussion. The text is well illustrated, and where new operative methods are described the different stages are diagrammatically shown.

A second feature of the book is a carefully compiled index of all the original contributions dealing with this subject which have appeared during the foregoing year.

APPENDICITIS IN CHILDREN: A STUDY OF SEVENTY CASES OCCURRING BETWEEN THE AGES OF TWO AND FIFTEEN YEARS.*

BY CHARLES N. DOWD, M.D.,

OF NEW YORK;

ATTENDING SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE GENERAL MEMORIAL HOSPITAL.

THE peculiarities of appendicitis in children are sufficient to call for special consideration. The diagnosis is sometimes particularly difficult, the course of the disease often differs from that in adults. The prognosis in certain forms of inflammation is distinctly better than in adults, whereas in others the overwhelming virulence is even more startling. Many articles have been written on the subject, some reviewing the general subject as it stood at the time the article was written, others calling attention to the particular elements which had most impressed their authors. McCosh[1] calls particular attention to the insidious and often rapid course of the disease, and he and de la Carriere[2] have emphasized persistent vomiting as a symptom of much diagnostic importance; Richardson,[3] Griffiths[4] and Morse[5] called attention to the remarkable way in which beginning pneumonia gives pain and rigidity in the appendicular region, and hence leads to great difficulty in diagnosis. Erdmann[6] has found that the movements of the hand and arm which the child makes to protect the tender abdomen are characteristic. Karewski[7] and Selter[8] emphasize the frequency of previous attacks of gastro-intestinal disturbance; also the importance of rectal examination, since the child's pelvis is small and the inflammation usually extends along the right pelvic wall. Karewski also refers to the frequent desire to urinate and pain on doing so, and Selter to the frequency of diffuse peritonitis which is relatively more common in children than in adults. Mayo, Bloodgood, Albaran, Rally and Metchnikoff record instances of intestinal worms causing either the disease or symptoms which suggest it. All of these writers, and many others in addition, indicate that there are certain peculiarities of the disease as seen in children.

Since not many studies or groups of cases have been published, the writer has, with the help of Dr. Charles E. Farr, ex-House Surgeon of St. Mary's Hospital for Children, studied the records of 70 children, two to fifteen years of age, who have been operated upon for appendicitis either in that hospital or in private practice since 1895, comparing them with a considerably larger number of adult patients whom he has operated upon during that same period. They were mostly acute cases sent into the hospital during the course of the disease and operated upon without delay.

A clinical division of the cases which has often been used in considering the subject, is the following: (1) *Early cases,* whose operations came within the first two days; (2) *Later, active cases,* whose operations came during the progressive or retrogressive stage of the disease, but later than the second day; (3) *Interval cases,* whose operations came after the inflammation has subsided.

In this series there were eleven early cases, forty later active cases and nineteen interval cases.

Group I. Early Cases.—Forty-eight hours has frequently been set as an arbitrary time dividing the period of intra-appendicular inflammation from that of abscess formation or spreading peritonitis. Even in adults, this division is subject to many exceptions. In children there are even more. The following history illustrates the characteristics of the early causes as they have come to the hospital. The symptoms were pain, vomiting, prostration, fever and localized muscular rigidity of a very definite character. Their duration was less than twenty-four hours. Operation revealed a perforated appendix and beginning peritonitis.

Annie A., aged nine years, was in her ordinary health until the night before admission to the hospital, when she began to have much pain. The maximum intensity was a little to the right of the umbilicus, but she felt it generally through the abdomen. She vomited several times. Felt much depressed through the day and was brought to the hospital at the end of the afternoon. At that time the pain was much less, but there was tenderness on pressure over the lower right part of the abdomen, and muscular rigidity, much more marked on the right than on the left side. This was so great and so distinctly defined that it seemed almost as though there must be a mass below it, the lower part of the rectus being so definitely hardened as to give the impression that the mass extended only to about the level of the umbilicus. The facies indicated severe illness. The abdomen showed no distention and no tympanites. Temperature 101.4° F., pulse 134, respiration 26. The pulse was weak and thready and not of good quality. Leucocyte count, 3,200; 91 per cent. polynuclear. Operation done without delay, *i.e.*, twenty-four hours after the onset of symptoms. On incising the peritoneum there was a gush of purulent

* Read before the Hospital Graduates' Club, April 27, 1905.

serum; thin, but whitish. The appendix was found to contain a large concretion. The mucous membrane of the terminal inch and a half was gangrenous; it was perforated in two spots and intensely inflamed. The intestines in the vicinity were covered with fibrin, but so much of intestine as was seen at a distance from the appendix was only moderately congested, although bathed in cloudy serum. The appendix was removed. Stump ligated and buried. One gauze drain inserted. She recovered promptly without incident. Drainage entirely removed on seventh day; wound completely healed on sixteenth day.

This case represents fairly well the eleven cases whose operations came within the first two days, but was more acute and rapid in its progress than the average. These eleven cases may be summarized as follows: Three had had previous attacks. In all of them pain had come at the beginning of the attack; in four the first pain was described as "abdominal" or in the umbilical region; in all it finally became most marked on the lower right side of the abdomen; all vomited; all had distinct localized muscular rigidity. In six of the cases the appendix had ruptured. In four there was beginning peritonitis away from the appendix. All recovered promptly.

In this group of cases the rapidity of the progress of the inflammation is the notable peculiarity. It would be difficult to find a group which in other respects conforms more completely to the classical symptoms of the disease.

The good results are what would be expected in patients whose operations come within the first forty-eight hours of the disease, and forcibly illustrate the importance of prompt diagnosis and early operation.

Group II. Later Active Cases.—The main interest hinges about the group whose operations came between the second and twenty-second day. They stand in marked contrast to those whose operations came on the first or second days. The inflammation had extended further, sometimes to the formation of diffuse or general peritonitis, sometimes to the formation of single or multiple abscesses.

There is a mortality rate in these cases; among 32 children whose operations came on the third to the seventh day there were four deaths, and among eight whose operations came in the second and third weeks there were three deaths. This makes the mortality rate 10 per cent. for the entire series, a rate which stands about midway in the reports of appendicitis which have been made; not so good as some, not so bad as some; probably as good as can be expected, in the present state of surgery, in children whose inflammations have reached the advanced stage which this series shows. Many of the patients were only sent to the hospital when it was manifest that they would soon die if left at home; these patients were regularly operated upon with the exception of one in a moribund stage, who died six hours after admission. This method has been followed in these desperate cases because it is particularly in children that recovery has followed operation in advanced peritonitis, and it seemed unfair to withhold the slight chance of recovery which it offered. The results have justified the method, as some very desperate cases have recovered. The mortalities occurred almost entirely among these far-advanced cases. In four of the fatal cases there was general peritonitis at the time of operation, with the dissemination of pus and fibrin throughout the abdominal cavity. Two patients had multiple abscesses in different parts of the abdominal cavity. The seventh presented peculiarities which are worthy of note. She had suffered from a rather mild attack of appendicitis, but as the symptoms were diminishing when she came to the hospital operation was delayed until they had subsided. After ten days no symptoms of inflammation could be detected and the operation was done. The tip of the appendix, however, was found to lie in a very small abscess cavity at the outer side of the cecum. This was four years ago when much was being written and said about small drains or even no drains in cases of this kind, and accordingly after cleaning the cavity with dry gauze a single small gauze drain wrapped in rubber tissue was inserted. The child died seven days later of general peritonitis, which had progressed, with daily stools and without early tympanitis in the insidious way which is so much dreaded in children. The small cigarette drain was a distinct error, I believe; a good-sized gauze drain not wrapped in rubber tissue would have been much better.

In this group there were 10 patients who had diffuse or general peritonitis. Where the inflammation at a distance from the appendix has been slight the peritoneum has been trusted to care for it and only the local abscess has been drained. When the general inflammation has been severe, thorough irrigation with saline solution has been used.

It is not the purpose of this paper, however, to discuss the method of dealing with general peritonitis. Each surgeon is likely to use with children the method which he has adopted for adults. The aim of the paper is to call attention to the peculiarities of the disease as seen in children.

One of these peculiarities has a very strong bearing on the treatment of this late group of cases. It is in this group that the cases come for which some surgeons advocate delay, others immediate operation. Children, however, are peculiarly liable to the insidious, rapidly spreading form of peritonitis which does not give the ordinary symptoms. Hence surgeons generally advocate immediate operation in them no matter what they advise in adults. The subject is important, since delay is distinctly more dangerous for them than for adults. McCosh has particularly advocated this measure, and Ochsner[9] calls

attention to the difficulty in limiting inflammation which young children and greatly emaciated adults show, "because of the absence of a sufficiently large omentum to surround the diseased appendix." He, too, advocates early operation in these cases.

It is manifest that operation without delay is important for these cases. The technic need not materially differ from that of adults.

Group III. Interval Cases.—In this group there was no mortality. Eight of the patients had suffered from several attacks; two of them from two attacks each, nine from one attack each. In one instance an appendix which contained a concretion was found in a urachal sinus, and in one instance a congested appendix was found in a hernial sac. Nearly all the appendices showed adhesions, constrictions or thickening at the time of operation. The number of cases in this group was relatively small, 27 per cent. of the entire series, whereas in Murphy's[10] 2,000 cases they constituted 66 per cent. of the series, and in 1,000 cases which Ochsner reported in 1904 they were 54 per cent. of the series. The small percentage of interval cases manifestly makes the general mortality rate seem higher than it otherwise would.

General Consideration of Symptoms.—In order to study the peculiarities of the disease as shown in this group of children, we may consider the symptoms in turn, not counting the interval group, many of whom were not seen by the writer in primary attacks. *Pain* was a constant symptom, and it was almost always in the upper or middle part of the abdomen, at first and localized near the right iliac region later. In one instance the tip of the appendix lay slightly left of the median line, and the pain was most marked on the left side. In many instances where the tip of the appendix lay high the pain was correspondingly high. The expression of pain was naturally not so definite as in adults, and several times the symptom to which Dr. Erdman calls attention, of holding up the hand in protection of the tender abdomen, was very noticeable and was a valuable guide.

Muscular Rigidity and Tumefaction.—The physical examination of the abdomen in this series of cases was much more satisfactory than one would expect from studying the other records of this disease in children, possibly because so many of the cases were seen late. The abdominal muscles of children are peculiarly sensitive to inflammations below them. The writer has seen as characteristic muscular rigidity in an infant of six and a half pounds with an abdominal lesion as he has ever seen in adults. With a localized appendicitis this muscular rigidity is also localized, and a distinct difference can usually be made out between the two sides of the abdomen and between the upper and lower part of the right side. In only one instance in the entire group did this symptom fail. That was a child whose tonsils had previously been removed without anesthetic, and who was so terrorized at the sight of a strange doctor that he cried and kept both sides of the abdomen equally tense. Pressure on the thigh was followed by the same evidence of pain as pressure on the abdomen, and the right and left sides of the abdomen seemed equally tender, and the vigorous crying of the child was not what one would expect with a severe disease. He had, however, a beginning peritonitis from a ruptured appendix, and the physical examination was therefore entirely misleading. With this exception the abdominal palpation has been rather more satisfactory than in adults. In a recent article on the subject chloroform anesthseia is advised for abdominal examination. This has never seemed to the writer advisable, since the anesthetic takes away the muscular rigidity which is so important in diagnosis. Usually abdominal palpation has been more satisfactory before the anesthetic than after it. After the patient was on the table and anesthetized it would sometimes seem that there must have been a mistake in diagnosis, since so little evidence of inflammation remained. There has always, however, been much disease in or about the appendix which had occasioned the muscular rigidity.

Vomiting has been practically a constant symptom. Sometimes it has been repeated, and may be considered rather more definite a symptom in children than in adults.

Rapidity of the Disease.—Without question the spread of the inflammation is more rapid and more insidious in children than in adults. All observers seem to agree to this, for all who have observed many cases occasionally note one in which the disease pursues a most rapid, insidious course which leads to general peritonitis of a most violent type. It is this characteristic which makes surgeons fear so much the disease in these patients, and advise immediate operation in all active cases.

The *pulse* and *temperature* have usually increased gradually, the former reaching 120 or 130 per minute on the second or third day and the latter 102° or 103° F. The variations seem to be dependent on the degree of septic absorption.

Blood Examination.—Very good authorities have stated that the blood examination in children is not a valuable guide. This series does not furnish large statistics on this point, because many of the cases occurred before blood examinations were so common as they now are, and in most of them the diagnosis was clear without that aid. The following counts were made in eleven cases: 52,000, 21,000, 27,000, 13,500, 11,000, 16,000, 20,000, 21,000, 32,000, 28,000, 35,000 per c.mm. It will be noticed that with two exceptions the count was very high indeed, and this seems to be characteristic of children. The primary leucocyte reaction is usually very marked, five of these being between twenty-seven and fifty-two thousand. The later reaction, in which

leucocytosis fails, also seems to be about as marked. Two of these patients who had severe inflammation with abscess, pulse of 130 and 132, temperature 102.4° and 102° F., had only 13,500 and 11,000 respectively. Their blood examinations were made, the first on the fifteenth and the second on the seventh day of the disease. We do not know whether they had an early leucocytosis or not.

Dr. Frederic E. Sondern has kindly furnished six leucocyte counts from cases of appendicitis in children which indicate the value of the increased proportion of polynuclear cells in them as well as in adults. In three of them who had gangrenous appendices the percentage of polynuclear cells was 86 per cent., 85.8 per cent. and 95.2 per cent., the number of leucocytes per c.mm. respectively 7,700, 14,000 and 29,800. The low leucocytosis in the first of these cases was apparently not a reaction, but a condition found early in the disease due to weak body resistance. In three other patients who recovered without operation the polynuclear percentage was respectively 63.5 per cent., 62 per cent. and 63.8 per cent., the corresponding leucocyte counts 25,100, 8,800, 11,700.

Beginning pneumonia occasionally gives symptoms which closely resemble appendicitis, particularly in children. Many observers have referred to this. Griffith has collected the histories of 26 such cases. Richardson in recording five of them comments on the great difficulty in diagnosis which they sometimes give. The writer has seen four such cases, two in children and two in adults. Fortunately in each instance crepitation or harsh breathing had appeared in the chest when examination was made. The rapid respiration rate and the sudden high rise of temperature which pneumonia gives are important aids to diagnosis.

Constipation is much less frequent in children than in adults in peritonitis. The writer has seen several cases of peritonitis in children accompanied by diarrhea.

Gibney[11] has called attention to the occasional resemblance between *hip-joint disease* and appendicitis. One case of hip disease simulating appendical abscess has come to the writer's notice.

A word should be said about the ability of children to stand operative procedure in appendicitis. They are more likely to recover from general peritonitis than adults. They react from a short operation very well indeed, but prolonged operations on them are to be avoided if possible.

In considering the series as a whole, we may agree with Deaver[12] that the percentage of more severe grades of appendicitis is greater in children than in adults, and to recapitulate the peculiarities of appendicitis in children we may say that (1) the rapidity and insidiousness of the disease are much greater; (2) that the percentage of diffuse and general peritonitis is greater, probably because the omentum is less apt to inclose the inflamed appendix; (3) that the pain is almost always present, but is more difficult to interpret; (4) that the vomiting is almost always present and is frequently many times repeated; (5) that the abdominal palpation in the majority of cases is as satisfactory or more satisfactory than in adults, but in a few cases is absolutely misleading; (6) that constipation is much less likely to be present; (7) that they have a greater ability to deal with general peritonitis than adults do; (8) that during the acute progress of the disease delay is more dangerous than in adults, because of the insidious course of the disease and the greater tendency to peritonitis, and immediate operation is to be advised.

OVARIAN TRANSPLANTATION.

BY JAMES P. WARBASSE, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE GERMAN HOSPITAL, BROOKLYN.

One of the most important fields of knowledge, in which surgery has come to the aid of physiology, is found in the study of the internal secretions of glandular organs. The practicability of grafting in the human animal glandular tissue, the secretion of which is essential for the normal functions of the body, has been demonstrated by surgery. Thus far these researches have been brought the farthest in connection with the thyroid gland and the ovary, and undoubtedly other glandular structures will be added to this list. In passing, it should be remarked that the transplantation of the skin from one person to another is the pioneer operation of this class, and although we may be ignorant of the character of the internal secretion of the skin, still it belongs properly to the glandular organs.

Before the importance of the internal secretion of the ovary was appreciated, women were deprived of these organs much more freely than is the case at the present time. The study of cases in which all ovarian tissue has been removed by surgery, and of cases in which the ovaries have become gradually destroyed by disease, has given us a pretty clear idea of the symptom complex of the cachexia incident to the withdrawal from the system of the internal secretion of the ovary, or what may be called cachexia ovaripriva. These symptoms may also be somewhat dependent upon the interference

with the ovarian nerves in this class of cases; but the following case which I am about to report points to the internal secretion of the ovary as the thing of chief importance.

As every bit of information bearing upon this subject will help in its general elucidation, the following case is reported, illustrating the cachexia ovaripriva, following the removal of both ovaries, the relief of symptoms by the use of ovarian extract, the cure of the condition by the transplantation of ovary from another woman, and the final recurrence of the disturbances at the end of a year:

The patient, a woman of twenty-seven years, had been operated upon in other hands in 1894 for double pyosalpingitis with adhesions and involvement of the uterus in inflammatory products. A hysterectomy had been done, together with removal of the tubes, one ovary and a part of the other. Much pain had developed later in connection with the remains of the ovary which had evidently become involved in adhesions, and in 1898, in the hands of still another surgeon, this remaining stump of ovary was removed. After the removal of her last ovarian tissue, marked constitutional symptoms developed, such as we have become familiar with in these cases. She came into the hands of the reporter, a striking example of this miserable picture—fainting attacks, hot flashes, gastric crises, nausea, vomiting, perversions of sensation, attacks of dizziness, obstinate constipation, etc. The whole catalogue of nerve sedatives was exhausted without relief. Ovarian extract—inspissated and pulvarized ovary—was then administered in five-grain tablets, and was found to be the first remedy that gave relief. After some experimenting it was found that five grains of dried extract of ovary taken three times daily for about two weeks during each month kept her fairly comfortable. When this was omitted for a month the symptoms recurred. She became dependent upon this product of the cow's and sheep's ovary. Ovarian transplantation was suggested to her without any promise of benefit but simply as an experiment. The operation was delayed because of the difficulty of finding a suitable case from which good ovarian tissue could be secured. Finally, my friend Dr. George R. Fowler had the case of a young unmarried woman, without history of pelvic inflammation, who had a small cystoma of the ovary, which he proposed to remove. Accordingly, on November 14, 1903, at the Methodist Hospital, with the two patients side by side on adjoining tables, I opened the abdomen of my patient, excising the old suprapubic scar, and made a slit in the remains of the right broad ligament about 3 cm. long between the bladder and the brim of the pelvis. Dr. Fowler removed the cystic ovary from his patient, and handed it directly to me. The whole mass, cyst and ovary, was the size of a medium-sized lemon. The ovary lay on one side of the cyst, and was scarcely changed in size or shape. The cyst wall was extremely thin, and represented but little more than peritoneum. The cyst was rapidly cut away from the ovary, leaving a mass of apparently healthy ovarian tissue fully the size of a normal ovary, somewhat flattened, covered on one side with peritoneum and on the other by the lining of the cyst. This was button-holed into the slit in the broad ligament, already prepared for it, peritoneal side exposed. Less than a minute of time was consumed in the transit of the ovary from one woman to the other. The broad ligament wound gaped sufficiently to leave exposed to view in the free peritoneal cavity about one-half of the area of the peritoneal surface of the transplanted ovary. A single, fine catgut suture was introduced at either end of the wound, catching the ovary to prevent rotation or displacement, and the abdomen closed.

The next menstrual crisis occurred ten days after the operation. No ovarian extract was used, but the patient was given a little bromide. This was associated with markedly less disturbance than usual. Following this the nervous disturbances and the signs of her cachexia failed to appear for nearly a year. During that time she attended to her business, and felt rewarded for trouble. Her general health was much better than formerly. The old distressing symptoms did not recur during that time. In October, 1904, the hot flashes first reappeared, and have recurred monthly since that. They are not so bad as before the operation. The attacks of fainting have not returned. She feels that since October there has been a decided change for the worse in her condition, and that the relief which the operation secured for her is passing away.

The experience in this case seems to correspond with that of Dr. Robert T. Morris, whose experiments along these lines, both in rabbits and in the human female, are so well known.[1] He has found that ovarian tissue thus transplanted survives and furnishes its secretions to the system for a certain period of time, and then undergoes degeneration. Whether the benefits from this operation can be made more permanent is a question yet to be solved.

WHAT MEANS DOES THE MODERN OBSTETRICIAN EMPLOY TO PREVENT OPHTHALMIA OF THE NEWLY BORN?[2]

BY J. CLIFTON EDGAR, M.D.,
OF NEW YORK.

IT goes without saying that no measure should be neglected which can assist in preventing the occurrence of ophthalmia neonatorum. From the standpoint of the obstetrician there are two means at our command for reducing in frequency, if not practically preventing, ophthalmia neonatorum. These are: First, the ante-partum preparation of the maternal passages in cases in which

1 Medical Record, 10, 1, 1901; Am. Jour. Obstet., 6, 1903.
2 Read before the New York Academy of Medicine, Stated Meeting, May 18, 1905.

they are suspected of infection; second, the dropping into each conjunctival sac immediately after delivery of some antiseptic, as nitrate of silver, protargol or argyrol.

When the maternal passages are suspected, a preliminary course of treatment of the vagina should be instituted, beginning about two weeks before delivery. This should consist in daily or twice daily vaginal douching, first with a mild alkaline solution and then with one of bichloride of mercury in strength 1-5,000. Just before delivery something must be done to provide a substitute for the normal lubricating mucus which will have been washed away by the douching process, and a one per cent. lysol solution will be found useful for this purpose. The vagina may be washed out with it when labor begins.

The scientific gospel of Bumm and Krönig, namely, that the vaginal mucus has a bactericidal action, has been misunderstood as applying to gonococcus infection. It has no such action. To-day there is abundant evidence from many sources to prove that the fetus is in certain cases infected with the gonococcus *in utero* and hence born with gonococcus infection of the conjunctiva. Thus no prophylaxis either in the nature of ante-partum vaginal cleansing or post-partum instillation into the conjunctival sac of antiseptics can in a small percentage avail anything.

If the vagina, as many to-day believe, is usually sterile, it needs no preparation for labor to prevent ophthalmia, if the reverse is true, it does.

At the Emergency Bellevue service and at the New York Maternity, after repeated experiments with and without ante-partum antiseptic preparation of the vagina for labor, I have finally been compelled to use it in all cases without exception, in order to keep my morbidity rate from ophthalmia neonatorum at the lowest figure. Both of these services, however, are largely venereal in character.

At the Manhattan Maternity and Dispensary I am now making use of antiseptic preparation of the vagina in selected cases only, but as the service is at present only three months old we can report nothing of value. In this time we have had one case of ophthalmia neonatorum, and that in spite of Credé's post-partum treatment.

In private practice I am not accustomed to use ante-partum vaginal cleansing—this being a concession to the popular belief that there is less gonococcus infection in private practice, and yet every now and then I see gonococcus infection in spite of Credé's nitrate of silver method of prevention. I had such a case some years ago in my practice, where the husband had his acute gonorrhea in August and married in January. The baby all but lost the sight of both eyes, but finally recovered.

I have every faith in Credé's method for the prevention of ophthalmia neonatorum. In both hospital and private cases I am now accustomed to make use of this method without exception. After repeated experiments with protargol I have found nothing to compare with silver nitrate in 2 per cent. solution as a prophylactic. As soon as the child is born its face is carefully washed with boric acid solution, separate wipes being used for each eye, and the lids rubbed from the nose outward in each case. Then whether infection is suspected or not, two drops of a 2 per cent. solution of silver nitrate are dropped into each conjunctival sac. The excess is washed away in about thirty seconds with a normal saline solution.

In my experience, solutions of less than 2 per cent. do not destroy bacteria, and although solutions of 3 per cent. are harmless, they are apt to cause "silver catarrh," and are not required.

Of the many substitutes recommended it is very difficult to determine whether they are equal to or have any superiority over Credé's 2 per cent. nitrate of silver, but in my experience, after experimentation in hospital practice, protargol and argyrol are not equal in efficiency to the nitrate of silver treatment.

Ante-partum vaginal cleansing in suspected cases and Credé's nitrate of silver method after birth cannot absolutely abolish gonorrheal ophthalmia, because of the small percentage of intrauterine gonococcus infection, but they can reduce the morbidity to practically *nil*. As long as men with gonorrhea are permitted to marry and women with gonococcus infection to conceive, so long will there be danger of gonorrheal ophthalmia in the newly born child.

My faith in the prophylactic power of the nitrate of silver method is so strong that I attribute all apparent negative or ill effects of the method to the presence of ante-partum infection of the eyes, to unskilled application or to improper or inert solutions.

Dauber[1] states that antagonism to Credé's method has developed in quite recent years. First, it has been shown that the method has not been carried out properly—this, of course, being no fault of the method itself; still, as gonorrheal blindness has only been reduced less than one-half, something is wrong. Midwives should be compelled to use it. The second objection is that Credé's method tends to increase eye morbidity by causing "silver catarrh." This has led to the use of argyrol and protargol. Zweifel uses the former, and neutralizes with sodium chloride. His morbidity in over 5,000 cases has been but 0.23 per cent. Scipiades finds argyrol a certain prophylactic. From a number of other clinics come equally good reports as to protargol.

Recently in Hofmeier's clinic Credé's solution has been reduced from two per cent. to one per cent., following the custom of Runge, Fehling and Gusserow. Since this reduction the morbidity in over 5,000 cases has been but 0.33 per cent., with no silver catarrh worth mentioning. Thus while there was no dissatisfaction with Credé's method, the author concluded

[1] Münchener medizinische Wochenschrift, February 16, 1904, Hofmeier's Clinic.

to give argyrol and protargol a suitable trial. Not only were the results less favorable, but more silver catarrh was caused by Zweifel's method than by any other single procedure. Hence, at the Hofmeier clinic, Credé's one per cent. is regarded as the best prophylactic. Hofmeier also uses an ante-partum douche in his clinic, which is naturally prophylactic to ophthalmia neonatorum. Incidentally it is stated that the morbidity of this condition varied in the past with that of sepsis. When puerperal fever used to be epidemic, there was an eye morbidity of 50 per cent. at times. General asepsis, etc., brought this down to 10-12 per cent., while Credé's method has almost obliterated morbidity of the eye in individual clinics.

Wintersteiner [1] analyzes 122 cases of actual ophthalmia neonatorum. Two were undoubtedly cases of ante-partum infection. In forty others the disease did not develop until after the fifth day, and at various intervals, hence regarded as possibly of post-partum infection, although some authorities believe in delayed intra-partum causation, due to weakened virulence of germs. Credé's method is of great value within certain limits, but cannot prevail against anomalous cases, such as those of late development. To include the latter, whatever the causes, prophylaxis must be kept up through puerperium.

Wintersteiner uses Stellwag's method—potass. permanganate douching (1-1000) at short intervals, with Credé's solution twice daily. In his series of cases he obtained complete cures in every instance.

Alvarado [2] has been an industrious compiler of statistics, but does not always give the clinics. In one series of 6,397 cases a single drop of Credé was instilled and not a single infection followed. In a large series of over 15,000 cases about two per cent. developed the disease in spite of Credé's method. Other clinics go still higher (up to five per cent.). However, in clinics in which the solution used was but 1.5 per cent., the morbidity was much greater, running as high as 7.5 per cent., and even 12.2 per cent. As the author is a Spaniard, many if not all of his figures are probably of local origin. As for protargol, the only large figures he knows of are those of Rubesca, of Prague (morbidity of two cases in 1,100). These read well, but what are they in comparison with the old records of Leopold (3,000 cases of Credé's method without any morbidity)!

Does Credé's Method Cause Conjunctivitis?—Neither Leopold (in 3,000 cases) nor Rosthorn (in nearly 25,000 cases) ever witnessed this accident. Author cites Bischof's view that conjunctivitis never results if technic has been correct.

In regard to treatment, Alvarado sent out a circular of inquiry to colleagues (oculists) in all parts of the world as to relative merits of Credé's method on one hand and the substitution of *protargol*, on the other. He received 31 replies, all but one in favor of Credé's. The exception was the Lyons clinic, where protargol is in use.

Ernst [1] discusses Credé's method very briefly with reference to the conjunctivitis which it is said to cause. No gonococci are ever found in these cases. They are due therefore to the nitrate. He experimented with a 1.5 per cent. solution and still got the conjunctivitis. Finally he found that the one per cent. solutions were non-irritant. At the Cologne Maternity, from January 1, 1902, to July 1, 1904, this author employed the one per cent. solution in 1,111 births. Not a single case of ophthalmia developed.

RATIONAL DIET IN DISEASE.*

BY EDWARD C. HILL, M.D.,
OF DENVER, COLO.;
PROFESSOR OF CHEMISTRY IN THE DENVER AND GROSS COLLEGE OF MEDICINE.

SINCE the days of Hippocrates dietetics has occupied an important place in therapy. In most diseases proper feeding is more essential to the patient's welfare than the use of drugs. As Homer says, "The belly is the most important organ," and without its aid nutrition is practically impossible. To be adapted to the needs of the body, foods must be digestible, absorbable and assimilable. In gastric or intestinal diseases we should give such food as will be digested below or above the seat of the malady.

The quality of diet for the sick should be simple but faultless. Gastro-intestinal auto-intoxication is a danger that threatens with particular liability those debilitated by disease. When a certain dietary scheme is laid down for an individual it should be adhered to as closely as practicable, since "the regular use of certain classes of foods develops corresponding types of glands (Pawlow), and digestive disturbances are often set up by sudden changes in diet, owing to temporary insufficiency of the glands concerned." Within the limits of each class, however, there is always to be had an agreeable variety. With a mixed diet a person will digest a larger proportion of nutrients than with a diet composed of a single food material (Woods and Merrill). Moreover, the acid fermentation of carbohydrates checks the more serious putrefaction of proteins. To overcome pinguidity, Benedict advises limiting the patient to one viand at each meal.

As to quantity of food, the recent researches of Chittenden prove that men are well nourished on from one-half to two-thirds the total calories (3,000 or more) usually stated as required by adults. It is probable that an excess (over 60 gm. for 70 kg. body-weight) leads to more rapid metabolism, with accumulation of irritating waste products, which cause gastroenteritis and favor arteriosclerosis. Men and women who work with their muscles usually need three meals a day. For the middle-aged sedentary city-dweller two meals

1 Centralblatt für Gynäkologie, 1904, p. 1215.
* Read before the Medical Society of the City and County of Denver, April 18, 1905.

are amply sufficient. Such a practice ensures a keen appetite and consequent normal successive secretions, eupepsia, eutrypsia, freedom from flatus and proper peristalsis. Less food is needed when a person is warmly clothed.

After a full meal the stomach should empty itself within six hours (three hours for light meals). Failure to do so shows defective motility (gastroptosis, ectasia) and calls for small feedings at frequent intervals, which are likewise indicated in hyperchlorhydria. If, on the other hand, the secretory function is feeble, it is generally best to prolong the interval between meals. The marked lowering of motor and secretory functions, together with increased tissue waste, in acute febrile diseases, indicate a special need for proteins in the most nutritious and digestible forms, and at short periods (three to five hours). Solid foods often cause vomiting or dyspeptic pains in febrile patients. For the first few days of gastric or intestinal disease, particularly appendicitis and hemorrhage, absolute abstinence from food is best. In pulmonary tuberculosis, present or impending, we should advise and direct the patient as to the necessity of ample nourishment in appetizing variety. In organic heart disease, the minimum of concentrated and easily digested food is indicated at short intervals. Cachectic conditions in general call for frequent fatty and nitrogenous feedings. The stools and urine should be closely watched, however, lest alimentation be pushed beyond the limits of digestion and assimilation.

Diet must be adapted to the sensibility of the stomach as well as to the state of secretion, motility and absorption (Hemmeter). The indications of the palate are oftener correct than not. Thorough mastication is of the utmost importance in dyspeptic cases. One needs to individualize the dietetic treatment of indigestion, particularly the nervous form, in which restriction should not be carried too far. Taking meals at short intervals prevents stagnation of bile, and thereby cholelithiasis.

The ideal temperature of food is that of the body (Uffelmann). Extremes of temperature give rise to gastric catarrh (Hutchinson) and injure the teeth. Very hot drinks may lead to ulcer. Uncooked foods are liable to convey active bacteria or parasites. Shakespeare preceded Pawlow in saying that "Good digestion waits on appetite, and health on both." This psychic relation is especially noticeable during sickness, and it explains the need of a high esthetic standard in catering to nutrition at this time. No dirt, no slops, no cold potatoes or cooked-over messes, but the very best cuisine and service which the household or hospital affords, should be provided for the sick one. The eye and the nose, as well as the palate, must be pleased. Automatic rhythm of the digestive functions is to be cultivated by the utmost punctuality as to meals. All gastric sufferers in whom neurasthenia or deficient motility is a factor should rest after meals (Hemmeter). Children and invalids should always eat dinner about midday. In infectious conditions it is a good sanitary rule to rinse the mouth with a mild antiseptic solution (boric acid, glycerin, lemon juice) before taking food. In old age the diet should be especially light and digestible (non-fatty), in frequent small feedings, with gradual restriction of proteins. Unconscious patients can be fed slowly with a teaspoon or by the stomach tube, or with a catheter through the nostrils.

Milk.—The fat-protein-carbohydrate composition and easy digestibility (one-third the digestive energy that bread requires) of milk render its range of service the widest of all foods in sickness and invalidism. It is also an excellent excipient for the administration of irritant drugs. Many persons object to milk because it coats the tongue and makes them costive and bilious. These objections are generally overcome by gradually increasing the allowance, by the use of fruits and pleasant mouth-washes, and by skimming or diluting the milk or flavoring it with salt, baking soda, HCl, meat extracts, tea, coffee, cocoa, caramel or spices; also by the occasional substitution of broths.

Because of their greater rennin activity, young children digest milk more completely than adults (Rübner). Milk is deficient in iron (new-born infants have a hepatic accumulation), and its too prolonged exclusive use leads to anemia. Boiling milk breaks up some of the complex organic molecules, liberating H_2S from casein, and rendering the food less assimilable; so that children fed on condensed or sterilized milk are more liable to scurvy and rickets. Impure milk is a frequent cause of summer diarrhea.

Meig's method for the artificial feeding of infants is as follows: Take a quart of good, fresh milk, place in a high pitcher and allow to stand in a cool place for three hours; then pour off upper half, without shaking, and keep for use of infant. Make also a solution of milk sugar, 18 drams to a pint of water, in wide-mouth bottle and keep in cool place—not refrigerator—if it sours prepare anew. Make also lime water by putting three or four tablespoonfuls of clean, fresh-slaked lime in quart bottle, fill with clean water and shake; after an hour, pour off clean water through two or three thicknesses of muslin into another clean bottle—can make more lime water indefinitely by pouring water on sediment. Prepare food by mixing three parts of the weak cream, two of lime water and three of sugar water; warm, but do not boil, and it is ready for use. Begin feeding with this food (if necessary) when baby is two days old, giving about ½ ounce at first every two hours; in three weeks, 2½ ounces; at six weeks, 4 ounces—use food in same strength until baby is from six to nine months old.

The inhibitory effect of the fat of milk and eggs on gastric secretion makes these foods of special service in hypersthenic and irritative states of the stomach. Most diarrheal conditions in adults are benefited by a bland diet, largely of bread

and milk. The same is best for genito-urinary patients (Lydston) and in acute rheumatism. In nearly all skin diseases a milk diet with abundance of alkaline waters is helpful. Tuberculous patients derive most good from milk, gaining in weight and strength and unvexed by autointoxication. An exclusive milk diet enhances assimilation and diminishes the uric acid output.

The Weir Mitchell treatment of neuroses with emaciation consists in absolute rest and the administration of four ounces of milk every two hours, gradually increasing the amount and lengthening the interval to three hours, and soon adding poached eggs, chops and bread and butter. Burkart gives zwieback with 100 gm. of milk (flavored with sugar, cocoa, tea, lime water or salt) every two hours, gradually increasing the milk to two or three liters daily after a fortnight.

Pancreatized milk, one or two quarts daily, is a standard diet for typhoid fever. Junket must be made from fresh, uncooked milk. Milk is contraindicated in diseases of the small intestine (Rosenheim). Skimmed and diluted milk, buttermilk, whey and kumiss are very useful in acute nephritis and pyelitis.

Cream and butter may well supplant cod-liver oil and all proprietary emulsions. Children especially need large amounts of this milk-fat for their growing nervous system and because of their relatively greater radiation of heat. Well diluted cream is a useful substitute for milk in the digestive disorders of infants. Cream and carbohydrates, fruit, lemons and green vegetables are recommended by Vaughan in Bright's disease. Pure ice cream is soothing to a sore throat, and, when taken slowly, may be allowed in convalescence from fevers.

Fresh buttermilk (casein finely coagulated) is an ideal food for elderly people. Its laxative and antiautotoxemic effects, due to lactic acid, render great aid in relieving the obscure muscular pains of this period of life. It is also recommended in chronic gastroenteritis. Cottage cheese and the Swiss cheeses, containing hardly any purin bodies, are useful (Haig) in the "uric acid diathesis."

Eggs.—The eggs of fowls are very rich in fats (2 per cent. in white and 30 per cent. in yolk) and proteins (12 per cent. in white, 15 per cent. in yolk), hence are called for in nearly every cachectic condition. As part of the home treatment of pulmonary tuberculosis, Osler has advised giving 24 raw eggs daily. The organic sulphur and phosphorus (over one per cent. in yolk) of eggs quickly separate as offensive gaseous products, and eggs for the use of invalids should be "just dropped" if possible. Eggs are best cooked slowly at 160° to 180° F. Boiling hard or frying retards their digestion to double the norm. Raw eggs can be made more palatable by salting, peppering or spicing with nutmeg or other condiments, or by beating them up with broth or whiskey and sugar, or sherry or brandy. Eggs may also be beaten with boiling water and strained and dropped into consommé, light broth or gruel (Thompson).

Weakly children a year or more old are helped by eating daily from one to three soft-cooked eggs. The relatively large content of lime adds to their value in rickets. In diarrheal and febrile complaints the white of an egg may be beaten up with half a glass of water and pleasantly flavored, to be used as a drink. In feeding young infants Dr. A. E. Grant has suggested the use of a medicine dropper for conveying to the throat a mixture of equal parts of egg albumin and water. A solution of egg-white flavored with meat extract is a good substitute for beef juice (Pattee). Swallowed directly from the shell, eggs are soothing to an irritable larynx.

Following hematemesis or the violent pains of gastric ulcer, Einhorn feeds by the rectum for five days with a glass of warm milk in which a raw egg has been well beaten and a pinch of salt added—or a cupful of warm water containing a tablespoonful of a good albumose. If the gastric HCl is lacking in fevers, it may be added (up to 3.5 per cent. of dilute acid) to the ingested milk and eggs. The yolk cure is recommended by Stern in diabetes. He gives 10 to 40 yolks a day, boiled or in coffee, egg-nog, salad dressings, celery and cauliflower soups, etc. Custards composed largely of eggs are useful adjuncts to a convalescent dietary (Thompson). Eggs are contraindicated in flatulent dyspepsia or any serious gastric derangement and in severe acute or chronic nephritis.

Meats.—Animal proteins are more digestible than vegetable proteins, but they contain more extractives (one-third the N of beef) related to and convertible into uric acid and allied bodies. Red meats are no worse than white meats in gouty conditions. Young meats, though tender, are relatively indigestible and prone to putrefaction. Chicken, young pigeon and game are easily digested. Salt, smoked and pickled meats and most pork are generally contraindicated for the sick and infirm. Crisp breakfast bacon, however, is digestible as well as nutritious. The valetudinarian poet Horace used to find his dish of bacon and greens excellent in all ways.

Meats increase and vegetables diminish arterial tension in arteriosclerosis. Meats are especially indicated in anemias and chlorosis. Lean meat should form the basis of diet in obesity. A meat diet and constipation favor the multiplication of colon bacilli and appendicitis (Benedict), but surgeons, preparatory to abdominal operations, are coming to favor a meat diet for the flat gut it gives. The glandular portions of animals should be prohibited in goutiness, diabetes and nephritis.

The preparation of meats has much to do with their fitness for sick people. Steak that is broiled or finely divided will agree with a feeble digestion where fried meat would disagree. Ground boiled or roasted beef, heated in the oven on pieces of thin toast, or ground raw round steak

baked after stirring with eggs and crackers, is a good thing in atonic conditions of the stomach. Cold storage meats, particularly poultry, have always about them the possible dangers of ptomain poisoning.

The pleasant flavor and appetizing effect of bouillons depend largely on the muscle extractive creatin. Aromatic herbs are often added as a savor. These meat broths, aside from the contained gelatin (best extracted by long, slow cooking) and any cereal or egg additions, possess no nutritive value, favor the virulence of colon bacilli and are definitely contraindicated in goutiness and migraine. Boas recommends a soup diet for eight or ten days in proctitis and fissured rectum. Well-spiced broths are useful to "brace up" with after a spree. Rich gravies are almost never in order, but the fresh juice of broiled steak, with bread crumbs, is very good for young children with digestive disorders. Meat juice contains about 6 per cent. of proteids. It is objectionable because of the possibility of bacterial and parasitic contamination. Gelatin jellies, agreeably flavored and served ice-cold, with or without cream, are of special service in febrile diseases, since gelatin is a tissue-saver, having about one-third the caloric value of albumin. Gelatin may also be given with eggs or milk as blanc mange. The calcium-content of gelatin probably accounts for whatever beneficial effect it may have in gastrointestinal hemorrhages, scurvy, purpura and aneurism.

Zomotherapy (raw beef scraped to a fine pulp and served with salt and pepper or covered with a layer of grated chocolate) has advocates in the dietetic treatment of pulmonry tuberculosis. They claim that the distaste for raw meat is soon overcome, and that the danger from parasites in properly selected meat is of little relative import. Scraped beef sandwiches are useful in convalescence from fevers. Albumoses (best given in soups or purees) are of service in marked motor insufficiency of the stomach.

Fish.—The flesh of fresh lean fish ranks first in digestibility, particularly trout and whiting (Pavy). Fatty dark-flesh fish (salmon, mackerel, herring, eel) are rather difficult of digestion. Salted fish are often a useful addition to the diet in cases of hypochlorhydria. Fish decomposes rapidly, and when canned is liable to give rise to ptomain poisoning, especially if the can has been opened a day or two. The alkaline juice of fish may be neutralized with lemon juice or vinegar. In general, fish may be used as a substitute for meats when the latter are contraindicated.

Oyster (14 per cent. proteins, 15 per cent. fat) and clam broths made with milk are pleasant, digestible and nutritious foods in acute fevers, particularly grippal attacks. The soft part (liver) of the oyster is most easily digested raw, since the accompanying juice contains a diastatic ferment. Clam juice may be tried in the vomiting of pregnancy (Thompson). Crabs, lobsters and shrimps frequently excite urticaria and other signs of autointoxication, partly because they are scavengers by nature.

Fats and Oils.—These stimulate the pancreatic and biliary secretions, but tend to inhibit the secretion of gastric juice. Hence they are indicated in hyperchlorhydric, and contraindicated in hypochlorhydric conditions, and in jaundice, lithemia and skin disorders. They are not usually well borne in acute diseases.

Animal oils and fats are generally more digestible than the vegetable, whereas the mineral cannot be utilized at all by the body. Hot fats are more indigestible than cold. When closely incorporated with connective tissue, as in ham, fat is very refractory to digestion. Foods fried in grease develop irritating fatty acids and are not to be eaten by persons with feeble digestive powers. Graham and oatmeal crackers are rich in fat. Olives are about one-fourth oil.

Because of their tissue-saving value, oils and fats rank highest in the dietaries of most chronic wasting conditions, particularly pulmonary tuberculosis, and in convalescence from acute diseases. Strumous and rickety children should be induced in every way to take butter, cream, bacon fat, olive oil and bone marrow. Fats and oils are generally laxative, but good fats, even in large quantity, are usually well borne in chronic diarrheas (Boas). Taken in excess of the needs of the system, fat is stored as adipose tissue.

In diabetes mellitus the glycosuria and emaciation are best controlled by a diet rich in fats and proteins. Saratoga chips (little starch and much fat) are recommended by Thompson in diabetes. Kleen's diabetic diet consists in restriction of carbohydrates to 60-100 gm. daily, or exclusion from the diet for two to four weeks several times a year (except in severe cases), making up the deficiency with fats (butter), proteids (except milk, cheese and liver), green vegetables and alcohol. The oatmeal cure of Von Noorden may be tried in severe obstinate cases of diabetic acidosis. The patient is fed exclusively on oatmeal gruel, each day's ration consisting of 250 gm. oat flour, 250-300 gm. butter and 100 gm. roborat or other vegetable albumin (or white of eggs may be added after cooling), the mixture being prepared as soup and given at intervals of two hours.

Bone marrow is quite rich in fat, and consumptives do well to partake of it freely. According to Holt, artificial foods for infants contain too much sugar and too little fat, with consequent late teeth, soft bones and flabby muscles. At least 25 gm. of fat can be introduced daily by inunction (Benedict).

Cereals.—The breadstuffs are the principal foods of the human race. They require, however, more proteolytic units than meats, and an exceptionally high amlolytic power. Wheat bread is the most digestible form, and whole wheat bread is generally preferable as containing more proteins (12.2 per cent., as compared with

8.8 per cent. in white) and phosphates, the gluten layer being just beneath the cellulose husk. Macaroni is half again (16 to 18 per cent.) as rich in gluten as wheat bread, and when well cooked is a good substitute for meat.

Bread for invalids should be at least a day old, or, better, dextrinized into thin toast or zwieback. Plain and salt crackers are excellent in atonic dyspepsia, and are rendered more palatable by heating in the oven. Biscuits, pastries and puddings (except plain farinaceous) are to be avoided by persons with weak digestion. Pancakes lead to acne, and carbohydrates in general favor furunculosis. Gluten breads are deceptive in diabetes, since the best of them contain more starch than potatoes do. Oatmeal is very nutritious and may take the place of meats in persons with strong digestion. Like buckwheat, it contains much cellulose. Maize mush and milk is a good old-fashioned combination much neglected nowadays. Corn has specially harsh seed-coats, but the white part of popped corn is a very delicate and digestible form of starch and protein (Benedict).

The rye and graham breads owe their laxative action to the indigestible cellulose. In this connection, Dr. William H. Buehtel has employed for forty years in treating constipation, a half cup of bran steeped with water to the brim for twenty minutes, then the water is poured off and the bran is served for breakfast with cream or orange juice. Cereals containing husk and gritty particles are to be avoided when there is a tendency to gastric stagnation.

Ground barley and rice are particularly bland (little cellulose) foods when well cooked (best strained), and are most useful in the digestive complaints of infants and children. Rice is well flavored with the juice of steak or with butter. Barley is used largely for thickening soups. Infantile colic can often be prevented by giving before each nursing a tablespoonful of thin gruel. Corn and rice meals are less liable to become sticky than wheat flour, and so are preferred for muffins, waffles, gems and pancakes.

To make dextrinized gruels Chapin directs to beat up one or two heaping tablespoonfuls of barley, wheat or rice flour, or two to four heaping tablespoonfuls of rolled oats, with enough cold water to make a thin paste. Pour on a quart of boiling water, and boil at least fifteen minutes in a covered double boiler. Place cooker in cold water, and when gruel is cool enough to be tasted add a teaspoonful of diastase solution, and stir; strain, salt and cool. These gruels serve admirably as temporary milk substitutes in the gastroenteritis of bottle-fed infants and young children.

The dextrinized package foods are nearly all to be recommended, according to individual likings, to convalescents and the subjects of most chronic diseases. Served with or without sugar and an abundance of cream, they are very nutritious and easily digested.

Vegetables.—Many tubers are used as food, because of their starchy composition (potatoes, 20 per cent.). Baking potatoes renders them much more digestible, the heat of the oven being about double that of boiling water. Potatoes, like most coarse vegetables, on account of their water (90 per cent. in turnips and cabbages) and woody fiber, are prone to fermentation, and must be avoided in amylaceous dyspepsia and in cardiac troubles. Sweet potatoes are less suitable for the sickly than the Irish variety.

Vegetable proteids are less than half digested (Brubaker), because of their combination with cellulose. The legumes are rich in proteins, but are peculiarly indigestible, and are best given hulled (cellulose in seed-coats) or in a finely divided state. Legumin also liberates much H_2S in the bowel. In uricacidemic conditions with active digestive powers, they may replace meats. Bean flour (10 per cent.) added to wheat flour makes a very nutritious bread. Peanuts are nearly half oil.

The so-called green vegetables are relatively innutritious (below 5 per cent.) but are rich in iron (spinach has 35 mgm. per 100 gm.) and potassium salts, hence are useful in anemia and scurvy. They should be young and fresh, as on drying they become stringy and tasteless. They are best served in the form of purees. Their absorption as a rule is quite incomplete. In the form of salads (not for dyspeptics) they promote the appetite and the digestion of more nutritious foods. Along with acid fruits, they should form the basis of diet for gall-stones. Celery cooked in milk is wholesome and digestible; asparagus is easily digested; spinach and rhubarb have a laxative action. Cabbage is seldom allowable, but well cooked cauliflower can be taken even by delicate children. The calcium oxalate of rhubarb, spinach, asparagus and tomatoes contraindicates the use of these vegetables in oxaluria and the closely related lithuria.

Arrowroot furnishes a very pure starch, serviceable in gruels, puddings and blanc mange whenever a bland diet is needed, as in diarrheal complaints. This or baked flour may be added to milk. Sago and tapioca are similar to arrowroot. All starchy and saccharine foods, by fermenting to lactic acid, predispose to rickets. Carrots and parsnips are seldom indicated in the sick dietary. The pectin in the outer layers of the carrot serves as a flavoring agent. Radishes may be used as a relish with bread and butter for persons who are not subject to flatulence. The sugar of beets (10 to 30 per cent.) and carrots and the acids of rhubarb, pickles and tomatoes contraindicate their use in gouty conditions. Cucumbers are very indigestible, particularly the seeds. Tomatoes retain their flavor well, and tomato soup is a good means of giving milk to some persons. The sulphur constituents of onions, cabbages and turnips are generally obnoxious to persons of weak digestive powers.

Only soft, tender vegetables and well-strained

purees should be given to subjects of subacidity and anacidity. Most vegetables, sugars and the seeds of fruits are to be avoided in colitis (Boas), but they are useful in simple constipation. Vegetable soups unduly distend the stomach and increase cardiac labor in diseases of these organs. Fungi (mushrooms, truffles, morels) have no place in an invalid dietary.

Fruits.—The organic acids (malic, citric, tartaric) and their salts (K, Na, Ca, Fe) in ripe fruits serve as appetizers and secretory and excretory excitants. The flavor and odor are due to essential oils and compound ethers. The water (75 to 85 per cent.), cellulose, pectin and colloidal sugars promote peristalsis, particularly when taken on an empty stomach, that is, before breakfast. Stewed and baked fruits are more digestible than raw ones. To correct the acidity that causes flatulence, Yeo advises adding a teaspoonful of baking soda to each pound of cooked fruit. Fruits have an alkalizing effect on the blood and urine.

The levulose and mannose of fruits are comparatively readily oxidized, hence fruits are not contraindicated in diabetes. Fruit juices (orange, lemon, pineapple), diluted and given cold, are very grateful in fevers. Scraped apple, mashed potato and fresh fruit juices are curative in scurvy, perhaps by counteracting the mineral acid intoxication on which this dyscrasia is said to depend. It is essential that fruits should be neither unripe (acids and starches) nor overripe, either condition giving rise to bowel disturbance. Fruits are contraindicated in catarrhal conditions of the stomach or intestines, though for diarrhea Ewald recommends a laxative mixture of one part of figs and two parts of prunes. On account of their seeds, berries are best taken with bread. Bananas contain about as much starch (changed partly to sugar as fruit ripens) as potatoes; if used at all, they should be baked as potatoes are. Banana flour (made into a thin gruel or porridge) is recommended (Thompson) as suitable in cases of gastric irritability. Strawberries may give rise to erythema, urticaria or dermatitis. Cranberries, well cooked and sugared and passed through a colander, are a serviceable appetizer, as is likewise a good orange marmalade. Currants and citrons are wholly indigestible (Thompson). Pineapple juice contains a valuable proteolytic ferment (bromelin). Dried dates and figs contain 60 per cent. sugar and 6 per cent. protein, and are therefore very nutritious. Plums, peaches, apricots and raspberries contain the least sugar; apples, cherries, grapes and pears the most. A quantity of apples, peel and all, will check biliary diarrhea (Fothergill). As a preventive of infection, fresh fruit should be washed before eating.

Nuts are rich in oil (mostly 50 to 70 per cent.), and so are very nutritious, but, because of their cellulose, need to be well masticated (better, ground) to insure eutrypsia. They are probably best taken about two hours after meals, when they may pass almost directly into the duodenum. Almond and cocoanut bread and cakes are recommended in diabetes. Chestnuts contain ten times as much carbohydrates (70 per cent.) as of fat; walnuts, much fat and protein. Nuts full of oil all contain 15 to 20 per cent. proteins, except cocoanuts (6 per cent); pecans and chestnuts (10 per cent.).

Condiments.—Common salt is believed to be the source of the gastric HCl, hence is indicated in hypochlorhydria, although its primary effect (Pawlow) is inhibitory to the secretion of the acid. In ordinary asthenic dyspepsia salted crackers and salt fish are often beneficial. A lack of food salt leads to malnutrition; overdoses are irritant and cause diarrhea and diminish the solubility of urates in the blood. In edema and transudations the salt accompanies the fluid into the tissues and serous cavities, five gm. of salt holding a kg. of water here (Javal). For this reason dropsical conditions (especially renal) and effusions in general should be treated dietetically by dechloridation, as with a milk and rice diet. Common salt is contraindicated in epilepsy, and may be substituted here, even in bread, by sodium bromide. Salt and lime (eggs) are especially indicated in scrofulous conditions. Sugar is a prime source of heat and energy, excess being stored as adipose tissue. On account of its tendency to ferment, with production of acids and gases, and to cloy the appetite and impair digestion by depriving the glands of their water, it is best taken sparingly and at the close of meals. Glucose ferments most readily, lactose, least. An acid weak sugar solution (grape juice) is a nourishing drink in acute febrile disorders. When flatulence troubles, cream or lemon juice may be used on gruels in lieu of sugar. Sweets are to be restricted in gouty and rheumatic persons, since they are more oxidizable than proteids, which are thus insufficiently oxidized (Reed). Molasses is a good laxative for children when it agrees in other respects. Saccharin is often substituted for sugar in diabetes as a sweetening agent, but if long continued produces digestive disturbances.

The volatile oils and oleoresins of spices serve as psychic stimulants to digestive secretion and absorption (Boas), and have further some counterirritating reflex stimulating effects. They are particularly helpful in sub- and anacidity and in the atonic conditions of advancing age. They are distinctly contraindicated in irritative (hyperchlorhydric) and inflammatory conditions of the gastrointestinal and urinary mucous membranes and (along with tea, coffee, alcohol, sweets, pastries, pancakes, cheese, sausage, pickles and fried foods) in diseases of the skin and the heart. The choice of condiment is mainly a matter of individual taste; capsicum is about the most reliable, and is of special service in dipsomania. For children, cinnamon, ginger and vanilla are recommended. A skilful use of condiments (ginger ale, etc.) may obviate the necessity of alcoholic stimulation (Thompson). Vinegar has

rational use in salads, since it softens the cellulose of vegetables as well as muscle fiber.

Beverages.—Next to air, water is most immediately requisite to bodily functions, and is especially indicated in fevers to eliminate toxins. The average healthy adult requires three or four pints daily, in addition to that (50 to 60 per cent.) contained in solid foods. Cool water slows the pulse, raises blood pressure and stimulates peristalsis; warm water has the opposite effects (Baruch). Very hot water quenches thirst better than cold. Carbonated water is a gastric stimulant. Water is best drunk chiefly between meals, so as not to overload the stomach and unduly dilute the digestive juices.

Free water-drinking is very beneficial in thick-blooded melancholia, in constipation and in the obscure aches and pains of goutiness and malassimilation. It is the most important medical consideration in gall-stone trouble. It is urgently needed after severe hemorrhage, and massive serous discharges from the bowel. In order to ensure the drinking of a certain quantity (say a glass of water every two hours), it is often advisable to direct the patient to dissolve some harmless effervescent tablet in a whole glass of the liquid before taking. Hot water and hot diluent drinks (cream of tartar lemonade) are indicated in acute Bright's disease. Hot water on an empty stomach is of service in cholelithiasis and in mucous gastritis; cool water, in hyperchlorhydria. For obvious mechanical reasons, a relatively dry diet is to be recommended to sufferers from cardiac valvular and muscular disease with dropsy and other signs of incompensation, and in aneurism, ascites and pleural effusions. Much liquid by the mouth at or near meals is to be avoided in motor defects of the stomach (hyperkinesis, gastroptosis, pyloric obstruction, ectasia) and in nervous flatulence, obesity and asthma. In the last two or three months of pregnancy a diet restricted in fluids and carbohydrates lessens the size of the child without otherwise influencing its development (Friedenwald and Ruhräh). Manges recommends giving water cold (reflex diuretic effect) and in frequent small quantities in acute infectious and septic conditions. Ice produces dryness of the tongue by the action of cold, and glossitis and buccal erythema by thermal reaction. Large quantities of ice cream or ice water have caused sudden death, probably by reflex inhibition through the pneumogastric.

Tart lemonade is an excellent beverage in gouty and rheumatic states (citric acid being converted into carbonates, which render the blood more alkaline), and is a pleasant medium for taking alkaline salts. Hot lemonade, like other hot drinks, favors diuresis and diaphoresis, and thus the elimination of toxic products in coryza, grippe, etc. Sulphuric acid (15 m. to the tumblerful) lemonade is used as a prophylactic of plumbism.

The alkaloidal beverages (tea, coffee, cocoa, chocolate, kola) have as their active ingredients (caffeine or theine and theobromine) substances closely related to uric acid. They also contain considerable astringent (constipating) tannin (13 per cent. in green tea), which is extracted by long boiling and which is said to stay hunger. In black tea the tannin is rendered less soluble by fermentation. Cocoa is really nourishing, being nearly half fat and one-eighth proteins, and, when well borne by the digestive organs, should be drunk freely by thin and weakly subjects. Tea is an efficient gastric sedative in migrainous attacks and in opium sickness. Chocolate contains about 60 per cent. sugar, and is hence quite fattening. Because of the contained theobromine, chocolate or cocoa is an excellent diuretic drink in kidney troubles. Coffee is a cerebral and vasomotor stimulant, useful in collapse and in headaches with low vascular tension, in alcoholism and for opium coma (best given through colon tube). Tea and coffee are contraindicated in all states of nervous erethism, as exophthalmic goiter, and in irritable heart from any cause. They diminish proteolytic digestion in the stomach by one-third (Schultz). The cereal substitutes for coffee are to be recommended whenever hot water is in order.

The value of alcoholic liquors in diseased conditions is a much debated question. Alcohol is a tissue-saver (1 gm. equal 0.071 calorie), being burned in the capillaries to the extent of about two ounces daily. It would seem, therefore, to have some use in wasting fevers (hyperpyrexia, weak heart, low arterial pressure), tuberculous or otherwise, but it is readily abused and should be prescribed with as much care as other drugs. Over 5 per cent. of alcohol in the food tends to inhibit digestion.

The habituation of the patient to alcoholics renders their administration more necessary in acute conditions. Aged persons also bear such stimulants comparatively well. The average daily allowance for sick adults ought not to exceed four to eight ounces of pure whisky or brandy. The administration of spirits should be curtailed when they cause excitement or other mental symptoms, or when the odor can be noticed on the breath. Alcoholic liquors are generally undesirable in gastro-intestinal diseases, affecting the liver most injuriously. The acids of wines and fermented liquors have an irritant effect and make mucous conditions worse (Reed).

Chronic diseases and cachexias are seldom benefited by alcoholic beverages, and there is great danger of inebriety being superadded to the disease. Malt liquors favor the putting on of fat, partly from the contained carbohydrates and partly because of imperfect oxidation and elimination. The galactagogue effect of beer, ale, porter or stout is not to be compared with that of broths and cereal gruels. Malt liquors are contraindicated in gout, obesity, diabetes and urinary diseases (Friedenwald and Ruhräh).

Claret or cognac in water may prove of service in acute diarrheas (Boas). Whisky is some-

times laxative. White wines are more stimulating than red, since, containing no tannin, they are absorbed more promptly. Effervescent beverages, by distending the stomach, are hurtful in heart disease. A cup of hot milk, broth, punch or toddy at bedtime may overcome simple insomnia.

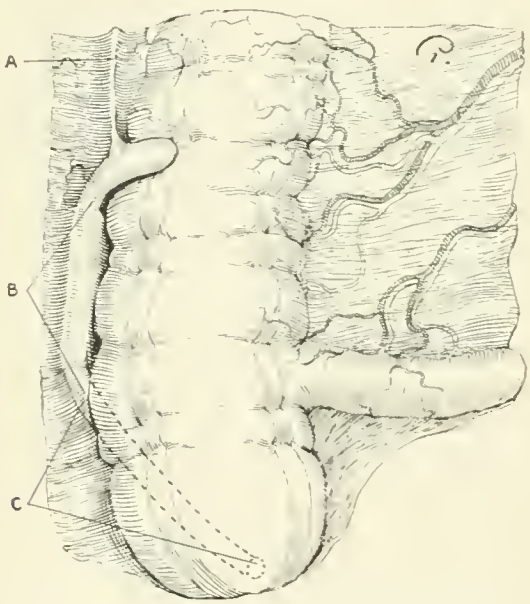
AN APPENDECTOMY WITH AN UNCOMMON LOCATION OF THE APPENDIX AND INVOLVING A MODIFICATION OF THE INTERMUSCULAR INCISION.

BY ALFRED S. TAYLOR, M.D.,
OF NEW YORK.

The patient, Sam'l C., seventeen years old, was operated upon in the surgical service at Randall's Island Hospital May 24, 1905. The history preceding operation presented no features of special interest, and operation was done while no acute inflammation was present. The interest of the case lies in the uncommon location of the appendix.

The peritoneal cavity was entered by means of the intermuscular incision, the cecum was with some difficulty pulled into the wound, and by following two of its longitudinal bands to their junction the base of the appendix was

Fig. 1.



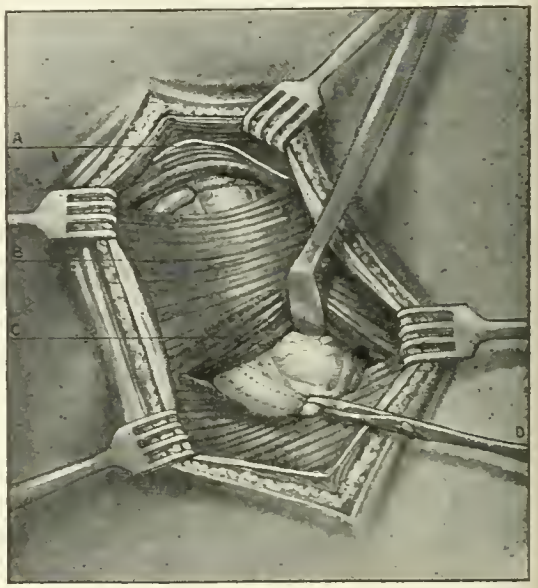
Schematic.—*a*. Peritoneal fold running upward from meso-appendix toward liver; *b*. Retroperitoneal portion of appendix; *c*. Retrocecal portion of appendix.

readily identified and caught with a clamp. (Fig. 2.)

Only a half centimeter of the appendix could be seen, as it seemed to pass immediately behind the peritoneum and cecum. A finger passed to the inner side of the cecum could not detect the distal portion of the appendix, but when passed upward along the outer side of the cecum, felt the clubbed curved tip of the appendix nearly 7 cm. above the upper edge of the incision. This clubbed end for about 2.5 cm. was free in the peritoneal cavity with a meso-appendix from which a fold of parietal peritoneum ran upward toward the liver. The middle portion seemed to be retroperitoneal, and the proximal portion retrocecal (Fig. 1).

The peritoneum was divided at the base of the appendix and an attempt made to enucleate

Fig. 2.



a. Tenth intercostal nerve; *b*. External oblique aponeurosis; *c*. Internal oblique and transversalis muscles; *d*. Clamp on base of appendix.

the appendix with the finger. The retrocecal portion was readily freed, but it soon became evident that the upper portions could not be dealt with by this method, which was blind and did not give sufficient control of any hemorrhage that might occur.

The patient's muscles were very well developed, and traction upward did not expose the necessary field.

Neither Weir's enlargement of the intermuscular incision, nor Kämmerer's incision through the rectus abdominis would give space where it was most needed, at the outer side of the ascending colon. To add the old-fashioned oblique incision through all the layers to the intermuscular incision already made would make a wound which would most likely lead to ventral hernia later.

At this moment the idea suggested itself that a second intermuscular incision at the level of the tip of the appendix would answer the demands of the case admirably. Therefore the incision was continued upward through the skin and external oblique muscle and a second intermuscular entrance to the peritoneal cavity made at the level of the tip of the appendix (Fig. 2).

The mesentery of the free portion was readily ligated and divided. The middle, or retroperi-

toneal, portion was pulled forward to make an artificial meso-appendix, which was then tied off and divided, thus practically suturing the parietal peritoneum beneath the appendix. The appendix was then passed from above downward behind the cecum, where it had already been liberated, and delivered through the lower wound. The appendix was removed and the stump inverted.

The wounds were closed by layer sutures. The patient made an uninterrupted recovery with primary union throughout.

This technic proved to be rapid, was very satisfactory, in that it gave a perfect view of the operative field, and left the patient with an intact abdominal wall.

152 West Fifty-seventh Street.

THE AMERICAN DISEASE: AN INTERPRETATION.[1]

BY WILLIAM BROADDUS PRITCHARD, M.D.,

OF NEW YORK;

PROFESSOR OF NEUROLOGY, NEW YORK POLYCLINIC; VISITING NEUROLOGIST, NEW YORK CITY HOSPITAL; CONSULTING NEUROLOGIST TO J. R. SMITH INFIRMARY, NEW YORK CITY.

MEDICAL nomenclature, certainly as regards names for many diseases, stands to-day the most neglected, the most incongruous, the least rational and the least progressive of all the minor divisions of the subject. Many of those most familiar justify a continued existence solely through the fallacious law of traditional custom. In some instances, both name and disease being inelastic—typhoid fever or epilepsy, for example—no special harm is done. In others, as hysteria and chorea, we continue to insult intelligence apparently without either consciousness of shame or hope or desire for reform. There is something of promise in the tuberculosis of to-day rather than the consumption of our fathers, but much remains to be done, the work having scarcely begun. The field of neurology, perhaps, more than any other, needs the scythe and pruning hook. The latter instrument could, in my judgment, be used with particularly beneficial effect if employed vigorously and with discriminating judgment in neurological nosology. Its first work, if in my hands, would be to clip and trim and shape into at least some semblance of definite form and substance that phantom, once a tree, now a forest and rapidly becoming a wilderness, so rank and riotous is its growth, neurasthenia. No shorter road to nervous prostration exists than along the route of present interpretation and mental comprehension of the term as generally understood or misunderstood. I confess to an antipathy—I think rational, though amounting to almost an obsession—for the word. Originally intended to possess a definite significance, its field of application has been so elaborated and broadened and abused that to-day it means almost anything and with equal truth almost nothing. The inspiration which gave it birth marked the genius, but the child has grown a monster, fattening upon the flesh of hundreds of brothers and sisters, and even its cousins. It is still from custom classed among the neuroses or psychoneuroses, and thus the special property of the neurologist, but like its twin sister—the only sister left, by the way—hysteria, it has wandered afar with an omniverous appetite, and is known to-day and claimed in some one of its hydra-headed forms in every field of medicine. To the stomach specialists belong the gastric and lithemic types, to the surgeon the postoperative and some of the traumatic cases. The sexual neurasthenic is the property of the genito-urinary specialists, the reflex cases are almost equally distributed to those who know the eye, the ear, the nose and throat, while the neurologists divide the remainder with the gynecologists, or play battledore or shuttlecock with all. The general practitioner alone is counted an invader in this field, and he, wise man that he is, with appreciative philosophy, rarely feels himself aggrieved.

My criticism is not of the term etymologically. On the contrary, properly restricted in interpretation, it is an excellent example of word-making. It should stand, however, for either fish, flesh or fowl—for a definite entity or syndrome—if retained in our nosology. If discarded in this field, by all means keep it, but restrict it to the broad descriptive significance of a generic term alone. I am not yet willing to accept the dictum embodied in the recent paper of an eminent American writer who, with a stroke of the pen, announces the passing of neurasthenia, for which he would substitute a group of pure psychoses, if for no other reason than that he leaves us none the better off for such a begging of the question; and yet one is almost tempted to let it pass away into final oblivion and without a protest on reading a serious thesis by another recent writer upon neurasthenia in babes. If it is to continue a neurological and general medical waste-basket into which we are to dump all forms and degrees of illness associated with irritable nervous weakness to which we cannot attach a standard label, then it cannot be lost too quickly. It means to-day to the student mind mystery, confusion, chaos and correlated aversion, curiously mixed with a contradictory fascination; to the patient it has become a term full of suspicion; to the medical teacher it is a term of reproach. No observation or experience during my fifteen years of postgraduate teaching has been more emphasized than this attitude of mind of the student body. Year after year and many times a year, the cry has been the same from all my classes: "What is neurasthenia?" I think you will agree with me that something should be done. The solution of the problem to me seems relatively simple. Let us stop running after strange gods and the making of false idols and return to the worship of our fathers and to one faith. There *is* a nervous affection—the very same which originally inspired Dr. Beard to coin the word, with a broadly constant symptom picture, a more constant etiology,

[1] The Address in Medicine read before the Ontario Medical Association, June, 1905.

a conjectural pathology, a fairly certain prognosis and a definite plan, in principles at least, of treatment, the chief and essential symptomatic manifestation of which is an irritable, quick exhaustion of nervous function in many or all directions. It has become almost lost, it has suffered degradation, it has fallen from the genus to the species in the literature of the subject, not so much through intrinsic conditions, but because of the confusion and chaos of interpretation. The dignity and importance of this subtype, its rapid and progressive increase, the charm and fascination of its study and of its remedial and curative treatment are such as justify and, indeed, demand that it be taken from this chaotic mass and be given a distinct identity. Let *this* be neurasthenia. We shall simply give back to Cæsar what was his—lost property to the original owner. It is but the restoration of a birthright. How the thief will cover his nakedness is his problem, not ours.

I have but borrowed for a purpose my title, and having explained my motive, I discard it. And yet it is not altogether bad. That it has the ring of cheap sensationalism is a just criticism, though nothing was further from my mind, a disavowal which I hope has been anticipated and is accepted. In much that the condition that I have in mind represents, in much that is peculiar to this affection—to neurasthenia—the term, the American disease, is both accurate and appropriate. As I conceive it, it *is* an American disease indigenous to this soil and essentially a product of causative conditions peculiar to this country. That it now exists elsewhere, and probably always did in sporadic form I do not doubt, but this is its home, this its soil, this the atmosphere in which it luxuriates. What is this disease? What are its symptoms? How differentiate it? What is its etiology and prognosis, and how is it to be treated? My limit of time will permit me to create the scheme of the picture only, but if the viewpoint be the proper one and the perspective liberal in breadth any one of my audience will, I am sure, be able to do the filling in. I would count my work well done and a good end accomplished if I did no more than infect you with the enthusiastic interest with which the subject inspires me. In the effort to do so I shall create part of the perspective referred to. First as to your material: Neurasthenia never occurs in fools. The idea constitutes a paradox. Neurasthenia may make a fool, but you cannot make a fool a neurasthenic. It is a disease of bright intellects, its victims are leaders and masters of men, each one a captain of industry. Each case is unique as a study if you are to study helpfully. There are no arbitrary limits to the horizon of studious effort. The political history of the world has been made largely by paronoiacs. Mahomet, Peter the Hermit and Oliver Cromwell are examples in point, to go back no farther. In each there was an imperative and an impelling monomania. The world of literature, of art and of science, of fruitful endeavor in all higher fields, is indebted in an analogous degree to the neurasthenic, analogously endowed with an imperative and an impelling energy. Dr. Gould's list includes such names as Carlyle, Wagner, Huxley, Spencer and many others. The confidence, the faith of patients of this type, is to be classed as an inspiring stimulus in itself and is well worth the struggle to grasp understandingly this subject. That yours is the helping hand depended upon by such men—such giants—whom you may lead as little children; the knowledge that you, and sometimes you alone, may bring back into the world's arena of action and into the old supremacy, such factors in the world's work, represents to my mind an objective, a purpose, a sphere of usefulness second to none of the many laudable ambitions along the highest planes of medicine.

In painting the clinical picture it would mar my scheme to paint an individual likeness. I shall give you first the basis for a composite photograph, made up of the case histories of fifty selected patients from private practice. Forty-two of these were American born, the remainder, 8, with two exceptions, had been residents more than fifteen years; 22 were from New York City, 4 from Connecticut, 3 from Massachusetts, 5 from Pennsylvania, 2 from New Jersey, 5 from as many different Southern States, 1 from Canada, and the remaining 8 from as many different sections. Forty-three were from cities of more than 100,000 inhabitants, although only 21 were city born. The average age was thirty-seven years, the oldest sixty-two, the youngest twenty-six. Without a single exception all were brain workers. Sixteen of these fifty had been makers of history in different spheres, some large, some small; mercantile, literary, religious, scientific, political or economic. Two of the number were among the hundred captains of industry assembled in a list made to commemorate a national function celebrated a few years ago. By occupation 13 were financiers, in multiple mercantile lines, really better described as promoters; 6 were lawyers, 3 clergymen, 2 merchants, 5 physicians, 5 brokers, 4 school teachers. Of the remaining twelve, 2 were professional politicians, 2 corporation officials, and 4 managers of large industrial plants. Four of the fifty were men of independent, self-acquired means, who described themselves as having no occupation at the time of record. They have been included in the groups mentioned according to previous occupation. Four of this series were women, 1 a journalist, 1 an actress, and 2 of them teachers. Fourteen of the fifty were unmarried, the age average of this series of fourteen being relatively high, forty-four years. The four females were all childless, though two of them were married.

Instead of an analytical elaboration of individual symptoms, let me give you a standard clinical history selected from the series of fifty as a type portrait.

M., aged thirty-three, male, born of healthy good stock, American parentage, the only handi-

cap being parental poverty. Driven by necessity and by that subtle factor, temperament, to early effort in extraordinary degree, he acquired the strenuous, ambitious, high tension, keenly sensitive habit. He could not afford a liberal or broadening education because his own dollars paid for it. At nineteen he was in business as apprentice in a large establishment manufacturing mechanical engineering appliances. At twenty-six, with a capital of $500, he organized a company, had it incorporated, was president, secretary, treasurer, superintendent, salesman and chief stockholder, entering into competition with established and lavishly capitalized rival corporations. Awake at 7 o'clock, he hurried through breakfast a few minutes later, mixing an omelet with an order or a countermand, assimilable sometimes with the former, always incompatible with the latter; taking in with his coffee the London market or the Paris bourse, dividing the steam supply between brain and stomach when it should have been all turned on at the point of physiological demand. A hurried walk to the train, possibly a delusional constitutional in this very walk, the steam being still turned on to the top floor. In the office a pile of mail, interviews with clerks, orders, directions, instructions, detail work in every department. Just here *en passant* is laid the immediate foundation of the breakdown. It is the man of detail, the man great in everything except the qualities which make the general, who becomes the neurasthenic. It is the crime of attending to minutiæ which makes the nervous derelict. The general is never a neurasthenic. It is the one flaw in the statue of true greatness. That quality, the highest, which helps us to select our lieutenants, is always lacking. The neurasthenic is the archetype of the Pooh-bah. He is not only general, but also colonel, major, captain and private. The penalty is inevitable. No man can do the work of four along higher lines without paying for it.

After four hours in the office this man goes to lunch, tired, nervous and with preoccupied mind. He takes his secretary or manager, and again the attempt is made to mix a steak or an omelet with a business problem. The steam is still turned on at the top, our patient eats fast and drinks a lot of water or other fluid, prematurely flushing the contents of the stomach into the intestine. Already by nervous inhibition he has interfered with biliary and other secretions. The intestine, the duodenum, cannot take care of the albumenoids—the proteids—properly. It cannot take care of its own. The alkaline reaction of duodenal secretion has been upset by the flushed overflow of acid gastric juice, the secretion of bile has been inhibited by the state of mental tension and the diversion of energizing agencies from digestive viscera to brain. Fermentative decomposition with resulting ptomain and toxin formation follows, deficient nutritional assimilation plus chemical irritation are added to cell fatigue along a routine line without rotation. Notices of protest begin to come into first subconscious recognition, but are disregarded. They may come from any one or many sources. Headache of the cincture or helmet type, vertigo, a sense of irritable weakness, mental and physical, follows; vague mysterious messages in a strange language, never heard before, are received, but not understood. This patient has always been well and has had no training along the lines of familiarity with symptoms. These messages, at first ignored, sometimes hushed with a cocktail or a highball, or many of both, become more and more continuous and imperative. The habit of almost mechanical activity of mind projects itself into the hours for sleep, insomnia develops, at first as dreamful anxious sleep, then with fitful, broken sleep, and later with an allowance cut by more than half from the normal. He wakes tired, irritable. The pneumogastric is one of the first and often the most emphatic of the aggrieved protestants. Palpitations, overaction, an irregularity partly toxic, lay the foundation for what later has become an obsession of fear of sudden death—præcordlangst—heart anguish. He fears to be alone, to walk alone, to sleep alone. To this other fears have been added. A perfectly legitimate dizziness has laid the foundation for an almost hallucinatory persistence of this impression. Rapid motion, as in the cars or a carriage, high places, sudden changes in the visual perspective, originate as many phobiæ. Every nerve gets on edge and this hyperesthesia of auditory, or visual, or olfactory, or gustatory, or pneumogastric nerve, varying, as it necessarily does, in degree, gives explanation for the protean system picture. It is the mystery of it all which leads to introspection in attempts at explanation, and finally to an exquisite exaltation of subject consciousness, a veritable delirium of anguish.

Neurasthenia is essentially a recoverable affection. In a majority the recovery is complete and final. In a few, usually neglected or mismanaged cases, the recovery is imperfect, relapses are common and the neurasthenic habit becomes almost a part of the individual. Even in these cases a steadily progressive tendency to recovery and to a normal poise as the final fixed habit may be established by persistent effort based upon an intelligent understanding of the general principles of treatment plus an appropriate application of such principles to the personal equation of the particular patient. Neurasthenia carries with it no penalty to succeeding generations. This statement is contrary to *à priori* reasoning, and also contrary to routine teaching and unthinking or ignorant belief. It is a statement based, however, upon careful observations in an extended experience, and I believe it to be absolutely true. The victim pays the whole penalty; the disease is free from the law of entail. The high average standard of good health and nervous poise in the children of neurasthenic fathers has been a frequent personal observation.

I do not believe that any individual case of neu-

rasthenia ever originated in a single cause. The very essence of the affection makes such an hypothesis a paradox. Equally true is it that no single agency is sufficient to explain the prolonged maintenance of this condition. Any one of many cases may appear to dominate in a given case and for a given time, but the carefully studied etiology will prove a complex one in every instance. The list of stereotyped and empirically accepted causes is a long one and undergoes a progressive expansion from year to year. Overwork, worry, prolonged mental tension and anxiety, malnutrition from deprivation of food, sleep and rest, toxemia of autogenous and heterogenous sources, shock, trauma, reflex irritation, and as many more are on the list. Most of these are contributory factors only, and some are effects which are essentially secondary, being part of a vicious cycle, vicious in fact and even more so in interpretation. The insufficiency alone of any of these factors is tacitly admitted in the usual statement that an hereditary predisposition is fundamentally necessary, a proposition not sustained in my own experience, though carefully investigated always. Neurasthenia is, I believe, essentially an acquired state and heredity, except of temperament, and a high grade cortex is an almost negligible equation. My chief criticism of the ordinary etiology as outlined is the narrow viewpoint with resulting technical limitation in treatment. What is the cause of these causes? *The* factor in neurasthenia, in the American disease—the factor common to all cases—is, broadly, that of atmosphere—the atmosphere peculiar to this country, the atmosphere of limitless possibilities, not in one field, but in all; in commerce, in art, in literature, in every field of intellectual accomplishment. It is this ether of limitless possibilities which stimulates the individual to a degree of effort, of tension, of strain, of superstrenuous endeavor, impossible and unknown, except by the infectiousness of example, elsewhere. There is no limit to the game, and anybody may sit in. America is the only country in which you can go in with one white chip and have a chance to quit the biggest winner. It is this atmosphere which is the incentive to overwork. It is the anxiety, the tension, the strain of the game, which brings worry, loss of sleep and all the rest; and even here the penalty comes indirectly. The intoxication of endeavor, the delirium of effort, is at the expense of all conservatism. The laws of nature—inexorable as fate—fate itself in fact is violated not daily, but every hour. The hygiene of life is set aside. All kinds and degrees of insult are offered to brain, stomach, heart and every other organ. Day after day the steam is kept turned on and at full pressure to the one floor, and, worse still, often to the one room. Is it any wonder that all the rest of the house grows cold, or that, the power being insufficient, the machinery of the lower floors works poorly and makes poor goods? Every function suffers sooner or later. One after another, and sometimes several together, they protest, then openly rebel and finally go on strike. Indigestion, toxin and ptomain formation, torpor of sewerage function and resultant defective elimination add the element of chemical irritation, or autotoxemia, or lithemia, to the situation. The tired brain cell gives way under this added handicap and goes out on sympathetic strike.

The accident of dominating symptoms in a given case is but rarely of any value in determining the etiology. Gastric and lithemic and other types may be recognized and distinguished symptomatically with some minor advantage, but no more serious error of interpretation exists than to conceive of them as primary etiological types with a correlated therapeusis. Anti-lithemic drugging will not cure a lithemic neurasthenia, nor will lavage make well your so-called gastric cases.

I have again and again noted a urine with specific gravity above 1.030 with 14, 16, 18 and even 20 grains of urea per ounce, with lime oxalate and urates in abundance, all these conditions giving way to the normal under direct treatment, the neurasthenia remaining essentially unchanged. I never knew a sexual neurasthenic, so called, to be cured by any plan of direct genito-urinary treatment, and this statement applies with equal truth and force to all efforts (and I have seen many) to cure the reflex cases by removal of a supposed cause in any peripheral irritant.

I know of no condition in medicine which demands more exactingly of the physician all the diagnostic resources of the profession, and yet mistakes in diagnosis should be rare. The symptomatic semblance of neurasthenia—the pseudo forms—which may sometimes present much of the picture, but will always show a radical omission or addition somewhere, should always be in mind and should be excluded carefully seriatim. More than one patient referred to me as a neurasthenic has been found to be the real victim of tuberculosis, of malaria, of Bright's disease, of gastric ulcer or some other similar affection. Anomalous forms of Basedow's disease in women and various toxic states among men have represented especially common mistakes in diagnosis. Paretic dementia in its incipient stages and some forms of melancholia, particularly the affective types, demand special mention. A guarantee of escape from the opprobrium of error as to the pseudo types is possible only through an exhaustive recourse to all measures and methods of accurate information. Elaborate urinalysis, blood examinations and often examinations of the sputum is a routine procedure with me. In any case in which the dominant symptoms are referable to a particular function or organ persistently, I am proportionately suspicious of a local disease at least complicating the general state. It should not be forgotten that a neurasthenic may have a coexistent Bright's. In Basedow's disease, which,

as we know, may utterly lack the spectacular symptoms, the absence of goiter and of exophthalmos may easily lead us to interpret the nervous irritability, the quick exhaustion, the fears, the digestive and other functional disturbances, the loss of sleep and the widespread vasomotor symptoms as due to a neurasthenia, but the habitual quick pulse, the shallow respiratory action, the diarrhea and the *tout ensemble* of constancy in the picture will always give rise to doubts which will be converted into negative certainty when the etiology is considered. From paretic dementia we can distinguish neurasthenia by the presence in the former and the absence in the latter of organic signs. No matter what the degree of incipiency, if the disease has advanced to the point of inducing symptoms, we shall find in paresis somewhere some of the physical signs. Special care should be observed in the melancholic (by the way, the majority type) forms of paresis. In melancholia we have, no matter what the subtype, a constant syndrome; a characteristic facies, a postcervical ache, a shortened sleep, an irrational melancholy and a tendency to suicide. In neurasthenia this facies is absent and the tendency to suicide is rare. Melancholiacs get to sleep as a rule with but little difficulty, but wake too soon, at 2, or 3, or 4, and sleep no more. In neurasthenia they sleep lightly, dream much and wake often. The postcervical ache may belong to both, but in neurasthenia it is often a cincture or helmet headache, quickly dissipated by mental diversion. The neurasthenic can laugh; the melancholiac cannot. For a melancholiac to laugh is to refute the diagnosis. From myasthenia gravis it is to be distinguished chiefly by the absence of dominant bulbar symptoms.

What is the pathology of neurasthenia? The answer is almost anyone's guess, and yet to know the lines of experimental research and investigation already established is a long step in the direction of what will finally prove the correct guess. The work of Hodge, familiar to you all, was a far call in the right direction, and while it has given us no final solution, it probably paved the way to the yet to be demonstrated pathological explanation of these cases. The effects of fatigue, of worry, of irritation, upon the brain cell structure was proven to be actual and demonstrably so, by his work. Barrows has added observations which demonstrate with equal positiveness the structural and sometimes actually organic changes and results which follow to the cell from malnutrition. All neurasthenics, it should be remembered, are examples of malnutrition from faulty assimilation and metabolism, usually secondary. The work along chemical lines with a final explanation in states of autointoxication promises much, but that which appeals most strongly, even though as yet it offers least in a tangible, material way, is a combination of the others with an imaginative elaboration of the ion theory. The analogy of the highest governing nervous system with a telephone service in a large city has occurred to many, appeals to most of us and is familiar to you all. We have all been able to grasp mentally some conception of the power plant, the conducting wires, the receiving and transmitting station of the subscriber and a central, but the plan of a central switchboard is where we stop. The hello girl of the central station will not do. She is too unreliable; she goes to sleep on post; she talks distracting gossip; she has no sense of duty at times. Her sole stimulus to duty well done is often the approval of the inspector only and the $10 per week. Neurasthenics don't gossip, they don't go to sleep—more's the pity—and yet the switch gets out of gear and you cannot get a connection, or if you do there is a buzz and you can't understand which stands for the weakness; to which we might add in carrying out the analogy, the usual profanity, to represent the irritability. Mendelssohn, Frankhauser and others, in attempts to give a tangible, graspable explanation of electrical action upon nervous function, have advanced and elaborated what might be called the theory of wandering ions. You will recall that, when first announced, the neuron theory, in addition to facts proven, claimed, but did *not* prove a distinct individuality for each neuron, with no anastomosis anatomically with other neurons. This undemonstrated claim was unaccepted for the reason that it left less explained than before the observed and familiar facts of concert of action and synergistic relationship of nervous function which seemed to demand some anatomical connection. Imagine bodies endowed with autogenous mobile life, which stretch an arm from 1 to 5, or A to G, wandering about with a restless usefulness, connecting two separate souls who want to get in touch in the same way but with infinitely more reliability, as the central hello girl connects you up with the number you send in from the transmitting phone. Imagine these little bodies, goaded day after day to extraordinary effort, allowed no rest, no sleep, whipped by alcohol, or tobacco, or coffee, suffering from deprivation and irritation in every way, rations served foul, working for a thoughtless, selfish, utterly inconsiderate master. Do you wonder that they get discouraged, tired, exhausted and confused, taking messages wrong, turning in a fire alarm here, calling in the police there, doing many things which they should not do and leaving undone those things which they should do? Very pretty, you will say, but fanciful. I admit it, but I deny any more of fact in any other theory.

The first step—the essential foundation of any plan of successful treatment in neurasthenia—is the establishment of a proper relation between physician and patient. The status of the physician should be firmly established before the question of treatment is considered at all. He will have laid the foundation of any plan of successful treatment well in a direct ratio with the thoroughness, the exhaustiveness of his diagnostic examination of the patient. Nothing should be taken

for granted—no second-hand information should be accepted. At the risk of being tedious, examine for yourself. Five minutes or less is often more than sufficient time for a final diagnosis in paresis or tabes—two hours is often time well spent in the first examination of a neurasthenic, and this is true even in the instances in which as many minutes only have been necessary to convince you of the nature of the case. Remember there are two parties to the transaction. Your own enlightenment is not the only requisite. The neurasthenic always takes himself and, at least, some of his symptoms seriously. To tell him abruptly that this or that means nothing is not convincing to him, however true to you. No obvious foundation has been laid for so positive a statement in so short and superficial an examination. To you many of the symptoms are distorted by exaggeration; to him they are real. Do not forget the axiomatic fact that neurasthenia does not develop in a fool, and as corollary to this fact make your appeal to the intelligence of your patient. Explain things; give the patient something tangible to grasp, some explanation which appeals to reason. He will leave the ether of imagination and come down to the terra firma of fact gladly. The effect at first may be upon the subconscious ego only, but the leaven of action will later rise into controlling consciousness. The physician, by the way, should never think, or believe, or guess; he should know. Therefore, he should lay at least a plausible foundation for such knowledge in a patient examination at the first interview. It is just as important that a reverse attitude should be the rule thereafter. Discuss with your patient in subsequent interviews every topic conceivable except his ills. At stated intervals go over the case objectively, taking an account of stock. Where favorable progress is noted, not only mention it —prove it; if still *in statu quo,* explain the delay in results. Silence is rarely golden in such situations. Equally important with this factor of proper relationship between doctor and subject is the control of the patient's environment. Just which is proper varies with different cases, but once settled, it should rarely vary with the case. Compromises and concessions are always dangerous. The patient's hand should never touch the tiller, once you have taken charge of the ship. First, place him so as to minimize the influence of all adverse factors, domestic, financial or otherwise. Break up, as far as possible, all subtle or obvious factors which contribute to a morbid introspection by conscious or subconscious association. Encourage objective consciousness by a change in the physical and mental atmosphere. Sometimes this must be done radically, and the patient cut out from the family or from his business. Never leave him alone, and never leave him idle. Put with him a tactful, resourceful, sensible attendant—train your own nurse, by the way—train him over again, if a hospital graduate. Don't call him a nurse in any event—neurasthenics resent trained nurses. Give all your instructions to this nurse-companion—never to the patient, who should have nothing whatever to do with his case. Arrange all details of diet, of exercise, medicines, baths, diversion, etc., with the nurse. Give your patient a chance to escape from a knowledge every hour of the day that he is a patient. Keep him busy, fill in every minute of the day. A salt rub in the morning, the patient standing in eighteen or twenty inches of hot water, three minutes of practice in deep breathing exercises, after which comes breakfast. All meals should gradually be made as full and as nutritious as possible. I observe idiosyncrasies, but no other law of special diet. After each meal from twenty to thirty minutes of recumbent rest is insisted upon—a habit observed by nearly every carnivorous animal, except man. Next comes the daily visit to my office, with treatment by the galvanic current, one electrode back of the neck, the other over the forehead, both as large as possible, in order to get the utmost diffusion at the point of contact and thus a maximum of electricity with a minimum of discomfort from local action. A steady battery, a rheostat, a meter, and proper electrodes are absolutely essential. Part of the benefit is undoubtedly due to suggestion. This is a small part, however, by comparison with what I am firmly convinced by years of careful observation to be an intrinsically dynamic effect of sometimes striking benefit from electricity thus administered in these cases. I never exceed five milliampères in amount, or half an hour for the seance. Usually I begin with one milliampère and a five-minute seance. On leaving my office, my patient goes direct, riding or walking, according to circumstances, to a gymnasium, the director of which, Dr. Watson L. Savage, is a medical graduate, whose life-work has been given with enthusiasm to the cooperation, elaboration and perfection of a plan, which we both believe will, when perfected, prove a specific, curative treatment for these cases, a proper environment and control being the only other essentials. By this plan of psychophysical, educational control, we secure, by the indirect method, what is always difficult, and often impossible, by any direct plan—a lowering of tension, a mental relaxation, a return to rational inhibition, to order from chaos. These patients are taught the lesson of physical, muscular relaxation —how to lie down, how to go through the mattress to the bottom, how to turn loose physically. That the muscular system is energized and overkeyed into states of hypertension through sympathy with states of mento-nervous exaltation is familiar to us all in the tense mouth, the corrugated brow, the clenched hand, the restless walk. We simply start at the other end, and re-educate the higher through the lower. The quickest, the surest, the most rational way to key-down a man mentally is first to key him down motorially. I have waited for ten years of results to accumulate before announcing publically, except in the

lecture room, the value of this procedure. I give you no experimental theory. My unqualified endorsement is based not only upon a rational conception but many confirmations in experience. I count this part of the plan of treatment in neurasthenia one of the most positively helpful and essential of all the major details. The afternoon, following lunch and another half-hour of rest, is spent out of doors—a drive, a horse-back ride, golf, tennis, a walk, a visit to some museum or place of public interest: a shifting from one to another of these various diversions largely based upon the personal equation of temperament and aptitude in your patient, fills up the afternoons. In suitable cases part of the evening must be filled, and occasionally the theatre or a concert can be utilized, but never at the expense of sleep, if insomnia be present. A half-hour of massage at bedtime closes the day's work.

This one symptom, insomnia, must be controlled always. Make your patient sleep—count a dreamful night insomnia. Veronal, trional, sulfonal, in 5. 10 and 15-grain doses, are effective and satisfactory. I often shift them. All should be given in some hot menstruum. No nervous patient should ever know his drugs—send the prescription yourself, and always mark it, "No copy. Do not repeat." Fifteen years ago a few neurasthenics under my care came back to health and nervous poise in spite of the drugs which I employed in treating them. For five years past, using less than half the drugs, my percentage of recoveries has increased fourfold. Drugs play a varying part—sometimes no rôle at all, again a vital one. Some patients demand them, others are indifferent, and still others need them neither mentally nor physically. Sleep must be secured and maintained, elimination and prompt sewage function regulated and complicating accidents combated. For temporary use, until the regime outlined becomes effective in lessening it, the mental state of habit unrest and hyperpsychical esthesia should be controlled, and the drug which most effectively accomplishes this purpose is opium in the form of the denarcotized, aqueous extract in doses from one-tenth to quarter-grain three or four times daily. Free water drinking between meals is a desirable habit to encourage and a positive water, always symptomatically remedial in cases in which lithemia is an aggravating factor, is the Royal Fachingen. I do not believe in the sanatorium treatment of these cases as I know sanatoria. If the ideal sanatorium existed, the sanatorium plan would be ideal. I add nothing to your personal knowledge, when I tell you that such an ideal does not exist. I can conceive of no more fitting nor important statement in conclusion than one of condemnatory criticism of the misapplication of the Weir-Mitchell plan of rest and isolation in these cases. It is to be condemned first, as involving the conception of a *routine system or plan* of treatment; second, as encouraging introspection; and third, as violating in principle all intelligent interpretation of the whole subject. For women and feminine males it will do no harm; for men and masculine women it is an insult to intelligence.

105 West Seventy-third Street.

MEDICAL PROGRESS.

MEDICINE.

Edema of the Feet and Legs.—During the last three years particular attention has been paid to the investigation of the relation between dropsy and the retention of chlorides in the tissues. It has been shown in a definite manner that the question of chloride ingestion and retention has a very important influence on the production of anasarca. It has also been demonstrated that in health an excessive ingestion of chlorides may lead to an increase in the weight of the body, as a result of the tissues retaining more fluid than under normal conditions. J. H. Bryant (*The Practitioner*, August, 1905) records a case in which the excessive ingestion of chlorides was followed by not only retention of fluid in the tissues and a consequent increase in weight, but also by marked edema of the extremities. The patient was accustomed to taking 300 to 600 grains of salt a day. Examination of his urine showed the presence of 1.86 per cent. of chlorides, *i.e.*, nearly three times the normal amount. After reducing the amount of salt ingested the edema disappeared and the urine contained only .98 per cent. of chlorides. Widal and Javal found that, in cases of interstitial nephritis, doses of sodium chloride up to 150 grains did not give rise to edema, but, in cases of parenchymatous nephritis, the result was different, edema was produced. They found that the chlorides were not excreted entirely, and that, as a result of their retention, the fluid in the tissues was retained. They further showed that by increasing the amount of chlorides in the diet the edema increased; but, on the other hand, if the ingestion of chlorides was diminished the tissues were drawn upon for their reserve chlorides, and as they were used up the edema disappeared. They also demonstrated that there was a definite relation between the hydration of the body and chloride retention, by changing three men suddenly from a diet rich in chlorides to one almost devoid of chlorides, the result being a reduction of the body weight of four or five pounds. The belief expressed by Widal and Javal, that the elimination of chlorides by the kidneys is a specialized function of these organs, offers the best explanation of the occurrence of edema of the legs in this case. It may be presumed that for a considerable time the kidneys had been able to deal with the excessive amount of chlorides presented to them for elimination, but it is equally reasonable to suppose that sooner or later there would be a limit to this overwork, followed by a breakdown if persisted in, and that it was a failure of this specialized function to continue at high pressure which led to an abnormal retention of chlorides in the tissues, and thus produced the dropsy.

Causation of Arteriosclerosis.—J. M. Cowan (*The Practitioner*, August, 1905) reviews the various theories that have been advanced to account for the production of arteriosclerosis, and arrives at the following conclusions: Arterial damage may result from many and various causes. Continued high blood pressure invariably, in time, affects the vessels, and this is one of the most important causes of widespread disease. High blood pressure may be secondary to renal lesions, or may originate without any renal flaw. It is in the latter case the result of alimentary wrong-doing. Excess,

relative or positive, of the foodstuffs or of alcohol, intestinal fermentation or putrefaction, hepatic, pancreatic or gastro-intestinal insufficiency, may thus all be the initial fault. The arteries may be damaged in various intoxications; the metallic poisons (lead, mercury, etc.) comprise one group, and the bacterial toxins (rheumatism, enteric fever, etc.) another. Bacteria themselves may be found in early lesions. Syphilis is a frequent cause of local lesions. Severe continued physical exertion, however it may act, is probably also a causal factor.

Physical Degeneration and Syphilis.—Referring to the question of physical degeneration F. J. Lambkin calls attention (*Brit. Med. Jour.*, Aug. 19, 1905) to syphilis, the prime factor in causing it. That this is true is generaly acknowledged, and the question arises as to what advance has been made in the treatment. Undoubtedly the treatment of syphilis has materially advanced, but it is questionable whether or not civilians have taken advantage of it. The immediate signs and symptoms have been greatly ameliorated during the past decade, but the returns of lunacy present a terrible record. In the army both the early and late signs and symptoms have been materially diminished. This has been accomplished there chiefly through the system employed. This consists of hospital treatment until the active signs have disappeared. Then the patient is injected intramuscularly once a fortnight with metallic mercury in form of cream, ℞x containing gr.i, for three months. Following this there is two months intermission, and again three months active treatment. Usually at the end of this period the disease has been stamped out. The insoluble salts of mercury are preferred, since the injections may be given at longer intervals. The injection method of treatment is recommended over the method of internal medication because then it is known that the medication is continuous, which in nine cases out of ten is not the case when people are depended upon to medicate themselves. Therefore, for those interested in degeneracy the problem becomes one of consistent and continuous antisyphilitic treatment among the masses.

Diagnostic Value of Digestive Leucocytosis.—In the normal individual there is, according to P. Vansteenberghe and M. Breton (*Arch. de Med. Expér.*, July, 1905), a post-digestive leucocytosis which attains its maximum two hours after the meal, and which markedly exceeds the daily oscillations of the leucocytosis curve of the fasting individual. The increase is principally in the mononuclears. In the fasting individual the periodic daily rise is in the polynuclears. Post-digestive leucocytosis is absent in certain morbid conditions, particularly in gastric and hepatic cancer. This absence has nothing to do with the cachexia or anemia which always accompany these affections. It appears to be dependent upon an irreparable functional embarrassment of the digestive organs. This absence is not an absolute diagnostic criterion, but it has an importance equal to if not greater than the various chemical methods of diagnosis.

New Test for Diacetic Acid.—The following new test for diacetic acid in the urine is recommended by L. Lindemann (*Münch. med. Woch.*, July 18, 1905): 10 c.c. of urine are acidified with 5 drops of 30 per cent. acetic acid. Five drops of Lugol's solution are then added and the urine shaken out with chloroform. If diacetic acid is present the chloroform will remain colorless, while under normal conditions the chloroform will dissolve out free iodine. The reaction should be distinctly acid, so that in case of alkaline urines more acetic acid will be necessary. By determining the amount of iodine necessary to tinge the chloroform, the percentage of diacetic acid present may be determined roughly. The only other substances which give the reaction are the thiosulphates and the sulphites, but these never occur in the urine in sufficiently large amounts.

Levulosuria.—Levulosuria is a very rare condition and in the few cases recorded some dextrose was usually also excreted. In a case of O. Neubauer (*Münch. med. Woch.*, Aug. 8, 1905) the urine fermented with yeast, reduced Fehling's and Nylander's solutions, turned the polarized ray of light to the left, formed an osazone with phenylhydrazine and gave the specific reactions for levulose with methylphenylhydrazine and with Seliwanoff's reagent. The sugar could be isolated from the urine, and was found to be free from glucose. The symptoms were those of true diabetes, with marked nervousness. On withholding carbohydrates the urine became free from sugar. The administration of starch, glucose, galactose and lactose did not provoke glycosuria; but after levulose and cane-sugar, the levulosuria reappeared. Inulin also proved to be harmless, so that the condition was more of an alimentary levulosuria than a true diabetes. On withholding all substances containing levulose or cane-sugar, the patient improved rapidly.

A New Hemoglobinometer.—Absolutely accurate instruments for measuring the amount of coloring matter present in the blood are too complicated and expensive for the practising physician, and the simpler instruments are usually so inaccurate that no two give the same readings. A very ingenious hemoglobinometer has been devised by P. Gruetzner (*Münch. med. Woch.*, Aug. 8, 1905). The principle is the same as in the Fleischl, except that the wedge is formed by the diluted blood, which is compared with a standard color. The wedge is moved up or down until the two colors correspond accurately. Two extra slits above and below will greatly facilitate the matching of colors, and artificial light is not required.

Epidemic Simulating Influenza.—R. A. Dunn and M. H. Gordon report an epidemic (*Brit. Med. Jour.*, Aug. 26, 1905) which clinically and bacteriologically simulated influenza. The chief symptoms varied widely. Some cases appeared to be scarlet fever, some influenza, and others cerebrospinal meningitis. Bacteriological examination of the tonsillar and nasal mucus frequently revealed a non-Gram-staining diplococcus. The onset was nearly always sudden; exceptionally there was a catarrhal prodrome. Sometimes there were rigors or chilliness. The temperature was usually from 99° to 101°. Sore throat, often severe, enlarged cervical glands and stiff neck were frequent symptoms. Headache and body pains were present in most cases, and drowsiness, photophobia, nasal discharge, sneezing, lacrimation, constipation, nausea or actual vomiting were noted. Desquamation was met with occasionally, even in the absence of rash. The usual sequelæ were weakness and debility. Children were more severely attacked than adults. The cases simulating scarlet fever had the usual onset. The rash appeared within twenty-four hours. It did not invariably begin on the chest, but often along the posterior border of the sterno-mastoid, spreading rapidly over the rest of the body. It consisted of an erythematous blush and punctate spots. Usually it lasted not longer than from one to three days, and was followed by desquamation, which, as a rule, began early. The typical "strawberry" tongue was occasionally observed, and hematuria and albuminuria were present in several patients. A very discrete papular rash was sometimes noticed a week or so after the primary rash. Sudaminal rashes were also seen, and in four patients purpura was noted. Recovery

was tedious. In the cerebrospinal cases the onset varied. In some, cerebrospinal symptoms were the first noticed, whereas in others these followed on those of an influenzal or typhoid condition. Severe headache was a constant symptom and was nearly always associated with pain in the back of the neck and stiffness. Pains in the lumbar region was frequently present. Vomiting was an early and constant symptom. The temperature was very erratic, sometimes low, sometimes as high as 104° F. Discharge from the ear occurred in several patients, and a copious mucopurulent nasal discharge was nearly always present. In only a few cases has marked opisthotonos been noticed. The nervous symptoms and paralyses showed no settled type. Dilatation of one or both pupils, incontinence of urine and feces, and trophic changes in the muscles were all met with. Ten patients had Kernig's sign. Clinically the differential diagnosis of this condition from influenza, scarlet fever and cerebrospinal fever is not easy. The number of rash cases, occasionally followed by nephritis, the association of cerebrospinal symptoms, the frequency of stiff neck, and the severity of the disease among children and its mildness among adults, are strong points against influenza. The absence of Pfeiffer's bacillus is confirmative. Again the absence of much fever and the irritability of the rash appear to be points against scarlet fever, but what was far more convincing was the association of the different types of the disease in the same invaded household. Evidence against cerebrospinal fever was the mildness of the epidemic, the comparatively small number of cases with typical cerebrospinal symptoms, the infrequency of the two concomitant rashes, purpura and herpes, and the fact that no organism having all the characteristics of the meningococcus could be obtained. The organism observed in twenty-two cases of twenty-four cases was a Gram-negative coccus, growing freely upon ordinary agar at 37° C., and gelatin at 20° C., and producing an alkaline reaction when cultivated in leucolitmus fluid, containing either glucose, gelactose, maltose, or saccharose. It would seem that this organism is closely allied to or identical with *Micrococcus catarrhalis*.

Asthma.—SAMUEL KOHN, presenting a paper upon this subject (*Med. Rec.*, Aug. 26, 1905), says the theories which to-day are most generally accepted as the direct anatomical cause of the asthmatic paroxysms are the bronchospastic, combined with the vasomotor paretic. Experience has proven that the disease occurs principally in persons of neurotic temperament, the predisposition being frequently hereditary. The essential etiological factor is probably some organic lesion of the nerve centers of the medulla, but this has not yet been demonstrated. The causes producing the first outbreak will be found in irritations of peripheral nerve endings of the vagus and other nerves connected with it. Since, no matter where the irritations are found, be they in nose, throat, bronchi, skin, viscera, circulatory media or brain, the paroxysms induced are so uniform and characteristic that the consensus of opinion entitles asthma to be considered a disease and not a symptom. The anatomical change responsible for the respiratory difficulty is dilatation of the alveoli of the lung. During an attack this grows more marked, the more strenuous the patient's inspiratory efforts become. The alveolar walls in time lose their elasticity and emphysema may follow, which, when this is the case, often moderates or entirely abolishes the attacks. The treatment is divided roughly into climatic, hygienic, symptomatic, gymnastic, psychic, hydrotherapeutic, medicinal, operative and institutional.

Abuse of Bromides in Epilepsy.—For a number of years the bromides have been losing favor in the treatment of epilepsy. After observations upon nearly two thousand cases W. P. SPRATLING (*Med. Rec.*, Sept. 2, 1905) concludes that the bromides, as ordinarily employed, do more harm than good. He claims that he has not yet seen an epileptic cured by bromides alone. A short time ago the amount of the drug that was being used at the Craig Colony was reduced nearly one-half. The result was a considerable temporary increase in the number of attacks, but these shortly fell to their normal number, most of the patients showing mental and physical improvement while free from bromism. The chief difficulty in administering bromides lies in the inability to prescribe the precise individual dose the patient's condition demands. In no case should it be lost sight of that there is a point of physiological toleration and of therapeutic usefulness which should not be exceeded. Only exceptionally does it ever become necessary to push the drug to the point of inducing bromic acne, whereas to cause bromic dementia is an inexcusable blunder. Loss of memory is frequently seen from blunting of the intellectual faculties. The physiological effects of these salts are generally deleterious if continued, resulting in depression, anemia, emaciation, and feebleness, facts which sufficiently show their little use in epilepsy. Abandonment of bromides, and the use of other harmless depressants instead, and a general recognition of the principle of first treating the individual instead of the symptom would soon more clearly show their very limited value.

Rats in Relation to Plague.—A causal relation between rats and plague has been recognized since the earliest time. In a study of the habits of rats BRUCE SKINNER makes some interesting observations (*Brit. Med. Jour.*, Aug. 26, 1905). It is inferred that the rat, the indigenous species of the plague areas, causes or spreads this disease. There are certain seasons when rats betake themselves to houses. In the cold countries this occurs during the winter months, whereas in the warmer regions shelter is sought during the rainy season. Reference to the literature upon plague shows that the height of the epidemic is usually attained at the time when rats should be in the fields, and the minimum is reached when they take shelter from the rain. He suggests as borne out by the examination of the habits of rats, so far as they are known, that though he suffers from plague, he is not the source of the disease. Were he the source, the epidemic should be most severe when the rat is in most intimate contact with the human population. Again there is nothing to show that the destruction of rats reduces plague incidence. But inasmuch as rats suffer from plague, which some have suggested is conveyed from them to man by the flea peculiar to *M. rattus*, many may consider it politic to exclude rats from dwellings. Rats avoid lime, for it burns their feet. Therefore the free use of unslaked lime about the premises, and particularly along their runways to water, will effectually keep them away. The intelligence, assisted by the acute sense of smell possessed by rats, is so keen that it is very likely that they would not return even in the rains to plague-infected houses if the cause of that disease were inherent in the dwellings. The rat, however, does return at that season and remains throughout the rains; so it may be allowed that he cannot be responsible for the recrudescence which occurs after the rains, and which must be due to some other cause apart from rats coming into play after a period of quiescence.

Syphilis of the Third Generation.—In presenting a digest of this important subject, C. F. MARSHALL con-

cludes (*Lancet*, Aug. 26, 1905) that the degenerative or dystrophic effects of syphilis are transmissible to the third generation or possibly further, only to die out with eventual sterility. Although difficult to prove, the transmission of virulent hereditary syphilis to the next generation is scientifically possible, the question depending chiefly on the factors of time and treatment. Hereditary syphilis may not become manifest until the procreative age, hence a hereditary syphilitic genitor in a virulent state might transmit the disease in a virulent form to the offspring. The reason why such cases are rare is the fact that a small proportion of cases marry while suffering from hereditary syphilis in virulent form. At the time of marriage the disease is usually attenuated by time and also by treatment. Reinfection of a hereditarily syphilitic genitor increases the virulence of the disease and its fatal effects on the offspring. The two chief obstacles to actual proof of transmission to the third generation are the possible reinfection of the second generation and the possible intervention of another syphilitic genitor.

Contracted Muscles of Infantile Paralysis.—The usual theory accepted as accounting for the production of talipes is that, owing to the unbalanced state of the muscles, the stronger have been in a condition of overaction, have overpowered their weaker opponents, and by gradually approximating their own points of attachment have become permanently shortened. F. R. Fisher contends (*Lancet*, Aug. 26, 1905) that this is certainly inaccurate in one respect, the contraction of the muscles precedes the drawing together of their points of attachment, the latter being not the cause but the result of contraction with which the shortening of the muscle is coincident. It is also extremely doubtful if a muscle will acquire from overaction a condition of permanent contraction. The term "contracted muscle" by no means conveys a correct idea of the muscular lesion. Contraction is a normal attribute of muscular fiber; here, a distinct abnormality obtains, consisting in the deprivation of the tissues' ability to relax; "intractile muscle" better defines the state of inextensibility, which, as the main feature, should be especially considered. In theorizing on the development of paralytic talipes writers have hitherto overlooked the point that muscular intractibility is as distinctly a loss of natural function as is muscular paralysis; in the one ability to relax is reduced, and in the other power of contraction is lowered. It is known that the loss of contractile power is due to the degree of destruction of the motor cells in the anterior cornua; it is possible that from the loss of a controlling influence naturally exercised by the same central structures arises the development of intractility. In considering the obscure changes consequent upon poliomyelitis the most difficult task is to throw light upon those cases in which the muscles, apparently deprived of contractile tissues, are able to generate very evident distortions. Voluntary movement can hardly account for the phenomena, nor does it seem possible that reflex action can be existent. The only solution which suggests itself is that some feeble stimulus may be issued from the cord, erratic messages from a directing center which has been thrown into a state of hopeless confusion. Be this as it may, the development of paralytic talipes probably depends entirely upon neuropathic influence.

Hiccough, Its Physiology, Pathology and Treatment.—A comprehensive and exhaustive essay on this subject, as gathered from a study of an enormous bibliography, is furnished by J. Bertier (*Gaz. des Hôpitaux*, July 8, 1905). Hiccough is defined as a sudden contraction of the diaphragm, causing a sudden motion of the abdominal and thoracic walls, and accompanied by a coarse and inarticulate sound caused by the closing and sonorous vibration of the lips of the glottis. The diaphragmatic spasm is but one of the factors of the syndrome which comprises other associated phenomena, glottic and gastric. There is a double nervous control of the act of hiccoughing: through the phrenic the diaphragm is made to contract; by means of the vago-spinal nerves there are brought about the closure of the glottis, the contraction of the stomach and the relaxation of the pyleric sphincter. A center co-ordinating these movements is supposed to exist in the neighborhood of the vital center, and the center of vomiting. Numerous centripetal paths bring the hiccough center into relation with numerous peripheral sources of irritation. Clinically these irritations are found in the domain of the pneumogastric (foreign bodies in the lung, pleurisies, affections of the liver, stomach, intestines, peritoneum, esoplagus, pharynx), of other visceral nerves (pregnancy, diseases of the prostate, kidneys, bladder, uterus), or the nerves of general sensibility (exposure to cold). Besides these reflex causes of hiccough there are direct central forms of stimulation of the center controlling this act. Thus it may be due to imagination (hysteria, imitiation, epidemicity), to toxic products (uremia, tobacco, alcohol), and to anoxemia (agony, severe hemorrhage). The irritation may affect the centrifugal limb of the reflex arc (luxations of the cervical vertebræ, tumor of the mediastinum, aneurism of the aorta, pericarditis, diaphragmatic pleurisy, wounds of the diaphragm, splenomegaly and perisplenitis). Hiccough is sometimes preceded by a sort of aura, a sense of epigastric tension. Sometimes diaphragmatic spasm is so violent as to cause a synchronous raising of the shoulders, limbs and trunk, rapidly producing fatigue if the attack is prolonged. In other cases the glottic element is the principal one, producing an intense sound like the bark of a dog (a case being reported in which the sound was heard at a distance of three-quarters of a mile). Ordinarily the spasms have a rate of 6 to 15 per minute, but in severe cases there are as many as 60 to 80. They have already been observed in one case synchronous with the cardiac pulsations. Generally hiccough stops during the night; sometimes it persists. In severe cases hiccough causes a considerable amount of functional disturbance: anxious respiration, cyanosis, difficulty of deglutition and serious impairment of nutrition. In the course of diaphragmatic pleurisy it causes intense pain and insomnia. Speech is sometimes impossible. At times hiccough relieves the distress of dyspeptics by causing eructation of gas. Ordinary attacks of dyspeptic hiccough last a few minutes; those due to inflammation of the pleura or peritoneum may persist for hours or days. Certain hysterical cases have lasted for twenty to thirty years. The following clinical forms are enumerated: A. Reflex. (1) Diseases of the stomach; liquids too hot or too cold, unchewed food, carbonated liquids, indigestion; it may be a troublesome accompaniment of cancer, ulcer and hyperchlorhydria. In nurslings it indicates an overloaded stomach. (2) Affections of the pharynx, aphthæ, abscess, esophageal spasm due to benign or malignant stricture. (3) Diseases of the peritoneum; every time the peritoneum is irritated hiccough is apt to arise; it is less constant in the localized varieties. (4) Intestinal disorders, including dysentery, lumbricoides. (5) Diseases of the liver. (6) Diseases of the spleen, most frequently hypertrophy. (7) Genito-urinary disorders, above all; affections of the bladder. (8) Uterine disorders. (9) Pregnancy, in this case due to toxemia, like vomiting.

(10) Abdominal wounds. (11) Diseases of the respiratory organs, particularly diaphragmatic pleurisy and pneumonia. In the former it is the source of agonizing pain. It is seen in subphrenic abscess. In pneumonia it occurs on the fifth or sixth day and is ordinarily very violent. (12) Mediastinal compression. (13) Pericarditis, in which it is a bad symptom. (14) Exposure to cold. (15) Affections of the peripheral nerves, as in sciatica. (16) Spinal disorders, as displacement of cervical vertebrae. B. Hiccough of central origin. (1) Hysteria. Boerhaave reported an epidemic in Haarlem. The hysterical cases may be easily differentiated from those of symptomatic origin. In the former the glottic phenomenon is the most marked, and the sound produced is intense. In these cases the prognosis is good, as regards life, but interference with sleep and nutrition may cause a general debility. (2) Emotion. Seen in neuropathic subjects, transitory, and sometimes occurring in the course of laughing or crying, when it is really a sobbing. (3) Chorea and epilepsy. (4) Intoxications; lead colic, nicotinism, alcoholism. (5) Auto-intoxications, as uremia. (6) Infections. The hiccough of typhoid fever has been most studied. It appears late, most frequently in some epidemics, at first is intermittent and then incessant, sometimes accompanied by biliary vomiting, preventing sleep, interfering with speech and swallowing, and disappearing at the end of a few days. It has been attributed to various causes: abdominal distention, splenic hypertrophy, ulceration of esophagus, and most recently to the action of the typhoid toxins upon the bulbar center. Hiccough is also seen in scarlatina, scurvy, yellow fever, cholera and hydrophobia. (7) Cachexias. (8) Hemorrhages. (9) Death agony. (10) Bulbar diseases. (11) Cerebral affections. In diagnosis hoccough may be easily distinguished from pharyngeal and laryngeal spasms, yawning and aerophagia. In treatment the following have been used: A. Medicinal: Injection of morphine; valerianate of zinc, belladonna and camphor, belladonna plaster over the phrenics, bromides and belladonna, opium and chloroform, inhalations of chloroform, ether injection of pilocarpine, infusions of peppermint, musk, theriac and belladonna, cocaine and belladonna. B. Non-medicinal. (1) Peripheral irritation, causing inhibition of the motor phenomena. For this purpose the following have been used: epigastric acupuncture, tickling of the pharynx, compression of the auditory meati with extension of the head, actual cautery, chloroform compresses on the epigastrium, epigastric ether pulverizations, raising of the hyoid bone, drinking slowly while pinching the nose, sinipisms, vesicatories, catheterization of the esophagus, tetanizing galvanization of the esophagus, pharyngeal irrigations with cold water, compression of the fists, compression of the cubital region, compression of the ball of the thumb with the little finger, a little salt or sugar placed on the tongue, and thrusting the tongue systematically out of the mouth. (2) Increasing the oxygenation of the blood by means of 40 to 50 rapid and deep respirations. (3) Direct action on the phrenics; compression, galvanism, vesicatories. (4) Magnetism, applied to lower part of thorax. (5) Mechanical interference with movements of diaphragms; forcible manual compression of the diaphragm, forced expiration or inspiration, abdominal bandage, and suspension of respiration. (6) Cold baths and wet packs. (7) Suggestion in all its forms; most of the above act in this way. The following are the main points in the treatment. If the case is due to hysteria, remove the provoking cause, give preparations of valerian, employ the mechanical methods, and if all else fails, resort to suggestion or the hypnotic sleep. (A trip to Lourdes has cured one bad case.) In the symptomatic forms, try to remove the cause. Combat the underlying neuropathic element; diminish the bulbar excitability by means of the various mechanical inhibitory methods; if in spite of these the hiccough persists, use morphine, and if nutrition is interfered with gavage.

PATHOLOGY AND BACTERIOLOGY.

Recurring Phlebitis of Obscure Origin.—U. B. BRIGGS (*Bull. Johns Hop. Hosp.*, June, 1905) reports a series of cases of recurring phlebitis which clinically are characterized by a progressive and relapsing course which are obscure alike in their pathology and etiology. Their clinical picture is so consistent and their cause so obscure that the author considers them to be instances of idiopathic recurrent thrombophlebitis. The cases seem, after the most careful consideration, not to be dependent upon a gouty, septic or traumatic origin. The author makes the following etiological suggestions: We are familiar with the predilection of thrombotic processes within the arteries for such portions of the vessel wall as are affected by arteriosclerosis. The acute and inflammatory affections of the endocardium are specially prone to attack valves already damaged by preference over those with unaltered endothelial coverings. We also know that phlebosclerosis is a condition quite analogous anatomically to arteriocapillary fibrosis, that it is frequently associated with the latter condition, may occur very early in life, and has hitherto attracted rather a curious interest, as having no particular significance. May it not be that the cases of venous thrombosis with which we are dealing depend for their immediate and localizing cause on such sclerotic changes in the walls of the veins? If a cachexia may determine the production of a thrombus within an artery, it seems very easy to believe that with the much slower current of the blood within the veins, an extreme or even beginning phlebosclerotic change might determine the deposition of a fibrin coagulum from the blood stream. Sclerotic alterations of the vein walls are often observed to progress by fits and starts, at times with great rapidity, and then to remain in a stationary condition for years. It is suggested that such a rapidly progressive stage of the fibrosis, if associated with a small, even at first a purely partial thrombosis, might produce just such a series of phenomena as are shown by the present group of cases.

Amount of Katalytic Ferment in Blood.—The amount of katalytic ferment present in the blood can be best determined according to A. SOLLES and M. OPPENHEIM (*Virchow's Archiv*, Vol. 180, No. 2), by adding hydrogen peroxide in excess and then retitrating the undecomposed amount of peroxide by means of permanganate or thiosulphate. It was found that normal human blood will decompose a constant amount of peroxide, namely, 23 grams to the liter. Lowering or raising the temperature, and the addition of various poisons, will materially diminish the power of decomposition. In disease there may also be a marked diminution, though constant factors could not be determined. The blood of amphibia can only break up the peroxide very slightly, and in the blood of animals living altogether in the water this property is absent almost entirely.

Relation of Chlorides in Urine to Gastric Function.—The amount of chlorides present in the urine during different parts of the day has been carefully investigated by A. MÜLLER and P. SAXL (*Zcitsch. f. klin. Med.*, Vol. 56, Nos. 5 and 6). They found that the

effect of meals is undeniable, for directly after there is a rise, followed by a fall and then a second rise. These fluctuations are only moderate after breakfast, and during night there is usually a marked diminution. The excretion of nitrogenous matter runs a curve very similar to that of the chlorides. The first rise is due to the absorption of chlorides, the depression to the fact that the salt in the blood is being used up for the hydrochloric acid of the gastric juice, and the final rise is accounted for by the absorption from the intestines. The acidity of the urine varies only slightly, but frequently the urine is slightly less acid after the chief meal of the day. Other interesting details of the chloride excretion are: If a large amount of salt is taken with the meal the initial rise will not appear, probably because the salt interferes with the absorption from the stomach. The depression is more or less marked if the secretion of gastric juice is excessive or diminished. If there is complete absence of acid in the test-meal the depression will often be absent altogether, and a very low curve will be obtained if bicarbonate of soda is taken after meals, since more acid will be secreted to neutralize this. Hydrochloric acid, on the other hand, will flatten the curve.

Experimental Researches on Adrenalin.—Two of the best known properties of adrenalin when introduced into the body are to bring about a glycosuria and to reduce the temperature. B. Wolownik-Charkow (*Virchow's Archiv*, Vol. 180, No. 2) has proven that the glycosuria is due to an escape of excessive amounts of glycogen from the liver, for the liver in rabbits treated with a single, large dose will always be found to contain less glycogen than that of a control animal. If rabbits are fed upon levulose, glucose instead of levulose will appear in the urine, since the leoulose is first converted into glycogen in the liver. The adrenalin glycosuria may be inhibited by fever, probably because the germs which cause the fever bring about more active sugar metabolism. If spermin be injected with the adrenalin, the glycosuria will be less marked for unknown reasons. A peculiar and not investigated property of adrenalin is that the temperature of the animals falls 1.5 to 2 degrees about thirty minutes after they have been injected; after six to seven hours normal temperature is again reached. If the animals be rendered febrile by infecting with bacteria, this depression will not be so marked as in the artificial fever induced by brain injury. This peculiarity could only be explained by assuming that adrenalin has a direct influence upon the heat-centers. The nitrogen metabolism was not affected in any manner.

Suprarenal Hemorrhage of the New-Born.—S. Oberndorfer (*Wien. klin.-therap. Woch.*, June 18, 1905) states that common pathological changes found in the suprarenals are hemorrhage, which converts the medulla of the organ into a pulpy mass, and embolism of the suprarenal artery, whereby the entire organ is destoyed. Occasionally, one or both organs will be converted into large bluish tumors, whose contents are fluid blood. This is especially common in the newly-born, and many believe that the motions necessary for artificial respiration are the real cause. In a number of cases observed by the author, however, artificial respiration was not resorted to, and it is likely that severe labor, particularly if the child is in the breech position, will furnish the necessary trauma to rupture the friable suprarenal tissue and thus give rise to a hematoma. If both organs are affected the symptoms are those of Addison's disease, and death rapidly sets in.

PHYSIOLOGY.

The Origin of the Sugar of Pancreatic Diabetes.—A burning question in physiology to-day, according to E. Pflüger (*Pflüger's Archiv*, May 15, 1905), is whether the large amounts of sugar excreted in pancreatic diabetes are derived from fat or albumen, or from both. In order to answer this question a careful investigation was made by the author. Dogs were fed upon large quantities of proteid food, which contained neither carbohydrate nor fat. Such food was found to be codfish, which in winter and spring contains no glycogen nor glucosides, and only traces of fat. With such a diet pancreas-free dogs excrete for months such large quantities of sugar (amounting to 30 per cent. of the body-weight) that the sugar cannot possibly be derived from the glycogen or other form of carbohydrate stored up in the body. The excreted sugar, moreover, weighs more than the proteid substance of the body. The sugar, therefore, is derived either from the fat of the organism, or from its proteid and that of the food. The immense amount of sugar, however, did not exceed that which might theoretically be derived from the fat stored in the body. In spite of the abundant albuminous diet the dogs emaciated to the very bones, as if they had been starved, and only the brain and heart remained intact. One marked difference between these and dogs that were actually starved is that in the former the fat alone mostly disappears. A second difference is that in the diabetic animal at death the weight of the liver exceeds that of the liver of the healthy animal. The enormously large diabetic liver has the normal chemical composition, and thus behaves exceptionally like the brain and heart of starved animals. This is explained by the fact that the liver by continuous effort in its struggle for existence with other organs, particularly for food, maintains its functional capacity. The most plausible explanation of diabetes is that the formation of sugar is the work of the cell-substance of the liver, by which not only glycogen, but also fat, is transformed into sugar. Every stimulation of the liver cell, either by innervation, or by carbon dioxide, phloridzin, adrenalin, or other poison, increases the production of sugar. If the organism is fed on large quantities of proteid, then the liver must naturally work over many nitrogenous derivatives of albumin. The more proteid is thus offered to it, the more its cells are stimulated, and thus its sugar-forming function is increased. The administration of ammonium carbonate similarly stimulates the liver cells. Besides, the administration of large amounts of proteid increases the entire bulk of the liver cells. It may thus be understood how in different individuals very different quantitative relations exist between proteid metabolism and sugar-formation, and why, at the lowest ebb of albuminous metabolism, any poison or other irritation acts as a stimulus of the liver cells, increasing the sugar-production, without an accompanying rise in the metabolism of proteids.

Effects on the Rate of Transformation of Glycogen into Dextrose.—It was found by C. H. Neilson and O. P. Terry (*Amer. Jour. Physiol.*, August 1, 1905) that by increasing the dextrose, which is a product of the decomposition of glycogen, the rate of this decomposition is retarded. This agrees with the facts that the products of a chemical reaction retard that action, and that when the blood is rich in sugar, there is a decreased transformation of the glycogen into dextrose. It is also seen that calcium chloride has a retarding action, and sodium citrate an accelerating action, on the breaking up of glycogen. This agrees with the fact that such salts as sodium citrate, acetate, etc., are used as therapeutic agents to increase elimination, probably by stimu-

lating the cell-substance and its enzymes, possibly by making the cell membranes more permeable. It also agrees with the fact that calcium chloride has a retarding action in elimination, especialy in salivary secretion and inhibiting the secretion of sugar in phloridzin diabetes, as shown by O. H. Brown and M. H. Fisher, working independently. This latter fact may possibly be explained by the calcium chloride lessening the permeability of the kidney membranes; but possibly by retarding or inhibiting the transformation of the liver glycogen and the muscle glycogen into dextrose.

The Properties of Thalassin.—In the tentacles of the sea anemone, CHARLES RICHET (*Pflüger's Archiv*, June 17, 1905) has discovered a powerful poison, which he terms thalassin. This is soluble in 95 per cent. alcohol, is not destroyed by heat, and is widely distributed among marine animals. In doses of one-thousandth of a milligram per kilogram of body-weight, injected into dogs, it causes itching, biting and sneezing, and a congestion of the mouth and conjunctiva. A larger dose causes stoppage of the heart's action. This poison is an antitoxin for another poison which is also found in the tentacles of the sea anemone. This animal may be said to possess a toxin having two components, namely, congestion, whose injection into an animal makes the latter more susceptible to its action, a property which is called anaphylaxis; and thalassin, whose injection into an animal makes the latter less susceptible to the action of congestion. This property is called prophylaxis.

The Immediate Effect of the Accelerans and the Vagus upon Automatically Contracting Strips of Heart Muscle.—That the impulse conducted along the heart from base to apex is carried by the muscular substance itself is the thesis maintained by H. E. HERING (*Pflüger's Archiv*, May 31, 1905). Independently contracting strips of mammalian heart-muscle are independently of one another affected by the centrifugal heart-nerves, not only as regards their strength of contraction, but also as regards its frequency. The extra cardial centrifugal heart-nerves do not conduct the excitatory impulse from auricles to ventricles, if the muscular connection between these has been severed. Changes in the strength of auricular contraction are not followed by corresponding changes in the strength of the ventricular contractions, even when the former have been brought about through the influence of the nerves.

The Specificity of the Digestive Ferments.—It has been found by K. KIESEL (*Pflüger's Archiv*, May 31, 1905) that the proteolytic and rennetic ferments of the dog and cow are specific in their action on the casein of the animal furnishing the ferment, with the exception of the trypsin and pancreatic rennin of the dog. The latter two have a greater affinity for the casein of the cow than that of the dog. These results show that the ferments and the casein of the various species of animals have at least a different molecular structure. The differences between the various kinds of casein have for a long time been recognized, but until now the specificity of only the rennetic ferment has been known. The specificity of the gastric ferments with respect to casein furnishes another argument in favor of the natural feeding of infants, and explains the difficulty in the digestion of cow's milk by young infants.

OBSTETRICS AND GYNECOLOGY.

Spinal Stovainization in Gynecology.—The fatal accidents, the discomfort after the administration, the necessity of skilled assistants with a general anesthetic have led many surgeons to frequently use a local anesthetic. In spinal cocainization the gynecological region participates in the anesthesia as well as the lower limbs, the inguinal and perineal regions, although this form of anesthetic for laparotomies has been given up because of the variable height of anesthesia, the difficulty of holding the intestinal pads in place and the necessity of using maximum doses. Incited by the recent communications of Dukelus and Chaput on stovaine, and because of its comparatively innocuous properties, as proved both by laboratory and clinical experiments, T. A. DALERIS (*La Gynécologie*, Feb., 1905) has used spinal stovainization in gynecological and obstetrical operations. At the time of anesthesia there was absence of all reaction of vomiting, sweats, pallor of the face, increase in pulse-rate, all of which are phenomena observed with cocaine. Five cgs. can be safely given as a maximum dose for gynecological operations of average duration. In general surgery stavaine has all the advantages and few of the disadvantages of cocaine. In long gynecological operations 7 to 8 cgs. may be used, which amount is within the domain of perfect safety. A modified Tupper's needle may be used with a beveled end and an opening on the side so that the injection may be given an upward direction. Using the method of Guinard, the cerebrospinal fluid is drawn into the barrel of the syringe and the mixture, new opalescent, is injected into the spinal canal. With 7 to 8 cgs. the anesthetic always goes above the pubes, at times to the mammary line, in the majority of cases between the xiphoid and the umbilicus, but the genital region is always perfectly insensible. The anesthetization goes rapidly to the lower limbs. After ten to fifteen minutes it attains its maximum degree, at which time the perineum and anus are anesthetized. The insensibility of the uterus comes sooner than that of the skin at the same level, a fact especially noticeable in obstetrics during labor where the contractions are scarcely perceived by the patient after three or four minutes, although in reality they have become more energetic. With a dose of 3 cgs. the anesthesia lasts forty minutes, and then gradually decreases. Ten minutes after the injection there is noticed a complete relaxation of the perineal muscles, the levator ani and the external sphincter. The anus opens spontaneously, a fact to be considered to insure protection of the operative field. This can be done by a preliminary tampon in the rectum. Urine is not expelled except by mechanical pressure. The uterine musculature contracts energetically in the gravid state. The oxytoxic power of stavaine occurs either during labor or during pregnancy. Pregnancy is a contraindication to this use of stovaine, as abortion or premature labor is apt to result. Contracting of the muscle in the non-gravid uterus is also marked. A case is on record in which a Hegar bougie was forcibly expelled from the uterus. This awakened contractibility of the uterus may prove of service which alone will be determined by further experience. Furthermore, the contraction of a subinvoluted uterus is made more complete and hemorrhage is lessened. The subjective phenomena observed at the time of the anesthesia have been almost nil. On the other hand, in 12 cases out of the 27, quite serious symptoms followed some days after the spinal injection, such as severe headache, occular and spinal pains, vertigo, nausea and vomiting. On the average the symptoms came two days after the injection, at times the spinal pain came on at the end of twelve hours. Generally, by the fourth to the fifth day, the symptoms had disappeared, but in four cases they lasted until the tenth and twelfth days, hindering somewhat alimentation. In the treat-

ment of these after-effects it was found that quinine was best for the headache and spinal pain. In six cases good results were obtained by spinal puncture and the withdrawal of 10 c.c. of the cerebrospinal fluid. In conclusion, the writer believes that spinal stovainization has its place in a number of gynecological and obstetrical operations, in spite of the postoperative symptoms mentioned. But, on the whole, none of these symptoms were of a character sufficiently grave to condemn its use.

Can the Bossi Method be Recommended to the Practitoner?—Based on extensive observations and personal experience, Dührssen (*Archiv f. Gyne.*, Vol. 75, No. 2) returns a negative answer, and sharply criticizes the cases reported from Leopold's clinic. He claims that many children who died during birth might have been saved if the vaginal Cæsarean section had been employed instead. Only an expert obstetrician should venture to employ the instrument, as the severe cervical tears and the necessity of having to apply a high forceps often present severe difficulties. The modern specialist is also perfectly familiar with vaginal Cæsarean section, and this permits the delivery of the child within a few minutes even where the cervix is closed and rigid, while the application and use of the Bossi instrument requires considerable time. Where the cervix has begun to dilate, the elastic bags give the same result with much less danger than the dilator. Dührssen reports two more cases of vaginal section which ended favorably for both mother and child. The one was an eclampsia, the other a narrow pelvis with an overdue child and a rigid cervix. In the latter class of cases the vaginal Cæsarean section has the advantage of relaxing the tension of the lower uterine segment and thus diminishing the risks attendant upon a version.

Toxemia of Pregnancy.—Following up a former important contribution upon this subject, W. S. Stone (*Med. Rec.*, Aug. 19, 1905) reports seven additional cases with urinary determinations. From these studies he concludes that the theory which places the pernicious vomiting of pregnancy upon a hysterical or reflex basis is without foundation. The mental symptoms usually stamped hysterical are essentially cerebral manifestations of disordered hepatic function, as evidenced by the urinary changes. Whereas the lesions presented in pernicious vomiting of pregnancy and eclampsia are in the majority of cases different. Yet there is clinical and pathological evidence that they are closely related. Symptoms of either may be present without change in the urine so far as ordinary tests show, but the persistent presence of even a trace of albumin, especially if accompanied by casts, and a persistent increase of indican demand a more complete examination, which seems best accomplished by a determination of the total nitrogen and its partitions. He recommends the incorporation of the test for indican in ordainary clinical tests because errors of diet and intestinal intoxications seem to be important contributing factors in both of these conditions.

Ulcer of the Stomach and Pregnancy.—Mild dyspeptic troubles and subacute gastritis are of frequent occurrence during pregnancy, but ulceration is rare. M. Le Play (*Annal. de Gynecol. et d'Obstet.*, May, 1905) describes the case of a woman twenty-seven years old, six months pregnant, who had vomited almost continuously for over three months. Her stomach was dilated and very tender. Later she passed large quantities of blood from the bowels and had several attacks of hematemesis in rapid succession. She rapidly became very weak and died after presenting a clinical picture resembling progressive pernicious anemia. At autopsy the larger curvature of the stomach showed an ulcer 12 cm. x 9 cm., with raised margins. The base extended to the peritoneum, but there was no perforation. There was marked sclerosis of all the adjacent vessels. Owing to this condition of the blood-vessels, the nutrition of adjacent areas suffered and had undergone degeneration, offering but feeble resistance to the action of the acids of the gastric secretion. The writer considers that pregnancy by favoring sclerotic changes in the blood-vessels would thus predispose to the formation of a gastric ulcer.

Malignant Embryoma of the Ovary.—Two cases of this rare form of ovarian tumor have been reported by H. T. Hicks and J. H. Targett (*Jour. Obstet. and Gyn. Brit. Emp.*, Aug. 1905). One case occurred in a girl fourteen years old who entered the hospital with a high temperature, rapid pulse, and a rigid and tender abdomen. A large tumor rose from the pelvis and extended to the umbilicus. After operation the patient remained well for three months, when she returned to the hospital suffering from ascites and rapid wasting. At a second operation a large quantity of serous fluid was evacuated, sessile and pedunculated growths studded the intestines and omentum and a large mass extended deeply into the pelvic cavity. After paracentesis had been performed five times the patient died seven months after the first operation. Miscroscopical examination of sections of primary and secondary growths showed the tumors to be composed of tubules and cysts, nodules of cartilage and bone, epithelial pearls and a groundwork of fibrous, muscular and fatty tissues. The second case occurred in a girl, six years old, who died two months after operation. The manifestations of recurrence and the microscopic findings were similar to those of the first case. These rare tumors usually occur in young adults, but may be met with in childhood. They may attain a large size, are usually pedunculated and devoid of adhesions unless the pedicle has become twisted. Secondary growths are frequently restricted to the peritoneum, they may be of the same composite structure as the primary growth or be wholly composed of sarcomatous elements. Pain and ascites are constant symptoms. Ovarian tumors exhibiting an irregular disposition of embryonic elements are very liable to be malignant.

Cystoscopy of the Female Bladder.—There has been much advance toward the perfection of cystoscopic methods of late, but after testing many instruments L. Luys (*Annales de Gynecol et d'Obstet.*, May, 1905) advises the use of the simple endoscopic tube which has many advantages over reflecting or refracting cystoscopes. In the simple tube vision is direct and the parts are seen in normal position under natural conditions since the condition of the bladder walls is not altered by distention with water. The distention alters the color of the mucosa and interferes with a proper examination of inflamed vessels or areas. In many cases of cystitis it is impossible to distend the bladder sufficiently to permit of the use of the prism cystoscope. With direct vision the difficulties met with in cases of pyuria and hematuria are not present to the same extent as when the refracting cystoscope is used. This direct method also allows of the direct application of various remedial agents to the mucosa of the bladder, which is often a distinct advantage. The writer finds that catheterization of the ureters can be performed with more certainty and with less danger of introducing

bacteria from an already infected bladder by using the simple endoscopic tube.

Spontaneous Amputation of the Tube.—Among 1041 laparotomies performed in the clinic of Pestalogga, Florence, since 1894, there were two cases of spontaneous amputation of the tube. M. GUICCIARDI (*La Gynecol.*, May, 1905) describes these two cases together with a third that came under his observation. In the first case a hysterectomy was performed for multiple fibroids. The right appendages were normal, the uterine end of the left tube was normal, but ended in a rounded stump in which there was no trace of an opening. The missing portion of the tube was not found. In the second case amputation of the tube followed torsion of the pedicle of an ovarian tumor. In the third case the abdomen was opened for the removal of a cystic tumor felt through the posterior vaginal fornix. The tumor proved to be a sactosalpinx which had become inverted and spontaneously amputated from the uterus and adherent to the anterior layer of the broad ligament.

Uterine Metastasis in Cancer of the Stomach.—Metastatic deposits in the uterus in cases of primary involvement of other organs is very uncommon. A. COUVELAIRE (*Annal. de Gynecol. et d'Obstet.*, May, 1905) reports the case of a primipara thirty-one years old who was seized with severe vomiting and pain in the stomach when ten weeks pregnant. A hard tumor in the epigastrium led to the diagnosis of cancer of the stomach. There was a progressive cachexia, ascites and edema of the limbs and abdominal wall being noted in the eight month. A vaginal examination 301 days after cessation of menstruation, revealed an induration of the fornices, cervix and lower uterine segment. A condition which was not present a month previous. A dead child was removed by Cæsarean section and the uterus removed. The patient died fifty-one days after operation. The autopsy showed a general adhesive peritonitis with malagnant growths in the stomach, intestines, uterus and vagina.

The Appendix and Pelvic Disease.—R. PETERSON (*Am. Jour. Obstet.*, Aug., 1905) in a series of 285 cases in which the abdomen was opened for other purposes, removed the appendix regardless of its apparent condition. The microscope showed about 50 per cent. to be normal. Inasmuch as many appendices which looked diseased were shown microscopically to be normal, and vice versa, the writer concludes that when the abdomen is opened for any reason, it is wise to remove the appendix in all cases in which a prolongation of the operation would not be too profound a shock. When there is disease enough in the pelvis to demand operation, there is reason to expect that the appendix may be diseased also, which, if left behind, may prove a subsequent source of suffering to the patient.

Menstrual Urticaria.—D. J. M. MILLER (*Med. Rec.*, May 13, 1905) epitomizes the literature of this condition and describes its occurrence in a girl of fifteen years, who menstruates regularly, and whose attacks of urticaria make their appearance seven or eight days before and cease two to three days before each period. Occasionally the urticaria persists until the flow begins, free from attacks and she is perfectly healthy in other rarely during the first day or two of its course. During the intervals between the periods the patient is quite respects. The urticaria itself is of the ordinary type.

Tuberculosis and Pregnancy.—According to the statistics of Fellner, pregnancy tends to increase the susceptibility of the individual to tuberculosis. Cases occurring during the pregnant state are severe, with a marked tendency to laryngeal involvement. The pregnancy is as a rule not interrupted, but it is not uncommon for an advanced case of phthisis to be delivered at full term, the child dying in a few days and the mother in a few days or weeks. G. E. MALSBARY (*Am. Jour. Obstet.*, July, 1905) has been led to consider that tuberculosis in itself predisposes to pregnancy. In view of the special susceptibility, pregnant women should be protected from tuberculosis as from other infectious diseases. The habit prevalent among pregnant women of going into retirement, should not be tolerated, if such retirement precludes hygienic surroundings, pure air and sunlight. Fresh air, exercise and proper diet combined with the use of tuberculin and creosote constitute the essentials of treatment. The desirability of artificial interruptions of pregnancy is problematic in these cases, especially when the objective symptoms do not show progression of the disease. As far as pulmonary tuberculosis is concerned, the operation is of no especial benefit.

Lacerations of the Cervix Uteri.—ARTHUR H. GARDNER, in an article embodying an exhaustive résumé of the opinions held upon this subject by the most distinguished obstreticians (*Med. Rec.*, Aug. 26, 1905) draws some conclusions. Many ills are the result of unrepaired lacerations of the cervix. These tears may be lessened, both in frequency and extent, by allowing more time for dilatation and by a more judicious resort to either forceps or podalic version. The most frequent cause of subinvolution and prolonged convalescence is unrepaired lacerations, but, in all probability, many of the morbid conditions ascribed to lacerations are rather an infection of the lacerated surface. Many cases of severe hemorrhage are due to unrecognized tears, and immediate repair offers the best means of controlling such bleeding, and also of preventing infection of the torn surfaces. Primary tracheloplasty is easily and quickly done, whereas a secondary repair is a difficult and tedious procedure. Even in case union should not obtain in immediate repair, the condition of the woman is none the worse, whereas if successful, the patient is spared the subsequent ills which cervical lacerations sooner or later entail. Medical students should be taught that where hemorrhage persists with a well-contracted fundus, to look for spurting vessels in the torn cervix, and to suture. As to immediate repair without bleeding, they should be taught the advantages, and impressed with the evils which might arise from poor technic and lack of asepsis.

Intestinal Obstruction and Pelvic Operations.—The frequency of intestinal obstruction occurring as a postoperative condition in pelvic surgery is shown by the statement of E. M. CONNER (*Practitioner*, Aug., 1905), that it is relatively frequent. He considers the operation which stands pre-eminent among all others in causing this complication, to be supravaginal hysterectomy. While adhesions may be present without producing any symptoms, the presence of attacks of localized abdominal pain, associated with vomiting, after an abdominal operation, and especially after a pelvic one, should raise the question of the advisability of exploration. The intestinal obstruction usually results from the intestine forming a kink, or better a volvulus, using the uppermost adhesion for a fixed point on which to rotate. The cause of this volvulus, in far the majority of cases, is an increase of pressure within the bowel, produced by gas formation, meteorism. The origin of the meteorism is to be found in some error of the diet or the digestion. Sometimes strong peristalsis draws out the adhesion into the form of a band, under which a coil of small intestine may be ensnared. Meteorism pro-

duces a volvulus in almost every obstructed loop. These adhesions antedate the obstruction, showing that the latter is merely a complication, and raising the suspicion that, for every case in which this does occur, the probability is, that there are many in which it does not occur. The presence of the uterine stump among the small intestines undoubtedly disposes them to become adherent. How this adhesion takes place is not quite clear. Perhaps the most favored suggestion is that the row of sutures and knots offers the opportunity for the bowel to adhere. In consequence of the sutures being tied firmly, if not tightly, the tissues within their grasp are lessened in bulk, fluids being squeezed out of them. There is a tendency for each stitch to lie in a groove of its own making. The fluids which have been expressed in tying the ligature will swell the bulk of the contiguous tissues. The slight injury, thus inflicted, calls forth a reparative inflammatory reaction, augmented later by the irritative action of the aseptic stitch, causes a small effusion of lymph which soon covers the stitches. In the case of a uterine stump, with gaping of the peritoneal edges, the formation of adhesions with the intestines is invited.

PEDIATRICS.

Infant Feeding.—F. S. CHURCHILL (*Journal A. M. A.*, May 28) discusses the embarrassments of infant feeding when breast milk is not available, and the unsatisfactory results of the common practice of diluting cow's milk with water in such cases. He summarizes practically as follows: Cases of difficult feeding in infancy are: (1) Those of fat indigestion; (2) those of sugar indigestion; (3) those of proteid indigestion. Each of these may occur alone or in combination with the others. Proteid indigestion is most common, but fat indigestion is also frequent. Each must be treated individually, the form of indigestion present must be ascertained if possible, and appropriate measures be adopted. The treatment is almost exclusively dietary; the fats and sugar can be regulated by varying the amounts of cream and sugar in the food. The composition of cows' milk, with its high caseinogen and low lactalbumin content must be remembered in treating proteid cases, the caseinogen must be cut down or eliminated, if need be, and the lactalbumin retained. This twofold object is attained by feeding whey. Increase in quantity and quality of the food must be made gradually. In conclusion, he suggests the desirability of careful study of artificially fed infants and publication of the results.

Pyloric Stenosis in Infancy.—CHARLES M. SCUDDER (*Journal A. M. A.*, May 20 and 27) reviews the literature of pyloric stenosis in infancy, and describes the symptoms, diagnosis and treatment. He recognizes two groups, the subacute or chronic, and the acute fulminating cases. While most cases are fairly typical, in some the differential diagnosis is difficult, and a careful study of each symptom and the sequence and grouping of symptoms should be made till the diagnosis is reached by a process of exclusion. He has little faith in the medical treatment, and believes that the condition is practically hopeless without operation. The results of operations since 1898 show a saving of over 50 per cent. of the cases, of which probably all would have died if let alone. An analysis of the fatal cases shows that many of them were due to mistakes or errors of technic, too late operation, etc. The operation should be rapid, free from causes of shock, sepsis or hemorrhage, the parts to be handled gently and isolated outside of the abdominal cavity. The Lorta operation is condemned. Pylorectomy is too severe and pyloroplasty is not recommended save in exceptional cases. Some form of gastroenterostomy is best for most cases, but owing to the shortness of the infant mesentery and other reasons the anterior operation should be avoided if possible. The Finney operation of gastro-pyloroduodenostomy may be suitable in some cases, or, if not feasible, Kocher's gastroduodenostomy may be useful. Aftercare is of vital importance, and, if possible, an expert in feeding a baby should have charge. Absolute quiet is essential, and rectal feeding may be needed for a few days. Scudder does not discuss the etiology to any extent, but thinks that a congenital hyperplasia may occur and a spasmodic contraction of this, after birth, is frequent if not the rule.

PRESCRIPTION HINTS.

Athma.—

℞ Potassii nitratis.....ʒss
Pulv. anisi fruct.....ʒss
Pulv. stramonii fol.....ʒi

M. fiat pulv. Let patient inhale smoke of a thimbleful of this powder, formed into a cone and lighted at the top. (Sawyer.)

Or the following:

Potassii nitratis.....ʒss
Pulv. stramonii flor.....ʒi
Pulv. anisi fruct.....ʒii
Pulv. lobeliae inflatae.....ʒi
Pulv. fol. theae sinemsis nig.....ʒi
Ol. eucalypti.....♏xv

M. fiat pulv. Sig. To be burned as above, using a thimbleful at a time.

A good asthma powder for emergency use is one part, by weight, of saltpetre and two parts of black tea, powdered. (Sawyer.)

Hyperchlorhydria.—

℞ Magnesiae ustæ.....ʒi-ʒiv
Cretae preparatae.....ʒss-ʒii
Bismuthi subnitrat.....ʒi-ʒii

M. et fiat chart No. xii.

Sig. One mixed with a wineglassful of milk or water an hour after each meal. (Reed.)

Or—

Cerii oxalat.....ʒiv
Bismuthi subcarb.....ʒviii
Magnes. carb. levis.....ʒii

M. Sig. One-fourth to a heaping teaspoonful in water two hours after each meal. (Stockton.)

In cases in which the alkalies are not well borne, the following prescription occasionally succeeds:

℞ Extr. belladonnæ.....gr. i-gr. ii
Ext. yerbae santae.....ʒi

M. et fiat mass. in pillulae No. xvi dividend.

Sig. One after each meal, or large doses of bismuth as follows:

℞ Bismuthi subnit.....ʒvi to ʒi
Fiat. chart. No. xii.

Sig. One mixed with milk or water half an hour before each meal.

Occasionally the following is a useful remedy:

℞ Argent. nitrati.....gr. ii-gr. iii
Ext. belladonnæ.....gr. i
Bismuthi subnit.....ʒii

M. et fiat mass. in capsulae, No. xvi dividend.

Sig. One after each meal. (Reed.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 23, 1905.

THE CHATTANOOGA MEETING.

THE meeting of representative Southern men, which has been called for November 9 and 10, at Chattanooga, is one that will be of the greatest importance to the entire country, though the South is naturally more immediately interested. Two subjects are announced for discussion: *First.* A uniform system of quarantine in yellow fever. *Second.* A reform in the matter, not only of landing an undesirable class of immigrants in Southern ports, but of the alleged custom of distributing them from Northern centers throughout the South. This second subject is thus stated in the call:

"Again there are coming into the United States at the present time a larger number of foreign immigrants than were ever known in our country's history. Among these are great masses who are wholly undesirable and whom it will be impossible to assimilate with our institutions. There is apparently a desire, or tendency, to bring many of these undesirable immigrants to Southern ports, and also to distribute them from Northern centers into the South. The South will welcome desirable immigrants from all lands, and it has already racial problems of such gravity that no others should be invited until proven safeguards are provided in advance of their coming."

As will be seen, the question of physical health comes first, as it justly should, for it is very important, and to the country at large just now represents the key-note of the situation. An outbreak of yellow fever, with no common purpose or plan to meet it, with no settled system to hold it in check, throws the Southern people, according to their own reports, into a panic that produces scenes and acts of almost indescribable inhumanity. Shotgun quarantines are a disgrace to civilization, and the very remedy, if there is a remedy, is in thoroughly organized concert of action, prepared and elaborated in advance to meet just such emergencies.

Unfortunately, the problem of securing uniformity of legislation in different States is a most difficult one to solve. After years of painstaking effort only two classes of cases, those of divorce and "negotiable" paper, have made any appreciable progress, and it is doubtful if even now, with the object lesson of this last epidemic staring them in the face, this coming mass meeting will accomplish any practical result, unless the aid of the national power is invoked. For with the greed of business enterprises, and the unwillingness of municipal authorities to interfere with commercial conditions (by the enforcement of a rigid quarantine at the beginning of the outbreak), it is only the strong arm of Federal authority that will prove able to prevent the constant recurrence of these epidemics.

Again, although the question of sanitation is put first in this call for reform, it is in reality the second subject, that of immigration, which is of the greatest interest to the originators of this movement, as it lies close to the very roots of permanent order in the South. Yellow fever, as they frankly say themselves, when present, is a matter of but a few months at the most, and there are sometimes years between the outbreaks. But if the labor conditions of the South become complicated, and racial problems are multiplied, the South will become, says a Southern writer, "the theater of such continuous and appalling disorder as will shake the whole section to the center and affect other centers as well."

For, it seems that some of the Southern planters, having become wearied of negro labor, have been considering the employment of help from Southern Europe, while others, acting in concert with Southern manufacturers whose eyes are fixed on Oriental markets for cotton goods, have been preaching the advantages of coolie labor, and here, as a Georgia editorial says, "would be a mess that would do as much damage as if served hot from the devil's kitchen."

The South is not under the dominion of the negro, but they are there in large numbers and there to stay, so that in remedying their deficiencies it will not do to force them into competition with a race like the coolies, who would arouse the very worst antagonisms of their nature, unless an attempted repetition of the Sepoy mutiny or the West Indian massacre are the objects to be attained. This the conservative element in the South fully recognize, so that to them the last of the two subjects will be the first, while to the medical profession and to the other sections of the country at large, the yellow fever problem will undoubtedly be the burning question.

Let us, however, hope that by the union of the two, some solution may be found that will prove a permanent blessing for both, even if in disguise.

STALAGMOMETRY, A NEW METHOD OF CLINICAL RESEARCH.

The resources of physical science have been amply drawn upon within the past few years in the zealous investigation of the occult phenomena of disease. No less in pathology than physiology does physics play an important rôle. Among the numerous procedures of the most modern research laboratories may be mentioned the determination of the specific gravity of the various body-fluids, cryoscopy or determination of the freezing point of the latter, the estimation of the coagulation time of the blood, the investigation of electrical conductivity of the various secretions, of their viscosity, polarization and osmotic pressure. Only a few of these modes of investigation have proven of any clinical value. Cryoscopy is no longer accorded much weight as an aid in diagnosis. Another method of investigation has been revealed, and according to present indications, it bids fair to become a valuable adjunct to clinical diagnosis.

The essentials of this method consist in the determination of the relative degrees of surface tension possessed by the body-fluids. A painstaking research into the significance of this force in physiology and its possible applications in practical medicine was first made by Prof. J. Traube (*Pflüger's Archiv,* Dec. 1, 1904). A further investigation based upon an extensive amount of clinical material has just been reported by J. Traube and F. Blumenthal (*Zeitsch. f. Exper. Pathol. u. Therap.*, July 21, 1905). In order to gain a clear idea of the nature and importance of this new diagnostic test, it is necessary to consider the part that surface tension plays in the organism.

Prof. Traube is one of the ablest exponents of the doctrine that physical forces underlie most of the important vital processes. Of these forces, the one that enters largely into the most diverse manifestations of life is surface tension. Otherwise known as capillarity, this force represents the tendency on the part of liquid surfaces to contract. The familiar method of measuring the surface tension of a liquid is by means of a capillary tube. But Traube invented a simpler method. He devised an instrument, which he named the "stalagmometer," which measures the number of drops that might be obtained from a given volume of liquid. The stalagmometer consists of a simple glass tube, bent in a certain manner, graduated at one part, and provided at its upper end with a rubber bulb, by means of which the liquid may be drawn up into the narrow bore. The lower end of the tube is slightly expanded into a flat surface, from which the drops may be allowed to fall. The greater the number of drops the less is the surface tension of the liquid.

A great many physiological phenomena, which have been attributed to the operation of osmotic pressure, are really the result of differences of surface tension. Thus, Traube discovered that a solution of low surface tension will pass through a membrane into a solution of higher surface tension. The surface tension of a liquid largely depends upon the nature of the substances dissolved in it. Thus phenol diminishes the surface tension of its solvent. A fact of great significance in relation to the subject of intestinal absorption is that peptones reduce to a great degree the surface tension of the liquid in which they are dissolved, while proteids do not. As the result of this diminution of surface tension, the peptones pass from the lumen of the intestine into the blood. This explains why the stomach and intestine contain only dilute solutions of peptone, as determined by Bernstein, for these are absorbed as rapidly as they are formed.

In digestive disorders in which the process of absorption is disturbed, there is a considerable accumulation of peptones, with a resulting greater diminution of surface tension. This would be indicated in the stalagmometer by the larger number of drops obtained from a given volume of the solution. For water the figure is

53; for normal stomach contents it varies from 63 to 66. Traube and Blumenthal determined the figures in a large number of cases of diseases of the stomach, and in cases of gastric disturbance secondary to some constitutional disorder. The severer the disease the higher is the stalagmometric index. Thus, in peracidity, atony, peracidity with atony, subacidity, carcinoma of the pancreas, anemia, etc., the figures ran between 65 and 68. In carcinoma, pernicious anemia, pyloric stenosis, chronic gastritis, and ulcers, the figures were between 67 and 74. It is evident from these sources that this method of investigation may serve to indicate the relative degree of severity of a gastric lesion. Beyond this, one can expect no diagnostic advantage from this test. But its extreme simplicity of operation recommends it as an initial step in the routine examination of stomach contents.

A second field for the application of this test is the study of the functional capacity of the kidneys. When these are healthy the surface tension of the urine is much greater than that of the blood. In nephritis the surface tension of the urine is diminished, which explains the disturbances in the secretory activity of the kidneys. It is obvious that if the urine had a surface tension equal to or less than that of the blood, the kidneys would be unable to secrete. As an instance of the wise provision for maintaining the high surface tension of the urine, may be mentioned the following: Capillary-active substances which diminish surface tension (such as phenol, indol, benzoic acid, etc.) on their passage into the urine are transformed into compounds (phenolsulphuric acid, indoxylsulphuric acid, hippuric acid, etc.), which are markedly capillary-inactive, maintaining the high surface tension of the urine. If substances like the former were allowed to enter the urine, the kidneys would soon cease to functionate. In unilateral kidney disease a stalagmometric test of the urine would be of diagnostic value. It is important to note that the presence of albumin or sugar in the urine has no marked effect upon the surface tension of the urine. Of great significance is the fact that diseased kidneys lose the capacity of holding back in the blood the capillary-active substances, to which they become permeable. The presence of these in the urine diminishes its surface tension, which necessarily embarrasses the further secretory powers of the kidneys. These facts have been established in cases of nephritis, cardiac disease, cirrhosis of the liver, pneumonia, lysol poisoning, articular rheumatism, scarlet fever, tuberculosis, cerebral lues, and other diseases, either localized in the kidney or affecting it from without.

The nutritive exchanges between the blood and lymph, and the lymph and tissues, respectively, have been attributed to two factors, namely, osmosis and the selective activity of the cells of the capillary and lymphatic walls. Yet, these forces are not sufficient to explain all the phenomena of the nutritive exchanges both in health and in disease. Thus, blood pressure largely determines the flow of the nutritive elements of the blood in the direction of the lymph. The rapidity of osmosis also depends in some degree upon the extent to which the opposing fluids are soluble in each other. Chemical forces, the frictional coefficients of the opposing fluids and the nature of the membrane itself, must all be considered. And if to these be added the surface tension of the blood and lymph, one may gain a complete picture of the mechanism of the bodily exchanges. It is quite probable that a routine examination of the relative surface tensions of the lymph and blood will be of diagnostic value in diseases giving rise to transudates, and in hemophilia, idiopathic edema, etc.

From the view-point of pharmacology, a promising field of research is afforded by stalagmometric observation. It is pointed out by Traube that the alkaloids, antipyretics, diuretics, narcotics, excitants, etc., besides belonging to the rapidly osmosing class of substances, and, besides, being freely soluble in the lipoids of the cellular membranes, at the same time markedly diminish the surface tension of the liquids in which they are dissolved. This diminution serves to explain the marked change in the surface tension of the circulating fluids, which occurs in various drug intoxications, which as a result cause a reversal of the direction of the fluid exchanges. The determination of the relative efficiency of diuretics may ultimately depend upon their degree of capillary activity, just as the latter has been found by Traube to be the test of the relative value of the narcotics. He has actually discovered an exact numerical relationship between narcotic power and surface tension.

It is noted that amyl alcohol contained in fusel-oil, by lowering surface tension and impregnating the walls of the biliary passages, causes an abnormal rapidity in the exchanges that occur through them. On the other hand, part of the

therapeutic value of ethyl alcohol as an aid to digestion, is attributed to the fact that, by lowering surface tension, the alcohol accelerates intestinal absorption, particularly that of the fats.

One very important application of these studies on surface tension is to the problems of immunity and to the therapeutics of antitoxins. Thus, tetanus toxin travels to the brain by way of the fatty nerve fibers, while antitoxin chooses the vascular path. The toxin penetrates the cells while antitoxin does not. The toxin is dissolved in the lipoids of the brain-tissue, while antitoxin is dissolved in the cerebrospinal fluid. The toxin dissolves red blood cells, while antitoxin does not. It is plain that tetanus toxin osmoses and dissolves in lipoids with ease, while tetanus antitoxin does not. Traube suggests that it would be necessary, in order to increase the efficiency of tetanus antitoxin, and probably of other antitoxins, to add to them capillary-active substances, so as to increase their power of traversing the cellular and tissue membranes.

Many other instances of the operation of surface tension in the normal workings of the body and in their pathological modifications, have been noted. Enough have been dwelt upon, however, to indicate that this force is a most potent factor in physiology, and that a recognition of its full value will give it a prominent place among the diagnostic resources of the clinical laboratory.

ECLAMPSIA FROM ANOTHER VIEW-POINT.

There is nothing more encouraging in present-day medicine than the larger view as to the causation of convulsive seizures occurring about the end of pregnancy which is coming to be generally accepted. There was a time, not so very long ago, when practically all puerperal convulsions were attributed to some defect of the kidney. The reason for this is not far to seek.

The presence of albumin in the urine was supposed to indicate definitely a lesion of the secreting substance of the kidney. As a consequence, it was supposed that there was in these cases an accumulation of material in the circulation that had failed of excretion because of renal inadequacy. The significance thus attributed to albuminuria has proved on further investigation to be greatly exaggerated. Albumin may be present, especially under conditions in which there is disturbance of intra-abdominal pressure without having any serious ulterior meaning at all. As a matter of fact, it is very rare for a woman to escape albuminuria during the whole course of a pregnancy. Not infrequently it has happened that young women, who, before marriage, showed signs of albumin in the urine, and to whom the question of the possible existence of Bright's disease had proved a source of worry, were better after a pregnancy or two as regards their renal condition than they had been before.

In recent years attention has also been called to the fact that even the presence of casts with albumin in the urine is by no means a definite indication of the presence of a serious kidney condition. They do indicate that a kidney is sensitive to irritation, and that some irritative process is at work. This irritation need not necessarily proceed to degeneration, however, and in fact never does, unless a condition of lowered vitality is present. Athletes, and especially those who take such violent exercise as long-distance running, rowing, bicycling, and the like, always present casts in their urine after their efforts, but this seldom has any serious significance, if there is not some intoxication at work in their systems at the same time. The kidneys of a pregnant woman seem to be called upon to do somewhat the same kind of extra work as that done by the athlete. Hence, the more satisfying conclusion in recent years—that except in extreme cases such manifestations in the urine of the pregnant should be neglected unless other symptoms of a serious kind are manifesting themselves.

To replace the kidney in the etiology of many cases of eclampsia, other organs have been found from which undoubtedly some of the symptoms at least must be considered to arise. In most cases of convulsions with rapidly fatal termination, it has been found at autopsy that the liver is even more frequently diseased than the kidneys, the pathological appearance being very much like that of an acute yellow atrophy of the liver. It has long been known that acute yellow atrophy occurred almost exclusively in pregnant women, and while it has sometimes been attributed to a specific infection, such, for instance, as produces a corresponding effect in yellow fever, it has generally been thought to be due to some intense toxic process at work in the economy. This opinion was supported by the fact that the hepatic lesions produced by phosphorus poison resembled those of acute yellow atrophy so closely that the two affections have sometimes been mistaken one for the other.

There is no doubt now, however, that in eclampsia the condition of the liver must always be considered, and that treatment must always include this organ in the purview. Unfortunately, when the liver is the main seat of affection, much hope of relief of symptoms by any ordinary remedies is justified.

Within the last few years, another element in the etiology of eclampsia has attracted considerable attention. The ductless glands undoubtedly produce conditions when diseased which may lead to convulsive attacks, not unlike those of eclampsia. It is not surprising that during pregnancy these important structures called upon to do work for two beings instead of one should sometimes prove to be inadequate. Nature has fortunately made provision for the temporary hypertrophy of these organs so as to compensate for this strain upon them. The well-known tendency for the thyroid gland to enlarge during pregnancy has been noted by all observers. At times, however, even this enlargement apparently fails to compensate. On the other hand, not a few of those women who have a cystic enlargement of the thyroid prove during the course of pregnancy to have some thyroid inadequacy, perhaps because of interference with the circulation, and it is particularly in them that some of the milder forms of eclampsia evidently dependent upon inadequacy of the ductless glands have been noted. On the other hand, the enlargement of the thyroid may at times exceed the physiological demands, and in like manner produce a nervous sensitiveness with tendencies to explosive attacks of nerve force resembling convulsions.

Finally, in nervous women, it has been noted over and over again that the strain of pregnancy produces a condition in which there is a lack of nervous equilibrium and a distinct tendency to the occurrence of functional nervous disorders that may manifest themselves apparently in convulsive seizures. This is especially true of women with hysterical tendencies who have heard much of eclampsia and its dangers and have learned to dread them. It has been a subject of frequent remark at medical meetings that the wives of physicians seem to be more liable to eclampsia than other women of a corresponding condition in life. Undoubtedly this is due to the fact that the doctor's wife is apt to know through her husband of any cases of eclampsia that occur in his practice, and may even add to the knowledge thus acquired by surreptitious reading of medical books. Under these circumstances, it is not surprising that occasionally what are genuine hysterical attacks should be mistaken for eclamptic convulsions. When an examination of the urine disclosed the presence of albumin so common in pregnant women in the old days, the diagnosis of eclampsia was confirmed. If the doctor's wife knew, as was frequently the case, of her albuminuria, then the nervous manifestations were likely to be increased from fright and worry. Not a few of the remedies that have acquired a reputation for the relief of eclampsia have obtained their reputation because of apparently successful use in such cases as these. Hence the large number of drugs that have, at one time or another, gained a temporary reputation as specific for eclampsia.

The whole of this newer and better outlook upon eclampsia is in line with the determination becoming every day more widespread—to view the patient as a whole rather than as suffering from one or more supposedly pathognomonic symptoms. It is not the urinary examination alone that can indicate the extent of the danger. The entire clinical picture must be taken into consideration. There is no doubt now that eclampsia is an intoxication, though not of renal origin alone, but of multiplex etiology. Undoubtedly, the constipation so frequent during pregnancy plays an important rôle in the development of these intoxications. It is in this matter, and from the very beginning of pregnancy, that most can be hoped for in the prophylaxis of eclampsia. The liver lesions that have been described as the basis of the severer forms of the affection owe their origin to an intensely toxic material resembling the substances produced when phosphorus is present in the intestinal tract. Each case, however, must be a separate and individual study. No single drug or set of drugs can reasonably be expected to accomplish therapeutic results in so multiform a disease. This is the encouraging part of the present situation and the foundation of hope for true progress in the etiology and, consequently, for the more successful treatment of eclampsia.

Cholera Under Control.—The official bulletin issued in Berlin, on September 18, says there were ten fresh cases of cholera and five deaths from noon Saturday to noon Sunday, and three new cases and one death from noon Sunday to noon Monday, making the totals 202 cases and 77 deaths. It was announced on September 19 by the German Government that the cholera has been checked and any danger of epidemic is entirely unlikely.

ECHOES AND NEWS.

NEW YORK.

Bequest to the Seney Hospital.—By the will of the late W. D. Toy, filed in the Surrogate's Office, Brooklyn, N. Y., $5,000 is left to the Seney Hospital for the endowment of a bed in memory of Lucy A. Toy, wife of the testator.

Medical Society of the State of New York.—The Business Committee, to have charge of the program of the next annual meeting of the Medical Society of the State of New York, to be held in Albany, Jan. 30 to Feb. 1, 1906, appointed by the president, Dr. Joseph D. Bryant, consists of Dr. Leo H. Neuman, chairman, Albany; Dr. Algernon T. Bristow, Brooklyn; and Dr. Herbert U. Williams, Buffalo.

College of Physicians and Surgeons.—The opening exercises of the academic year 1905-6 will be held in the Lower Lecture Room on Thursday, Sept. 28, 1905, at three o'clock P.M. After a brief address of welcome by the president of the university, an address will be delivered by Samuel W. Lambert, A.M., M.D., Dean and Professor of Applied Therapeutics, upon "Some Present Fallacies in Medical Education."

New Medical Directory Out.—This year's edition of the medical directory, issued by the Medical Society of the County of New York, has appeared in the form of a neat, clearly printed and handy volume of more than 600 pages, compact and comprehensive. It includes lists of legally qualified physicians of all schools resident both in New Jersey and Connecticut, as well as in New York City, together with the summer homes of New York physicians who are members of the society. There is also information concerning hospitals and asylums, health department officers and coroners, besides a street directory of physicians in the city.

New Jewish Hospital.—The roof of the new Jewish Hospital of Brooklyn has been completed, so one of the important Jewish charities in the country is soon to be well housed. The society had long been working for money sufficient to build a hospital, when, about a year ago, chance threw a desirable building in their way. This was the Memorial Hospital for Women and Children on Classon Avenue, extending from St. Marks Avenue to Prospect Place. A good sum of money was assured to back the enterprise, and the building of two additions was begun almost immediately. The new wing, together with the complete remodeling and refurnishing of the whole building will cost $150,000. Of this total, $100,000 is in hand, and the remaining $50,000 is to be secured by a fair, to be held in the hospital building the last week of November. All the Jewish societies of Brooklyn will be affiliated in this work, each having its special department. The president of the fair committee is Abraham Abrahams, one of the chief benefactors of the hospital. Its chairman is Nathan S. Jonas.

First Aid on Railroads.—The fourteenth annual meeting of the Erie Railroad Surgeons' Association was held last week in the Hotel Astor. Dr. F. A. Goodwin, of Susquehanna, Pa., presided, and about fifty physicians were present. Papers were read on many subjects, including the following: "The Eyes of Railroad Employees," "Reflex Pains," "Emergency Hospitals for Shops," and "Some Principles to be Considered in the Handling of Railroad Cases." The Erie Railroad requested the association to submit some plan or to suggest some course of instruction for certain of the railroad employees on the lines of "first aid to the injured," in order to minimize fatalities in railroad accidents. A resolution favoring the scheme was adopted, and a committee was appointed to formulate some plan of action. Speaking of "Emergency Hospitals for Shops," Dr. C. S. Parkhill, of Hornellsville, N. Y., recommended "emergency boxes" on all trains. "Every railroad should have a special 'first aid' department," he said. "under the direction of a surgeon, and a sufficient number of employees in all departments should receive instruction to enable them to render first aid to the injured."

Country Bred Typhoid in City.—Many cases of typhoid fever are reported from the various city hospitals as due to the conditions prevailing in the summer resorts up the State from which the sufferers recently returned from their vacations. Most of the patients came from Dutchess, Orange and Sullivan counties. The sanitary situation in those regions has been called to the attention of the State Board of Health and an investigation is now under way. Among the patients recently treated in the Presbyterian Hospital was a whole family of five persons, who were taken directly from a train at the Grand Central Station to the hospital. "Practically all these cases of typhoid," said Health Commissioner Darlington, "are now being brought into the city from the country. The drainage conditions at farmhouses and country boarding places and hotels are not of the best and as a result the germs of typhoid often filter into the wells and contaminate the water. The Board of Health, whenever a case is reported here, causes a full history of it to be taken, so that the source of the infection may be traced and measures taken to prevent a recurrence of the disease. The Board of Health has taken especial interest in the sanitary conditions in Dutchess, Orange and Sullivan counties, where so large a supply of the milk of this city comes from, and many of the dairies there were closed until their owners made alterations and repairs in conformity with the regulations. In many instances farmers used the water from contaminated wells in washing milk cans and pails. The amount of typhoid in the city at present is about normal for the present time of the year. According to the department reports the number of cases last week was twenty-three, which is slightly above the average for this season.

Copper to Stop Typhoid.—The application, properties and effect of copper sulphate, for the purification of water supplies, formed a topic of discussion at the convention of the New England Water Works Association, which met in this city last week. D. D. Jackson, of Brooklyn, in a paper on "Destruction by Copper Sulphate of Typhoid Fever Germs," said experiments he had made demonstrated that one part of copper in 50,000 of water was necessary to destroy typhoid germs, and that this was more than could be safely used. No more than one part of copper in 1,000,000 of water could be safely used, he said, and that such a solution would be insufficient to produce any beneficial results. Prof. Henry Krämer, of Philadelphia, in a paper on "Germicidal Properties of Metallic Copper," said that his investigations had convinced him that the introduction of copper foil into water would destroy typhoid germs and that certain forms of lower animal life were also destroyed by it. He said that all drinking

water used in his own family for more than a year had been treated with copper and no ill effects upon the health of any of its members had been observed; on the contrary, he said, their health had never been better. All vegetables used by his family, he said, when eaten raw were first washed in water treated with copper. Prof. Krämer was positive that copper in proper quantities could have no evil effect in the human system. Prof. Herbert E. Smith, of New Haven, speaking on "Toxicological Aspects of the Copper Sulphate Treatment," said that copper poisoning was seldom more than temporary in its ill effects, even in large doses. He said copper did not produce chronic poisoning such as is caused by lead and mercury. A single large dose of copper might produce acute poisoning, he said, but the continued use of small doses for lengthy periods produced no ill effects.

PHILADELPHIA.

Aid to Hospitals.—One of the latest methods of aiding hospitals is the introduction of street carnivals. In the southern section of the city the people have occupied several squares on the street with booths from which refreshments are sold, the proceeds of which will be given to the Methodist and St. Agnes Hospitals.

Factory Laws Violated.—During their visits the State inspectors have found that the factory laws are being violated in many of the mills of the northern sections of the city. The proprietors of these business places are extremely negligent in regard to the sanitary conditions, especially is this true of the cloak and toilet rooms. The labor unions are the chief instigators of the complaints.

Wills Eye Hospital Taxed.—As a result of the many defects found in the school children by the medical inspectors the Wills Eye Hospital is busily engaged in treating these patients. There are many requests for the hospital to furnish not only the medical treatment, but also the glasses which the authorities say they are unable to do under the present system of financing the institution. One of the members of the Board of Directors said the other day that if the institution were properly endowed all school children, or at least those too poor to pay, could be supplied with glasses.

Board of Health Physician Held for Damages.—Having heard of the awarding of damages, Mrs. Mary Fay, of 231 Montrose Street, conceived the idea of obtaining an easy livelihood hereafter, and accordingly entered suit against Dr. Alfred Marshall, a medical inspector of the Board of Health for unlawfully quarantining the said Mrs. Fay's home. The woman holds that after her child had been taken to the Municipal Hospital the sign of diphtheria, the disease from which her child was suffering, should not have been tacked upon her door. Then, too, she claims the smallpox placard which was placed upon the house was there unlawfully, since, in her opinion, her other child did not have this disease. The fact that the first child was discharged from the Municipal Hospital several days after her admission led Mrs. Fay to believe the child did not have diphtheria.

Who Owns the Prescription?—One of the daily newspapers in an editorial takes up this question, and before reaching conclusions as to the entitled ownership, reviews the arguments set forth by physician, druggist and patient in favor of their claim on the desired order. The physician bases his claim upon the right by creation and right to renew indefinitely, so the paper said; the druggist bases his claim on the right of possession, while the patient claims by right of purchase. The dispute, the newspaper says, is made obscure by treating the prescription as substantial property. The prescription is nothing more than a written order to the druggist, requesting him to put up an article accurately described therein. The patient does not buy the prescription, but the compound called for by the order; consequently the prescription rightfully belongs to the druggist, who retains it as a receipt that the order was correctly filled.

Typhoid Fever.—While the number of cases of typhoid fever in Philadelphia have fallen from 152 last week to 89 this week, the number of cases in Nanticoke, a town near Wilkesbarre, where an epidemic is now prevalent, has steadily increased; fourteen new cases were reported in one day, the average being ten daily; the total number is now 212. According to Dr. Dixon, the source of infection is removed. He stated that the water pipes have been cleaned, sulphate of copper has been put in the water, and in a few days the reservoir will be pumped out and cleaned. While an improvised hospital has been provided it is insufficient to accommodate the number of cases that have developed, so that hospitals in nearby towns have been asked to take as many patients as they can accommodate. The State Hospital at Hazleton, which is an hour and one-half by rail from Nanticoke, responded quickly; the other hospitals in the vicinity, especially in Wilkesbarre, also offered relief. Dr. Johnson, who has charge of the epidemic, found that in order to carry out the work funds were needed, and appealed to the citizens of the town for help; the appeal was not fruitless. In all, seven nurses from Philadelphia and Harrisburg have been sent to the town to care for the patients. The Director of Public Safety has ordered the police to locate all families who are using well water, in order that the water from all such sources may be tested bacteriologically. There are sixteen cases in Nanticoke.

CHICAGO.

Doctors Raise Visit Fee.—Because they need the money, is the simple and frank reason given by Evanston physicians for a rise in fees of one dollar a visit, which goes into effect this week. "Evanston is a more expensive place in which to live than Chicago, and for this reason prices for medical service should be at least as high in the suburb as in the city." For years Evanston physicians have been charging two dollars a visit, but they have recently organized a local medical society, and increased prices are the result. The society is also making an effort to secure physical examination of school children, and a plan for securing a lecture-room in the new library, in which popular talks on matters medical may be made, is also on foot.

Examinations for Positions on County Hospital Staff.—Examinations of candidates for places on the staff of the County Hospital will begin on September 28. Those who pass will be placed on the civil service eligible list, and will be assigned places on the staff when vacancies occur. Whenever a member of the present staff resigns or the place is made vacant it will be filled from the eligible staff. The life of the present staff cannot exceed six years, as it is fixed by the civil service act passed by the

State legislature, and no member of the present staff will be permitted to serve a second term. The examinations will be held by the County Civil Service Commission, but its chief details will be conducted by the examining board of reputable physicians and surgeons.

Staff of Vaccinators.—Dr. Heman Spalding, Chief Medical Inspector, reports that the appointment of a staff of vaccinators for the public schools was completed before the beginning of the school term. "Over two hundred vaccinators are equipped and ready to furnish free vaccination to all school children who apply on the school premises. Last year a few entered school upon false certificates of vaccination signed by doctors. Some of these contracted smallpox and a few died as the result of this criminal practice. One child permitted by the principal to enter school without any certificate of vaccination remained in school two weeks, contracted smallpox and died of that disease a week later. No vaccinated school child contracted the disease, though exposures to smallpox were numerous. The vaccine to be used by the public vaccinators is tested in the Department Laboratory, and is rejected if any impurities are found.

Laboratory Examinations.—During August, 1905, 488 physicians brought or sent to the Laboratory culture specimens, blood, sputum, etc., of patients suspected of diphtheria, tuberculosis, typhoid fever, etc., for examination. This is a daily average of more than twenty for the twenty-four working days of the month, and an increase of 41 per cent. over August, 1904. The practical value of this work to the health and life of the citizen may be inferred from the facts concerning typhoid fever. Out of 379 examinations made in the Laboratory of suspected typhoid fever, 111, or less than one-third, proved to be true typhoid, and the diagnosis was thus cleared up for the attending physician who modified his treatment accordingly. In 13 of the cases which showed the clinical or bedside symptoms of typhoid, and were being treated for typhoid, the Laboratory examination showed the disease to be intestinal influenza—the treatment of which is wholly different from that for typhoid fever.

An Ounce of Prevention.—The statement of the inadequacy of meat inspection in Chicago made by Health Commissioner Whalen merits serious attention. That constant and thorough inspection is the price of health is one thing modern municipal administration should have learned by this time. The city of Chicago may be poverty-stricken, but it cannot afford to neglect every reasonable precaution against such calamities as that which to-day is teaching New Orleans a tragic lesson. Dr. Whalen calls especial attention to the grave insufficiency of meat inspection. Where meat is distributed over the immense area of Chicago by hundreds of obscure retail dealers, it is impossible for a few inspectors to prevent the sale of meat which has become unwholesome after its inspection at the yards. Six inspectors are at work where forty are needed, and as a result hundreds of families are innocently imperiled by unwholesome meat. The matter is made worse by the fact that these victims are generally least able to protect themselves and to discover and combat disease. The staff of sanitary inspectors should be increased, says Dr. Whalen, at the same time, and there is little doubt that Chicago could not expend money more usefully than in the development of an efficient, well-equipped and non-political body of inspectors, and a scientific and comprehensive system of food and sanitary inspection. The present equipment is plainly insufficient. The city is healthy, but it is so in spite of rather than because of the adequacy of the sanitary machinery. What is being done is being well done, but the provisions made for the health department should be greatly enlarged.

CANADA.

Toronto General Hospital.—The trustees of the Toronto General Hospital will soon take decisive action on the question of a new hospital, but in the meantime they have wisely decided that the present building shall be as far as possible equipped in every respect equal to the best hospitals in other great cities. Some time ago the plumbing was all overhauled and replaced, and many other improvements carried out, and within the past few weeks through the generosity of a few wealthy citizens valuable appliances have been provided. The wisdom of renovating the present building and improving its equipment is obvious when it is borne in mind that probably three or four years must elapse before the new hospital can be ready for use, and it would be unfair to the staff, as well as cruel to the patients to refrain from making all needed improvements on the plea of waiting for the new building. The Toronto General Hospital will now be splendidly equipped, and can, as it always did, give to its patients the benefits of the very latest discoveries and inventions for the healing of the sick. When the time comes, as it must at an early date, for the trustees to take action regarding the erection of the new building, the present board of trustees who have no preconceived plan to propose, will call in for consultation and advice representatives of the Provincial Government, the City Council, the University of Toronto, and private donors to the hospital funds, and these representatives, all desirous of having the very best of hospital buildings for this city, will probably call into existence a new hospital trustee board, in whom will be vested the property and the government of the greatly enlarged and improved institution. This new board will have grave and serious duties to perform, and will have to assume heavy financial responsibilities. No definite estimates of the actual cost of a site and building have as yet been made, but it will amount to a large sum, probably a million dollars, and even more, and there should be a fairly large endowment fund from the very first. Toward the necessary funds the present trustees offer to hand over all the property of the existing trust, valued at about $600,000, and producing nearly $25,000 annually. The Ontario Government has granted $250,000 and authorized the University of Toronto to grant from its funds $50,000 additional, the latter amount to go toward the purchase of a site. The city of Toronto has granted $200,000, all of which must go toward the purchase of a site. Mr. Cawthra Mulock, one of the trustees, has given $100,000, and there is said to be in sight another $100,000. It will be obvious, therefore, that if the present endowment of $25,000 per year be retained as an endowment for the new hospital there will be a large amount to be raised otherwise. The citizens of Toronto will without doubt respond to any appeal for funds as soon as the proper authorities are ready to ask for donations. There are three or four suggestions as to what will be done with the present

buildings once the new hospital is ready for occupation. The most feasible one is that a small hospital be retained on the present site for the accommodation of the eastern portion of the city.

GENERAL.

Purdue University.—On September 1, by the unanimous action of their respective boards of trustees, assembled in Indianapolis, the Medical College of Indiana was made the Medical Department of Purdue University, with the title of Indiana Medical College, The School of Medicine of Purdue University.

New Hospital for Jersey City.—Ground for Jersey City's new city hospital, which will be built on the site of the present ramshackle structure, was recently broken by Mayor Mark M. Fagan. The Mayor used the spade with which he upturned earth for the free public bath, the People's Palace and the new high school building.

American Doctors at Hamburg.—Drs. Allan and McLaughlin, experts of the American Shipping and Immigration Society, have arrived at Hamburg from Naples to study the cholera and inspect the ships. They praise the city's sanitary arrangements and express regret that exaggerated accounts of the danger have been sent to America.

Mexican Health Officer Coming.—A Mexican cable despatch to the *Herald* says that Dr. Eduardo Liceaga, president of the Superior Board of Health of Mexico, with a party of twenty-three, passed through El Paso, Texas, on September 18, for Boston, to attend the session of the American Health Association, to be held on September 25.

A Healthy Town.—The Board of Health of Montclair, N. J., has issued a statement concerning the healthfulness of the town, especially with reference to the absence of communicable diseases. It shows that for the six months ending September 1 there have been but five cases of typhoid fever. This record of about three cases in every 10,000 of the population is remarkable. No communicable disease of any kind has been reported since August 24.

Typhoid Epidemic in Springfield.—Dr. G. B. Magrath, of Boston, an assistant of the State Board of Health and an expert pathologist, is now practically in charge of the typhoid fever situation in Springfield, Mass., which has now reached the epidemic stage. While the Board of Health made no direct request of the State Board to look into the matter, the assistance thus derived will be very welcome, and hearty cooperation is being given, not only by the Board of Health, but by the water department and the milk inspector.

A New Mosquito Killer.—It has been announced by Dr. J. H. White, United States Marine Hospital Surgeon-in-charge in New Orleans, that the new mosquito exterminator known as "Culicide," discovered by Dr. Mims, chemist for the city Board of Health, will be adopted by the Government. Dr. White announced that the disinfectant is composed of equal parts of carbolic acid and gum camphor. He has advised strongly against amateur use of the composition owing to its explosive character. None but skilled employees of the United States Marine Hospital Service will be permitted to use it.

Starts a Parasite Exchange.—Dr. L. O. Howard, who was sent to Europe in June by the Massachusetts entomological officers for the purpose of collecting and shipping to this country parasites for the suppression of the gypsy and brown-tail moths, has returned to Boston. He announced that he had made an agreement with European officers whereby they will ship to this country the insects needed for the moth warfare, in return for American parasites needed abroad. Dr. Howard said that the parasites he had secured merely would keep the moth pest in check, and that property owners should not in any way relax watchfulness over their trees.

Wholesale Vaccination in Newark.—All principals, teachers, janitors and pupils of the Newark public schools, numbering over 40,000, will be required within the next week or two to undergo a medical examination, so that it may be determined how many of them have not received a successful vaccination in the last five years. Those who have not will be vaccinated. The plans for this examination will be made at a meeting this week of special committees of the Board of Education and the Board of Health. It was accidentally discovered last week that at least 10 per cent. of the school children had not been successfully vaccinated within five years, notwithstanding the fact that nearly all of them held doctors' certificates which said they had been. It has always been known by the authorities that some of the pupils obtained fake certificates, but it was not imagined that the number was nearly so large.

The Harvey Society Lectures.—The first lecture of the recently organized Harvey Society will be given by Professor Hans Meyer, the distinguished pharmacologist of the University of Vienna. Professor Meyer will speak in German upon the subject "Die Theorie der Narcose." The lecture will be held on Saturday, October 7, at half past eight o'clock in the evening, in the New York Academy of Medicine. The second lecture will be given on October 14 at the same hour and place, by Professor Carl von Noorden, of Frankfort-a.-M., the well-known authority on diabetes. The title of Professor von Noorden's lecture is "Modern Problems of Metabolism." The lecture will be delivered in English. Other lectures of the course will be given by Profs. L. F. Barker, Howell, Lee, Levene, Mendel, Minot, T. H. Morgan, Novy, Park, Theobald Smith and J. C. Webster. It is hoped that the Harvey Society may be of use in furthering the wider diffusion of knowledge of the medical sciences. The Harvey Society cordially invites those interested to attend these lectures.

Getting at the Lazy Worm.—That the people of Porto Rico have become enthusiastic in their desire to rid themselves of the scourge of anemia, popularly designated the "lazy worm" affliction, is indicated in a report just received by the Surgeon General of the Army from Capt. B. K. Ashford, who is expending $15,000 this year in a campaign against that malady. During the months of June, July and August nearly 10,000 patients had been treated, with cures in nearly every instance. In August, at the medical station at Abonito, exactly one-third of the population was treated. This number was 2,482. Of these six died, 716 were discharged as fully cured, while the majority of the remainder are on the road to recovery. The effect of the disease is to render the victim anemic and absolutely unfit for work. The disease gradually wastes away the tissues, during which time the afflicted become a public charge on the community. The natives believed this wasting away was from lack of food and ridiculed the idea that a cure could be effected through the use of medicine.

A Neglected Epidemic.—Two hundred and sixty-one cases reported to the Board of Health, with victims ranging in age from nine months to forty-three years, and a total of thirty-three deaths, is diphtheria's record in Southbridge, Mass., since it began ravaging a year ago, or, to be precise, a year, a month and two weeks

ago. And even after this long siege of the disease, which has appeared in substantially every locality in Southbridge, it still continues, and the Board of Health now has eight new cases on its hands. The Southbridge Board of Health has issued orders and instructions enough to stamp out a plague, but the orders have not been enforced, and the epidemic continues. In a large number of cases parents have recklessly failed to adhere to the advice given them by the Board of Health to keep children in afflicted families indoors, but have freely allowed children to mingle here, there and everywhere in localities containing the disease. This point is the keynote to the situation. A rigid and effectual quarantine has never been maintained, in the face of one of the most dreadful epidemics of the disease in the history of the State.

Robs Marine Hospital Fund.—James W. Boyd, a clerk in the Marine Hospital Service, was arrested September 18 on a warrant sworn out by Chief Clerk W. P. Worcester of that office, charging him with embezzlement. He was held in $10,000 bail for examination. The amount of loss, according to Boyd's confession, is not less than $20,000. It was Boyd's duty to prepare bills for the approval of the Surgeon General, and when checks were signed they were delivered to him to be mailed. It is charged that he manipulated the bills by erasing dates and amounts of duplicates left in the office, and that he got the money on the checks by indorsing the name of the firms to which they were issued. It is alleged that the work has been going on for three years, but Boyd was not suspected until a recent illness last Thursday compelled him to be absent. When his desk was opened a number of suspicious documents were found. Property belonging to Boyd, valued at about $8,000, has been seized. He had been in the public health service for twelve years, appointed from Westchester County, N. Y., and was drawing a salary of $1,800 a year. His fondness for automobiling had attracted attention to him about town.

President Roosevelt Opens the Diamond Jubilee.—On Saturday, September 16, President Roosevelt touched the electric button that opened the diamond jubilee, given in aid of the yellow-fever fund in New Orleans. The city was a mass of flags and bunting as if prepared for a carnival. The President sent a telegram to Mayor Behrman, expressing congratulations and sympathy, and in the correspondence that followed made clear his intention of visiting New Orleans in October, if the people of that city wish it, "subject only to the feeling of other States on the quarantine matter." This message created a profound sentiment of appreciation in the city, and at a meeting of the citizens' committee an answer was sent by Mayor Behrman reiterating the invitation and advising that Dr. J. H. White, United States Marine Hospital surgeon in charge, had authorized the statement that absolutely no danger need be apprehended, and there is no reason on that account for canceling or postponing the visit. The only obstacle in the way is the rigid quarantine of Arkansas, which is included in the President's itinerary after leaving New Orleans. Communication has been opened with Gov. Davis and the President of the Arkansas Board of Health, and favorable action is expected.

To Deal With Morally Insane.—Prof. Liszt, of Berlin, in a paper on "moral insanity," which was read at the Congress of Criminologists, submitted that special measures must be carried out to render morally insane persons, whether criminals or not, harmless to society. Secondly, the professor insisted that morally insane persons must be punished with less severity than others. Prof. Thorp, of Copenhagen, opposed the second proposition. He said it was customary in Denmark to punish the morally insane less severely than ordinary criminals, but the system provoked general discontent. It was only suitable for those who were irresponsible from external causes, such as drunkenness. Experience showed that persons who were morally insane were not susceptible to improvement by punishment, and always relapsed into crime. They should not be punished, but should be dealt with by special treatment. Dr. Kielhorn, representing the schools of Hamburg, said the percentage of morally insane children was far greater than was generally believed. Over 1,000 were taught in nine Hamburg schools. Two per cent. were confirmed criminals, whose rescue was hopeless, but the remainder could be reformed by suitable treatment. Punishment by imprisonment or detention did more harm than good. After a long debate, in which many speakers denounced Prof. Liszt's propositions as unworthy compromises, both were adopted by a large majority.

Fever Fighters Encouraged.—Though hope that the fever in New Orleans would be eradicated by the first of October was some time ago abandoned, many persons feel that if the threats of the authorities have their effect and suppression is no longer practised, the fight will be virtually at an end fifteen days later than the day set. The situation indicates some improvement, notwithstanding the warm, wet weather. In several centers of the city where the fever heretofore prevailed it has disappeared and nests of infection are scarce. Two positive cases have been reported from Kentwood, a lumber town in Tangipahoa parish, not far from the Mississippi line. These are the first cases in that vicinity. From Tallulah and Lake Providence come reports of improvement in the situation, the absence of deaths being encouraging. At Lake Providence the situation is somewhat complicated by the number of walking cases that are discovered among the negroes. They spread the fever before they are discovered and isolated. For the purpose of reassuring communities in the South dealing with New Orleans, Dr. White authorized the statement that all cars loaded with freight will be sealed and fumigated by the United States Marine Hospital Service and so certified. This announcement is expected to cause a general raising of freight quarantines. Dr. Rosenau, bacteriologist of the Marine Hospital Service, has forwarded a jar of four hundred specimens of the stegomyia which he has gathered, to Surgeon-General Wyman, for study in the Government laboratory. Dr. Rosenau says that while some proof is needed it is not improbable that the local bacteriologists who have been at work in this field have discovered the germ of yellow fever.

Some Medicines Are Liquors.—Under a decision recently rendered by the Commissioner of Internal Revenue every druggist who after December 1 of this year may sell certain so-called patent medicines having whisky or other distilled spirits as the chief ingredient will be obliged to pay a special tax to the Government as a liquor dealer. The manufacturers of these medicines will be required to pay the special tax imposed upon rectifiers and liquor dealers. Commissioner Yerkes, who promulgated the decision after conference with Secretary of the Treasury Shaw, is convinced that several so-called medicines widely advertised and extensively sold are really not medicinal in their character beyond the inherent medicinal quality which may be possessed by the alcohol or other distilled spirits which forms their chief ingredient. In his order imposing the special liquor tax on dealers handling those so-

called medicines Commissioner Yerkes said: "The fact that these compounds during the existence of the statute imposing a tax on proprietary medicines were, without the necessity of investigation into their medicinal character, by the terms of the law made subject to that tax because they were held out to the public as medicines, does not afford ground for relieving the manufacturers from special tax as liquor dealers under the provisions of section 3244, revised statutes and amendments. It is held that the statute requires the exaction of this special tax from the manufacturer of every compound composed of distilled spirits, even though drugs are declared to have been added thereto, when their presence is not discoverable by chemical analysis, or it is found that the quantity of drugs in the preparation is so small as to have no appreciable effect on the alcoholic liquor of which the compound is mainly or largely composed. The same ruling applies to every alcoholic compound labeled as a remedy for disease and contagion containing, in addition to distilled spirits, only substances or ingredients which, however large their quantity, are not of a character to impart any medicinal quality to the compound. The Department has heretofore accepted the sworn statements of the manufacturers as to the ingredients. Hereafter this will be determined, not by the declaration of the manufacturers, but by the Government chemists, who will go into the open market and buy proprietary articles under suspicion. To-day the Department refuses to make known the ones which it believes will be subject to this tax on December 1, but by that time a list will be prepared, so that the country grocer who keeps a shelf of general family medicine, will be able to learn those which he can carry only by becoming a liquor dealer within the meaning of the Federal law.

OBITUARY.

Dr. LEWIS E. HANMORE died in Newburgh, N. Y., September 19, from consumption. He was a graduate of the College of Physicians and Surgeons, New York, with the class of 1884, and a member of various medical societies in Europe and America.

Dr. ROBERT ORMISTON, a physician of Brooklyn, N. Y., died September 19, at Stamford, N. Y. He was born at Rossie, St. Lawrence County, N. Y., seventy-three years ago, and was graduated from the University of Pennsylvania in 1858. He served in the Civil War as a surgeon with the Thirteenth New York Infantry. For thirty years he was head surgeon of the Brooklyn Hospital.

Dr. THOMAS JOHN BARNARDO, the founder and director of philanthropic institutions by which many thousand orphan waifs have been rescued, trained, and placed out in life, died September 19. Dr. Barnardo had suffered from angina pectoris for some years. He was born in Ireland in 1845. Early in life he was made a Fellow of the Royal College of Surgeons. In 1885 he received a medal from the French Société Nationale d'Encouragement du Bien. He wrote many pamphlets and founded various magazines explanatory of his work. Perhaps the best known of his publications is "Something Attempted, Something Done."

CORRESPONDENCE.

THE FIGHT FOR THE RIGHT.

To the Editor of the MEDICAL NEWS:

DEAR SIR: How to combat successfully the immense evil of quackery and secret, or even proprietary, medicines with published formulæ, is and has been a great and unsolved problem to all conscientious medical practitioners. After much thought and experience I know of only one practical way, as I believe.

Patients should not read or become familiar with their prescriptions. The nearest relative or friend should be told during the period of treatment and later, when the patient is well or no longer under professional advice, he may at times, as frequently be told, if he desires to know, what means *precisely* have been used to produce the desired result. But to permit any patient, and especially the one suffering from a chronic disease, to reason morbidly and imperfectly about what is being done for him is always prejudicial in greater or less degree to his present ultimate well-being. A physician *is* either skilful, reliable, absolutely square, or he *is not*, and no power on earth will change the one or the other. As a rule of action let the patient in advance, therefore, get all possible information in regard to his medical adviser before he places himself in his care. But once he has selected him for good and sufficient reasons let him trust him and rely upon him unreservedly. When this is generally done we shall then see the downfall of quackery, charlatanism, fraud, ignorance—no matter how thinly or thickly coated. But until that state of mind is reached by the public generally I for one am of the opinion that all our worthy efforts in other and different directions will remain necessarily only partially successful. These lines, Mr. Editor, are prompted by your editorial entitled "A New Hope in the Battle with Quackery" (MEDICAL NEWS, Sept. 2, 1905, p. 457). BEVERLY ROBINSON.

New York, Sept. 6, 1905.

EVIDENCE AGAINST ILLEGAL PRACTITIONERS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I have read with considerable interest the comment under the heading "Echos and News—General," on page 418 of your issue of August 26, and while I am informed there has not been for several months any prosecution actively carried on by the County Association and none by the State Association, yet the subject to which you refer is interesting, and in taking this matter up arrogate to myself the title of "Legal Luminary," referred to in the article.

For over five years I have conducted in the County of New York the prosecution of illegal practitioners of medicine in various branches, and in but one instance has there ever evidence been secured or attempted to be secured against a regular practising physician for the crime of abortion. In that instance I made use of an especially employed prostitute in preference to a legally married woman, for the reason that I considered the act itself degrading, and felt that no married woman ought to be asked to subject herself to any possible indignity, especially when she was actually child-bearing.

I consider this class of work undignified not only to the profession of law, but also undignified to the profession of medicine, and as wholly without the province of medical organizations, and while the crime in this one instance was not to be actually consummated, but only the attempt was to be charged, yet I felt and still feel a sense of abhorrence even to securing evidence against a member of the medical profession, a profession than which there is none more dignified, honorable and far-reaching in its influences and offices. However, in the direction of securing evidence against medical mountebanks, charlatans and what are ordinarily called quacks, the same ethical principle may be involved, and in that direction I differ absolutely with the sentiment expressed by the distinguished jurist in so far as it refers to the securing of evidence against this class of law-breakers.

The conditions which exist in the small cities of the State of Indiana are so divers and insignificant when compared with those in a great metropolis, that it is perhaps unfair to refer to the remarks of Judge Buckingham as applying to conditions here. Of course, the statement of the number of medical mountebanks in the County of New York as being twenty thousand is absurdly exaggerated; yet, with the laws as they exist at present, there is no evidence of a decrease in the number in the past five or six years. That is due in my judgment, to the inadequacy of our statutes in dealing with perhaps the most dangerous class in its effect directly upon the public health and their facilities for advertising their wares. The crime of illegal practice of medicine is a misdemeanor in the State of New York and is punishable by a fine or term of imprisonment, or both, limited only to a maximum in its degree of punishment, and leaving the minimum wholly within the discretion of our courts.

The investigation of complaints against this class of medical law-breakers has been conducted under my personal supervision by men and women of good morals and who have come recommended to me highly as to their integrity in every particular. To be sure, there are unpleasant features develop many times in the conduct of their investigations and discussions necessarily incident thereto, which would not be expected to be a topic of conversation for the drawing-room; yet, I have never continued a single individual in my employ, either man or woman, who I have not felt sure were only allowing such discussions as are ordinarily carried on in a reputable physician's office, and all of such employees have been instructed under no conditions to endanger their health or to permit any improper acts to be committed, nor to subject themselves to indignities under any conditions.

During this period I have caused to be investigated upward of eight hundred complaints. Still, I must confess that the results of the work are not satisfactory, though the criticism to be inferred from the opinion of the distinguished jurist cannot be accepted nor allowed to go unchallenged. The fact that in our State the Association making the charge and securing the conviction receives the fines imposed, is unsatisfactory in its results, though it seems almost impossible that these great organizations could carry on this work on account of its enormous expense, without the assistance which these fines afford.

The conduct of these prosecutions must be continued by medical organizations and with paid men and women acting as detectives to secure the evidence; the police department of our cities is wholly inadequate, but the law must be amended making the crime of the illegal practice of medicine a more serious one in the eye of the law before these charlatans can be brought to realize the enormity of their offenses. Public opinion must demand of such of our daily newspapers as publish the advertisements of these mountebanks that they are no longer to expect the aid of the reputable press, and with co-operation in this direction, together with a revision of the law, is the hope of stemming the tide of increasing violations of the medical law. Respectfully.

James Taylor Lewis,
Counsel, The New York State Medical Ass'n.
New York, Sept. 19, 1905.

Cholera.—Six new cases and one death were reported in Prussia as the record for the twenty-four hours ending at noon September 20.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighteenth Annual Meeting, held Sept. 19, 20, and 21, 1905.

The President, Howard W. Longyear, M.D., of Detroit, Mich., in the Chair.

The Association met in College Hall of Hotel Astor, New York City, and after an address of welcome by Dr. Geo. B. Fowler, of New York, which was responded to by Dr. Charles A. L. Reed, of Cincinnati, proceeded with the reading of papers.

Multiple Pregnancy Complicated by Double Pyosalpinx.—Dr. O. H. Elbrecht, of St. Louis, Mo., read a paper with this title and reported an interesting case in detail. The most striking feature of this case was the obscurity of this fortunately rare complication, for without the autopsy he would certainly have abided by his first and only ante-mortem diagnosis, *i.e.*, sapremia, and would have continued to believe that the general peritonitis was the result of the sapremic infection traveling upward through the tubes and thus into the abdominal cavity, for such a process to his mind would be all the more plausible in the large and flabby uterus of multiple pregnancy, more especially from the fact that large blood clots were passed on the first day, showing the relatively imperfect contraction of the uterus. The case also shows very plainly the ability or the degree of tolerance of the pelvic peritoneum to cope with infections, as it is his opinion that the peritonitis was not general until the sixth day, for up to that time there was no hiccoughing, no vomiting, no abdominal distention and no apparent weakness. Another deduction is that gonorrheal peritonitis, while not very dangerous, if confined to the pelvic peritoneum, is surely dangerous when it creeps out of the pelvis and becomes diffuse. It is also his firm belief that the pyosalpinx in this case was unilateral at the time of impregnation, and that the infection was transmitted by the escape of virulent pus to the open fimbriæ of the unaffected side. The only cases he could find analogous to his have been reported by Hare and Talley. The reports of two pathologists in the speaker's case, who worked independently of each other, both showed that the tube, which was secondarily infected, was infected by way of the fimbriæ, as its pathology was confined entirely to its outer third; the middle third showed only slight inflammatory changes, and the inner third, including the uterine attachment, was normal.

Blank projects the theory that virulent bacteria in the tube have a tendency to become pyosalpinx during pregnancy by reason of the hyperemia. He further states that 50 per cent. of those cases in which the tubes are adherent in the cul-de-sac rupture as pregnancy advances, from tension, pressure, or from stretching of the adhesions, which forces pus out of their fimbriated extremity. The experience of the essayist with three cases of this class substantiates Blank's theory. These three cases were reported.

Dr. Charles A. L. Reed, of Cincinnati, Ohio, in the discussion, said that this case, with the pus tube undetectable, only adds one possible condition that points to the reason why possibly these cases should be subjected to operation earlier and more radically than they have been heretofore. With a double pus tube, with antecedent conception, it follows that the deduction of the essayist, that the infection of the tube was unilateral prior to impregnation was absolutely incontrovertible. As to infection on the other side, the probabil-

ity is that it resulted from a progressive invasion of tissue, the mucous structure serving as a nidus of infection occurring within the uterus following delivery.

Dr. Herman E. Hayd, of Buffalo, N. Y., is inclined to believe that we see many cases of pyosalpinx complicating delivery that are due to a latent gonorrhea existing in the tube, which springs into activity as a result of the trauma incident to labor.

Dr. Charles L. Bonifield, of Cincinnati, Ohio, believes many cases of double pyosalpinx clear up sufficiently to allow the patients to become pregnant. In years gone by he told patients they would never become pregnant when he detected a mass on each side, and there were further evidences of pyosalpinx, and on a few occasions he has been deceived after six, eight or twelve years, the pus having become absorbed and the women having become pregnant. He cited a case he had many years ago of double pyosalpinx, or he thought it was such. The woman refused operation. Everything in the pelvis was matted together. She gradually got better, and at the end of six or eight years became pregnant, and he delivered her. She passed through labor nicely, but at the end of a week she suddenly raised herself in bed and dropped over dead.

Dr. Rufus B. Hall, of Cincinnati, Ohio, does not believe that a woman with double pus tubes can afterward become pregnant. If such a woman should become pregnant he would be inclined to doubt the diagnosis of bilateral pyosalpinx.

Dr. John Young Brown, of St. Louis, Mo., thinks the mere existence of pregnancy in the case narrated by the essayist precludes the possibility of the woman having had bilateral pyosalpinx. The pathology, as revealed by the autopsy, shows conclusively that the case was one of unilateral pyosalpinx, which was dormant and lighted up by the trauma of labor, and that the leakage from the pus tube produced the diffuse peritonitis, and the condition found on the other side was due to bathing this side with the pus that was produced by the peritonitis.

Dr. Lewis S. McMurtry, of Louisville, Ky., said abdominal section in a puerperal convalescent is a very serious procedure. The operation of vaginal incision and drainage, so enthusiastically advocated by Pryor, would accomplish very little in a case like the one reported from the standpoint of therapeutics; hence in the case reported, we have a very valuable addition to the scanty literature of the subject as to the possibility of pathology of the tubes connected with puerperal disease and a valuable guide to operative interference.

Some Considerations on the After-Management of Abdominal Sections.—Dr. Walter B. Chase, of Brooklyn, N. Y., said, in reviewing his personal experience, he is led to the conclusion that the principal and by far the most frequent condition after laparotomy requiring treatment is flatulence. The accumulation of gas in the intestinal tract is present to a greater or less extent in a majority of cases. The principal causes are reversed peristalsis, intestinal paresis, and the effect of the anesthetic itself. He seldom gives anodynes, except in conditions of pain, making a possible exception in cases when peritonitis was present prior to the operation, or other structures involved in the operation were so friable that peristalsis should be prevented for a time, or in cases following intestinal anastomosis. Its administration for the relief of pain is admissible and perhaps mandatory. It is a matter of much moment what anodyne is selected. Ordinarily he uses codeine hypodermatically in doses of gr. ¼ to ½, or more, if required. While its power to relieve pain and check peristalsis is much inferior to that of morphine, its lesser disturbance of the nervous system, checking of secretion, and tendency to undue constipation makes it an agent of great value. It is imperative that a reliable preparation be used. In troublesome cases of continued nausea the administration of small doses of cocaine, gr. 1-10 to 1-12, exercises a salutary sedative influence on the nerves supplying the stomach, and is attended with happy results. Either the nausea or flatulence, or both, may disappear in a few hours after operation. Among the newer remedies for the relief of intestinal paresis is the alkaloid of the calabar bean. Salicylate of physostigmine, given in doses of gr. 1-100 to 1-50, or even more, hypodermatically, repeated once in four hours, seems to induce a powerful contraction of the circular fiber of the intestinal tract. The diet of patients after abdominal section calls for the greatest circumspection, always following the rule that nourishment, taken per orem, before the stomach retains or digests it, is positively harmful. When shock is profound, minute doses of morphine sulphate are among the most powerful stimulants, and superior to most for prompt and sustained effect. The author discussed at length the importance of bodily temperature and position of patient after laparotomy.

Some General Principles in Conservative Pelvic Surgery.—Dr. John F. W. Whitbeck, of Rochester, N. Y., said it is decidedly advantageous to have a general knowledge and a general experience before making use of special methods in the treatment of pelvic disorders. Medical and mechanical means should be tried in suitable cases before resorting to surgical intervention. Only diseased organs should be removed. Sound organs and normal parts of healthy organs should be preserved. Conservative plastic surgery should be employed to save such organs as can be made functional, or to serve some useful purpose. Diseased organs should be removed in the order of their pathological precedence and importance, with a view to benefit the patient by promoting her comfort and prolonging her life, even if a perfect cure is not to be expected.

Trivial Pathological Conditions of the Uterus and Adnexa Considered as Causes of Severe Gastric Disturbances.—Dr. Francis Reder, of St. Louis, Mo., said that during the last two years eight of these patients came under his observation, six of whom presented a train of symptoms that would ordinarily be grouped as those of hysteria or neurasthenia, moderately severe in character, the remaining two patients being free from any such pronounced neuropathic phenomena, and some in fairly good health, with the exception that their stomachs were weak. The pelvic organs upon examination gave evidence of disease, and although the examination did not reveal anything of a serious nature, yet local minor surgical procedures afforded relief. In the cases cited by the author, it was a surgical procedure that anticipated the pathological conditions. He said to wait for pathological conditions to give evidence of their existence by more pronounced local symptoms in gynecological disease, where there is a marked reflex neurosis, would be to invite secondary conditions that might prove of a very grave nature.

Dr. Rufus B. Hall thought the case reported by the essayist had pathological conditions sufficiently marked to justify operation regardless of their neurotic condition. To cure nervous patients it is sometimes necessary to remove overy obstacle in the way of perfect health physically. He is convinced that if many of these cases had not been operated upon, their condition would have become worse, a more grave pathology would have resulted later, and it would have been more trying for the patients, thus making the surgery more

difficult, and harder for the patients to recover from the operation.

Dr. X. O. Werder, of Pittsburg, is not enthusiastic about operating on neurotic patients, as the results are not usually good, and he feared the essayist would have some of the patients upon whom he had operated return in a few months with the same symptoms having recurred.

Prolapsis Uteri and Its Treatment.—Dr. Herman E. Hayd, of Buffalo, N. Y., briefly spoke of the various conditions which contributed to the production of prolapsus uteri and then immediately discussed its treatment by surgical means only, and according to the degree of the descensus and the necessity for the preservation of the uterus, the operative treatment was carried out. He believed that in minor degrees of prolapsus uteri with rectocele and cystocele, the Alexander operation with well directed plastic surgery of the vagina and perineum would cure these simple forms. When the prolapsus extended to the introitus, or the cervix pointed through the vulva, a vaginal hysterectomy, with a well-performed anterior and posterior colporrhaphy and a perineorrhaphy accomplished the best results; and the effect was permanent if the vault of the narrowed vagina was sewed firmly permanent to the cut edges of the broad ligament. When it was desirable to save the uterus for the purpose of child-bearing, or to continue the function of menstruation, the cervix must be amputated and an anterior and posterior colporrhaphy and perineorrhaphy must be performed, and the uterus firmly ventrofixed to the abdominal wall through a median abdominal incision. Usually all these operations could be performed at one sitting, but if it was desirable to make two operations, the posterior colporrhaphy and perineorrhaphy must be done at the second time, say three weeks after the first operations. The author, however, preferred the removal of the uterus, as this operation had been infinitely more successful in his hands. He also depreciated the performance of all operations which closed the vagina, as he believed this unnecessary and because he had seen much unhappiness result from this procedure. For the extreme cases of pelvic hernia, he was particularly pleased with a reprint sent him by Dr. Crile, in which he advocated a very elaborate and extensive operation. For one such case, which occurred in his own practice, he sewed the united vagina and broad ligaments to the abdominal wall, and the result was very satisfactory. However, such extreme measures were seldom called for, as most cases could be cured by the other operations described. Dr. Hayd then detailed his operation upon the posterior vaginal wall and perineum, in which he cut out a large triangular piece of the posterior central part of the vagina, and then with the finger in the rectum as a guide to make tense the obturator fascia and levator ani muscle, he sewed these opposing structures in perfect apposition, with fine chromic gut, which layer of sutures was buried by bringing together the vaginal mucous membrane by another layer of sutures, and finally the skin was brought together by silkworm gut. This operation lessened the size of the vagina and lengthened it by producing an oblique canal instead of a horizontal one, and by carefully approximating the fascia and levator ani, the *sine qua non* of all perineal operations, the result remained fixed and permanent.

Surgery of the Liver.—Dr. William J. Gillette, of Toledo, Ohio, read a paper on the subject in which after discussing the control of hemorrhage, the power of the liver to regenerate itself, infection and cholemia, he described a means of controlling liver hemorrhage in certain cases of severe bleeding when the blood vessels cannot be easily reached. It sometimes happens that to tie them requires a further enlargement of the lacerated liver substance. This of itself increases the gravity of the patient's condition. Three years ago he was called in haste to see a young girl of fourteen years, who had been shot by a target gun, the bullet entering between the eighth and ninth ribs, near the costal cartilage, and passing through the right lobe of the liver, lodging behind the stomach. The low velocity of the bullet had caused it to make a tear rather than a perforation. When first seen the child was nearly pulseless, and had all the evidences of a severe internal hemorrhage. Her face and lips were white and bloodless. The abdomen was opened. An incision was made close and parallel to the costal cartilages on the right side. The abdomen was found full of blood which could be seen freely oozing from the torn liver. He attempted to control this first with catgut ligatures, but the friability of the tissues prevented. Some time previously he had had an experience with a similar wound of the liver made by a bullet, and had attempted to control the hemorrhage by packing with gauze; but the patient, a strong, robust man, had promptly died from the continued loss of blood. Post-mortem revealed that the gauze packing had been entirely inadequate to control it. Having this case in mind, he did not feel like trusting to gauze again, and inasmuch as it was not controlled by direct ligation, it occurred to him that by passing sutures from within, entirely through the liver substance and through the abdominal wall, making exit between the ribs after the manner of a staple, and tied firmly on the cutaneous surface, that permanent and constant pressure could be made, sufficient to control the hemorrhage without the ligature cutting into the friable liver tissue. Five or six such sutures were now introduced on the proximal side of the wound, each one embracing about three-quarters of an inch of the liver substance. Care was taken to link them together so as to include all the bleeding tissues in their bite. The ligatures emerged between the ribs the same distance apart as they were entered on the liver substance, and when firmly tied all the hemorrhage and oozing ceased at once. Other injuries to the viscera, which were slight, were repaired, a drainage tube inserted, and the abdomen closed. The patient made an uninterrupted recovery. He has since used this suture in two instances, in one of which in removing a very adherent gall-bladder he met with a severe hemorrhage, which was readily controlled with it. Recovery was prompt. The third case was one in which a hydatid cyst, the size of a small cocoanut, was removed, together with a large number of gall-stones from a suppurating gall-bladder. This patient unfortunately died from peritonitis a few days later, but the hemostasis was perfect. The author referred at length to the more recent contributions to liver surgery.

Papillary Cyst Adenoma of the Breast.—Dr. Edward J. Ill, of Newark, N. J., says that this disease is comparatively rare, but that he has seen eight cases in his practice. There is not very much literature about the disease. Its characteristic symptoms are a clear yellowish-pink to dark bloody discharge from the nipple. On palpating the breast a small tumor can be made out early in the disease, which may become multinodular later on. He has

observed cases for from a few weeks to eleven, twelve and twenty-one years. The pathological condition found is a papillary adenomatous mass projecting into the milk duct. It is non-malignant in character. The patient may get well without any interference. When the disease persists, he advises removal of the breast.

Dr. Miles F. Porter, of Fort Wayne, Ind., said that cystadenoma of the ovaries and other organs is prone to become malignant, and no one could tell whether the tumor is malignant or not until he has removed it. Some of these tumors are pronounced to be non-malignant by microscopists, but there is recurrence after operation. Others are pronounced malignant, but the disease does not return after operation.

Dr. Joseph Price, of Philadelphia, has never regretted the early removal of tumors of the breast for fear they might become malignant. He cited cases in point.

Dr. Gunther, in closing the discussion for Dr. Ill, said these patients are not aware they have a tumor. If they have a tumor it is very small. There is no involvement of the axillary glands, and they seek medical advice principally on account of the discharge mentioned from the nipple. The history and symptoms in these cases are sufficient to exclude malignancy.

The Byrne Operation and Its Application in the Radical Treatment of Cancer of the Cervix.—Dr. X. O. Werder, of Pittsburg, Pa., described the operative technic employed by Byrne, and said that Byrne places special stress on the importance of thorough and repeated cauterization of the wound surfaces and edges from which cancerous material has been removed, regarding it as the best safeguard against a recurrence of the disease. The most remarkable feature of the Byrne operation, when compared to all other operations undertaken through the vagina for the cure of cancer of the cervix, and one which seems to justify Byrne's conclusions, is the almost uniform absence of local recurrence. While employing the method described by Byrne in his first cases, he invariably followed it by the ablation of the remaining portion of the uterine body and appendages. Subsequently, however, he simplified the procedure very materially by dispensing with the preliminary amputation of the cervix in order. The principal features of the Byrne operation have been retained, namely, thorough and repeated cauterization of all wound surfaces and edges. The operation differs from the usual vaginal hysterectomy by the use of the cautery knife for detaching the cervix from its vaginal connections; the application of the electro-thermic clamps devised by Downes, and the final cauterization of the stump with the dome-shaped cautery. He described the technic as he employs it at the present time. Of the sixteen cases operated upon by him, only one died about four weeks after the operation, from uremia. She is supposed to have suffered from nephritis for ten years previously; the operation, he thinks, may have hastened, but not caused, her death.

(To be Continued.)

A Distinguished Japanese.—Dr. Suzuki, Surgeon-General of the Royal Japanese Navy, is at present a visitor to America. He attended as a special guest of honor the recent meeting of the American Association of Obstetricians and Gynecologists in New York.

THE AMERICAN THERAPEUTIC SOCIETY.

Sixth Annual Meeting, held May 4, 5 and 6, 1905.

Vice-President John V. Shoemaker, of Philadelphia, in the Chair.

The Therapeutic Art.—Dr. Oliver T. Osborne said therapeutics was a much-neglected science and one that deserves especial study and discussion in the medical schools. Without the final application of therapeutics, all scientific physiology, etiology and pathology of the world are of no value. Therapeutics, he said, arrests the etiology which produces the disease, helps physiology which is disturbed by the disease, and removes the pathology which is produced by the disease. To-day the educated physician rarely speaks of curing the disease; he prefers the term "manage," and leaves the term "cure" to quacks and nostrum venders. The management includes diet, hygiene, climatic water, electricity, if indicated, and the necessary drugs. He ventures the opinion that graduates in medicine even after a hospital training are less prepared in the bed-side management than in any other branch of medicine; for that reason each medical school should have a special chair of therapeutics, held by a clinical man, a specialist in internal medicine.

The Effects of Intravenous Injections of Ergot on the Mammalian Circulation.—Drs. Torald Sollmann and E. D. Brown, of Cleveland, O., prepared this paper. Owing to the absence of both Dr. Sollmann and Dr. Brown the paper was read by Dr. Morgan, of Washington, D. C. The principal results of their investigations show that the rise of blood pressure produced by ergot in dogs is insignificant or too short for any practical purpose; that its effects are cardiac rather than vasomotor. They do not believe that the drug is useful to modify the general circulation. It acts upon vascular areas and alters the distribution of the blood in individual organs. This, they say, might explain the efficiency which is claimed for the drug in certain obscure diseases. They made some 350 injections in 38 animals. The injections were first made into the muscles, but the results were poor, so that intravenous injections were then tried.

In opening the discussion of this paper Dr. F. P. Morgan, of Washington, D. C., stated that ergot was beneficial to produce contraction of the uterus and to check hemorrhage. In his opinion it should not be employed in labor cases until the child and the placenta are expelled. He maintained that if postpartum hemorrhage is well advanced ergot is inefficient. He finds ergot useful in menorrhagia and subinvolution of the uterus.

E. D. Fisher, of New York City, informed the members of the society that he has seen good results in some cases of tic douloureux follow the injection of ergot hydermatically.

Dr. C. T. Osborne said that he always injected the ergot into the deltoid, using the same muscle for each injection and applying a wet dressing after the introduction of the drug to prevent infection. He finds the drug of value in cases where the heart action is weak, and in such cases in which there is a tendency to edema of the meninges, or in delirium due to toxins. He believes ergot must have some effect upon the vessels of the nervous system for recurring headaches are benefited by its use. Dr. R. Reyburn, of Washington, D. C., finds ergot valuable in women suffering with headaches about the time of menopause. Dr. S. Solis Cohen, of Philadel-

phia, finds this drug beneficial in those individuals who believe they are suffering with a lesion of the heart, but merely have an intermittent pulse.

The Proper Sphere of Bromides in Epileptics.—This paper, by Dr. Frederick Peterson, of New York, was read by Dr. E. D. Fisher. Dr. Peterson announced that he is convinced that more epileptics are injured than are cured by the use of the bromides. He depicted some of the symptoms which, he said, are produced by this drug; he informed the society that the bromides produce some of the forms of insanity, especially melancholia. If it must be used small doses should be combined with antipyrin or some other similar drug. He is firmly convinced that outdoor exercise and a regulated diet are of great value, and maintains that ten per cent. of the cases sent to a farm or colony are cured.

In opening the discussion Dr. Fisher said he was not such an enthusiast in regard to the colony treatment, as he has seen epileptics go to those places and return without the slightest benefit. Although much attention should be paid to hygiene, yet he does not believe that the bromide treatment can be abolished, and he knows of no drug which can take its place. He has seen it used by a patient for twenty years without the slightest deleterious effect. He strongly inclines to the view that there is a pathological lesion in the brain in epilepsy because of the identity of the aura and the course in each recurring attack.

Dr. Cohen, of Philadelphia, stated that much of the depression which follows the use of potassium bromide is due to the potassium. Dr. O. T. Osborne, of Yale University, maintained that a better knowledge of the thyroid and of the parathyroid might throw some light upon the conditon of epilepsy; probably in this disease a symptom only is being treated. He does not believe large doses of the bromides are necessary and sodium chloride should be eliminated from the diet. Dr. A. J. Hall, of Washington, D. C., favored the use of the bromides. Dr. R. Reyburn believes the nitrogenous diet should be cut down as low as possible in epilepsy.

The Management of Chronic Parenchymatous and Chronic Interstitial Nephritis.—Dr. S. Solis Cohen, of Philadelphia, first outlined the types of this disease, the causes and the complications. In America he regards the "strenuous life" as an important cause of the disease. As the first item in the management he spoke of the hygiene, then of the diet, mentioning milk as a therapeutic element. The next food stuff after milk, that these patients may take, is eggs. In the chronic interstitial nephritis he finds meat necessary, but in the parenchymatous it should be avoided. Green vegetables, except those that produce much calcium oxalates, may be given. He mentioned clothing as very important. These individuals should have a moderate amount of exercise with rest, but if too feeble massage will act as a substitute. The amount of urea excreted must be watched, as this element is an index to the accumulation of that substance in the econmy which induces uremia. He finds two drugs of especial value to increase the amount of urea, viz., stromtium and aconite; of the two he prefers stromtium bromide. He finds aconite better than nitroglycerin, and although the strontium lactate will produce a greater excretion of the urea than the strontium bromide he prefers the latter because of some unknown action. He is not inclined to use the nitrites in chronic interstitial nephritis with hypertrophy of the heart, except in small doses. If the chloride of gold and sodium, in doses of 1-24 of a gr., are given in chronic interstitial nephritis for long periods of time, good results are obtained. Uranium nitrite will cause the albumin to disappear which persists in the urine of cases of diabetes mellitus after the sugar is no longer present.

In opening the discussion of this paper Dr. Judson Daland, of Philadelphia, referred to the frequency with which nephritis follows attacks of influenza, without giving rise to symptoms; he also referred to the forms of the parenchymatous nephritis which are clearly incident to intervening attacks of intestinal and hepatic intoxications. The rise in arterial pressure may be due to some toxine, the nature of which is still obscure, and to remove this substance from the economy he advises the use of hot baths which are so easily regulated. He has not seen the beneficial results from digitalin secured by Dr. Cohen.

Dr. T. E. Satterthwaite, of New York, stated that he has seen the amount of albumin in chronic interstitial nephritis reduced by the administration of nitroglycerin, and has found digitalin a useful diuretic. He explains the variation in the results obtained by different investigators by the idiosyncrasies to the drug. He referred to a series of investigations on dogs, in which variation in the results were obtained. Dr. Osborne is not favorably impressed with the use of digitalin.

Medical Treatment of Serous Effusions.—Dr. Thomas L. Coley, of Philadelphia, in discussing this subject, called attention to the importance of the study of osmotic disturbances and to the opinion of Loeb and others that this is of greater importance than the mechanical factors of blood pressure. He pointed ont the significance of the study of sodium chloride excretion and retention to the relation of the edemas as having a direct bearing on the dietetic treatment. He laid stress upon the value of sialogogues in selected cases and the dangers of diaphoresis in skin edemas; this process removes the watery portion of the edema, leaving the solid material in a more concentrated form and with consequent more toxic properties. The limitations and applicabilty of diuretics was discussed especially of calomel, caffeine, theobromine and digitalis.

Value of Physiological Salt Solution in Circulatory Failure.—Dr. H. C. Wood, Jr., of Philadelphia, said that from the results of his experiments he is convinced that by the introduction of from 750 cc. to four times the normal amount of blood in a normal animal the arterial pressure is not influenced. After bleeding these animals until the heart beat was now no longer perceptible the introduction of the salt solution causes the arterial pressure to rise, but it is transient only, for the animals soon die. He found that the escape of the fluids from the body through the kidneys is not nearly so rapid as is suspected, although the introduced fluid above the normal amount of blood in the vessels does not remain in these structures, but he believes it escapes into the tissue spaces where it remains until used, although he could not demonstrate subcutaneous edema during life; at autopsy he found edema of the peritoneum and mesentery and pulmonary edema. By the introduction of the physiological salt solution he could not reduce the hemoglobin below 50 per cent.; the hemoglobin of a dog which before the experiment was 115 per cent. was by section of the cord reduced to 100 per cent., then by the introduc-

tion of salt solution to 60 per cent.; some time after the experiment it was again examined when it was found to be 60 per cent., by the injection of a second lot of fluid the hemoglobin would not be reduced below 50 per cent. He finds that the temperature of the solution in the reservoir and where it enters the vein differs from 5° to 15° C., but he has demonstrated to his satisfaction that the difference in the temperature produces very little if any effects.

In opening the discussion upon this paper Dr. Robert T. Morris, of New York, informed the society that by the introduction of salt solution into the veins of a septic patient he expects to see the temperature drop and his patient improve. If the bleeding is slow in extrauterine pregnacy he does not use the salt solution, but if shock is present and the hemorrhage is rapid he gives the fluid before the operation, and if in any operation he anticipates much hemorrhage he prepares to introduce the salt during the operation.

Clinical Experiences with Certain Drugs in Heart Disease.—Dr. Thomas E. Satterthwaite, of New York, read this paper. During the course of the paper the author stated that adrenalin is the most powerful heart stimulant that is known. It increases the pressure immediately, and he has found that a single dose sometimes relieves palpitation at once. For heart failure he uses nitroglycerin, but if this drug produces throbbing in the temporal arteries he regards its use as dangerous, for it may give rise to apoplexy. He finds iodine a useful drug in arteriosclerosis of syphilis and of old age; it dissolves the hyperplastic tissue. He begins with a preparation containing ½ gr. of iodine and then gradually increases the dose to 2 grs. This drug may be given in acute simple endocarditis and even in acute malignant endocarditis. The edema and the dyspnea and pain due to heart disease of the aged are relieved by the administration of 1-200 gr. of arsenic. Strychnine is slowly absorbed and slowly eliminated and should not be given for a period longer than two weeks. Strophanthus, he says, accomplishes better results than digitalis; its action lasts for several days; it is not cumulative, but it is not so reliable as digitalis. Sparteine reduces the frequency of the pulse and increases the pressure, but it is not as valuable a diuretic as digitalis. He depends a good deal on camphor which is a diffusible stimulant, an antispasmodic and a sedative. He is convinced that moderate doses of digitalis may produce death, but if this drug be combined with the nitrites the danger is eliminated.

In opening the discussion on this paper Dr. Osborne declared that in heart disease the arterial system must be studied as much as the heart, if not more. He regards an alterative as a drug that in some way modifies the internal secretion. While speaking of the internal secretions he quoted the phrase, "We are as old as our arteries"; but added, "Our arteries are as old as our thyroids." Digitalis has been used too much, he said; strophanthus is better. Adrenalin should be administered with care, for, if pushed, depression, perhaps cardiac, sets in. He believes much of the digitalin on the market is really digitoxin. Wilcox, continuing the discussion, noted that the action of adrenalin was first upon the vessels which embarrasses the heart to a certain extent. Cactus is the only drug that acts upon the ganglion of the heart. Porter lauds benzoic acid and the caffeine salts as heart stimulants. Fowler believes in the combination of several drugs as a heart stimulant. H. C. Wood, Jr., informed the society that single doses of adrenalin has produced pulmonary edema and an excessive use of this drug gives rise to arteriosclerosis. Cohen suggested that the drug was not used long enough to produce the conditions referred to by Wood. Coley states that nitroglycerin should be given in small doses and often because of its transient effects. Shoemaker spoke of the misuse of strychnine and digitalis and of the efficiency of scoparius in dropsy.

Practical Medical Treatment.—Dr. John V. Shoemaker, of Philadelphia, spoke of the benficial results obtained from the galvanic current in the treatment of enlarged prostates and locomotor ataxia. It, of course, does not cure either condition, but the improvement is marked. He exhibited a case of xanthoma which has been benefited by blood tonics, and a case of alopecia areata treated with electricity and blood tonics.

Dr. E. B. Bronson, of New York, opened the discussion and stated that xanthoma is very frequently associated with diabetes mellitus. In the treatment of alopecia areata he uses sulphur, resorcin and naphthol.

The Recogniton and Treatment of Cholecystitis.—Dr. Robert T. Morris, of New York, maintains that the significance of the adhesions in the region of the gall bladder have been overlooked; they are produced as a result of the desquamation of the endothelial cells incident to the presence of the *Bacillus coli communis*, which, he said, escapes through the thin-walled gall bladder. Gastralgia and intestinal disturbances may be due to eye-strain, normal involution of the appendix, gall-bladder disease and adhesion in the pelvic organs. To differentiate these conditions he finds the following a very useful aid: If the gastric or intestinal distress is due to pelvic adhesions the ganglion on each side of the umbilicus is tender; if due to involution of the appendix the ganglion on the right side alone is tender, and if due to eye-strain neither is tender. In cholecystitis the temperature ranges from 99.5° to 98° F.; this variation in temperature is due to the adhesion dragging on the sympathetic ganglion. To prevent adhesions he uses powdered aristol or Cargile membrane.

Dr. John B. Deaver opened the discussion and said that in his opinion medical men should not attempt to cure gall-stones, and he does not see any beneficial results from the treatment at Carlsbad.

Dr. Carl Beck took an opposite view, and said the medical treatment should be tried first, and he does not believe that the gall-bladder should be removed in all cases of gall-bladder disease.

The Treatment of Intestinal Indigestion.—Dr. George B. Fowler, of New York, attributes the cause of indigestion both to the quality and to the quantity of the food. He mantains that there is no difference in the digestive quality of stale and fresh bread, and that rice and hominy do not tend to provoke fermentation. He does not allow his patients rich soups, steak, pork, chicken or turkey from storage houses, white potatoes (fried), sweet wine, cooked oysters, cheese, kidney, liver and cooked tomatoes. Intestinal indigestion is rarely present alone; therefore he always examines the mouth, nasopharnyx and the stomach. If the intestinal disturbance is due to alterations in the nervous system he prescribes the triple valerian or cannabis indica. He also spoke of the value of hydrotherapy in this disease.

Treatment of Chronic Diarrhea.—Reynold Webb Wilcox, of New York, said if the diarrhea be due to some mechanical irritation he frees the intestinal canal of the substance by the administration of a dose of castor oil; but if the condition is due to fermentation he gives hydrochloric acid. Increased peristalsis of the small intestines does not produce diarrhea. He employs adrenalin chloride if the stools are of a serous type, and ammonium bromide in the nervous types of diarrhea. To those types of diarrhea which he terms "neurotic," and due to hysteria, neurasthenia, migraine and the climacteric, he gives strontium bromide and later potassium arsenite, and to those which he terms "hemic" due to uremia and malaria, he gives arsenic, methylene blue and ergot. Opium should never be given to these patients unless the intestinal canal is empty, and only to check excessive peristalsis. The diet for patients suffering with chronic diarrhea should be milk.

Dr. D. O. Leech, of Washington, D. C., in discussing these two papers, stated that he gave liquids before or after and not during a meal because the gastric was diluted more than it should be.

Rectal Alimentation.—Dr. William H. Porter, of New York, maintains that small amounts of albuminous substances are absorbed in the rectum, but very little sugar or starches. This form of feeding may be employed when the stomach is partially disabled, but to him it is unsatisfactory.

In the discussion Dr. R. Reyburn maintained that when the patient is ill the economy needed much less food, and that the amount taken through the rectum may bridge him over to such a time when the food can be administered through the mouth. He never feeds by rectum oftener than six hours, and believes it better to do so every eight hours.

Etiology and Treatment of Infantile Atrophy.—Dr. John Blake White, of New York, in discussing this topic, takes the ground that the atrophy is due to disorders of assimilation and absorption, and that the enteritis is a secondary condition. He advised the use of warm baths, massage, outdoor exercise, cod-liver oil and strychnine nitrate 1-200 gr. He also spoke of the use of intestinal antiseptics, as guaiacol carbonate menthol, and of the use of thymus extract which exerts some influence on bone structure. He suggested the use of radium, the chloride of gold and sodium and, if the patients are tuberculous, manganese.

Notes on the Treatment of Hay Fever and Asthma.—Dr. Charles H. Knight, of New York, laid great stress upon the examination of the nasal cavities and the pharynx in all cases of asthma. In the treatment of hay fever he has found Dunbar's serum of value in some of the cases, but condemns the use of cocaine, and is not greatly impressed with adrenalin. He has used Clark's solution with some success.

Prophylaxis of Pneumonia.—Dr. James M. Anders, of Philadelphia, first spoke of some factors instrumental in propagating the disease, as close confinement, exclusion of light, individual predisposition and the bacteria-laden clothing of both the sick and healthy. Then he took up the prophylaxis, calling attention to the protection of individuals from barometric changes, from pneumonic patients and to excessive use of clothing, also to the correction of the mode of American living. The weak during an epidemic, he maintains, should have tonics and strychnine; lesions in the air passages must be attended to, in order to prevent mouth breathing and the sleeping-room must be well ventilated. He dealt with disinfection of the sputum both the healthy and the diseased, of the sprinkling of asphalt streets, and of the use of antiseptics, which should always be preceded by thorough cleansing of the mouth. He condemns the expectoration into cloths which are then burned. Pneumonia should be placed on the list of reported diseases, the regulation of the pneumonic patient should be under municipal government; he also laid stress upon the ventilation of all public places.

Recognition and Treatment of Pancreatic Disease.—Dr. Carl Beck, of New York, in taking up this question, pointed out that in pancreatic inflammations fat is present in the feces and sugar in the urine. The character of the pain is not a reliable sign. He referred to the sudden pain, the collapse, the constipation and the vomiting, none of which is pathognomic for the disease; in the subacute inflammation the symptoms are less severe. The chronic form may be due to bacteria, syphilis, arteriosclerosis, hepatitis, injuries and to gastric disturbances. In this type abuminuria and glycosuria are usually present; there may be constipation or diarrhea or vomiting. He favors operation in all cases where hemorrhagic pancreatitis is suspected, and uses hot irrigations, and packs with iodoform gauze. When the pancreatitis is due to cholecystitis operation upon the latter condition will cure the former.

Management of Injuries to the Knee-joint.—Dr. DeForest Willard, of Philadelphia, first dealt with sprains for which he advised ice and rest in the acute stage and later heat, if the fluid exudate is large aspiration is necessary. When he dealt with dislocation of the semilunar cartilages he recommended reduction by manipulation first, and if dislocation recurred operation. If the pain in passive motion is too severe the condition can be greatly aided by the use of heat. Sensitive joints are often the result of trauma, but may be hysterical; to this condition he applies the term "anklyphobia." When blood clots exist the joint should be opened and the foreign substance removed. He recommends that passive motion be begun as soon as the chronic stage is reached.

Value of the Correction of Errors of Refraction in Psychoses.—Dr. E. D. Fisher, of New York, did not read his paper because the time was too short, but said that in his opinion epilepsy is not relieved by the correction of errors of refraction; he does not mean to imply that these defects should not be corrected, however.

Treatment of Incontinence of Urine in Children.—Dr. Noble P. Barnes, of Washington, D. C., said in the treatment of this condition stress should be laid on the diet, the training of the child to retain the urine for a certain number of hours, the outdoor exercise and the cold bath to be followed by thorough rubbing. For highly acid urine only are drugs in this condition of any value, and then he gives atropine and strychnine.

THE STUDENT LIFE. A FAREWELL ADDRESS TO CANADIAN AND AMERICAN MEDICAL STUDENTS.

BY WILLIAM OSLER, M.D.,

OF OXFORD, ENGLAND;

REGIUS PROFESSOR OF MEDICINE, UNIVERSITY OF OXFORD.

EXCEPT it be a lover, no one is more interesting as an object of study than a student. Shakespeare might have made him a fourth in his immortal group. The lunatic with his fixed idea, the poet with his fine frenzy, the lover with his frantic idolatry, and the student aflame with the desire for knowledge are of "imagination all compact." To an absorbing passion, a whole-souled devotion, must be joined an enduring energy, if the student is to become a devotee of the gray-eyed goddess to whose law his services are bound. Like the quest of the Holy Grail, the quest of Minerva is not for all. For the one, the pure life, for the other, what Milton calls "a strong propensity of nature." Here again the student often resembles the poet,—he is born, not made. While the resultant of two molding forces, the accidental, external conditions, and the hidden, germinal energies, which produce in each one of us national, family and individual traits, the true student possesses in some measure a divine spark which sets at naught their laws. Like the Snark, he defies defintion, but there are three unmistakable signs by which you may recognize the genuine article from a Boojum—an absorbing desire to know the truth, an unswerving steadfastness in its pursuit, and an open, honest heart, free from suspicion, guile and jealousy.

At the outset do not be worried about this big question—Truth. It is a very simple matter if each one of you starts with the desire to get as much as possible. No human being is constituted to know the truth, the whole truth and nothing but the truth; and even the best of men must be content with fragments, with partial glimpses, never the full fruition. In this unsatisfied quest the attitude of mind, the desire, the thirst (a thirst that from the soul must rise!), the fervent longing, are the be-all and the end-all. What is the student but a lover courting a fickle mistress who ever eludes his grasp? In this very elusiveness is brought out his second great characteristic—steadfastness of purpose. Unless from the start the limitations incident to our frail human faculties are frankly accepted, nothing but disappointment awaits you. The Truth is the best you can get with your best endeavor, the best that the best men accept—with this you must learn to be satisfied, retaining at the same time a due humility and an earnest desire for an ever larger portion. Only by keeping the mind plastic and receptive does the student escape perdition. It is not, as Charles Lamb remarks, that some people do not know what to do with truth when it is offered to them, but the tragic faith is to reach, after years of patient search, a condition of mind-blindness, in which the truth is not recognized, though it stares you in the face. This can never happen to a man who has followed step by step the growth of a truth, and who knows the painful phases of its evolution. It is one of the great tragedies of life that every truth has to struggle to acceptance against honest but mind-blind students. Harvey knew his contemporaries well and for twelve successive years demonstrated the circulation of the blood before daring to publish the facts, on which the truth was based.[1] Only steadfastness of purpose and humility enable the student to shift his position to meet the new conditions in which new truths are born, or old ones modified beyond recognition. And, thirdly, the honest heart will keep him in touch with his fellow-students, and furnish that sense of comradeship without which he travels an arid waste alone. I say advisedly an honest heart—the honest head is prone to be cold and stern, given to judgment, not mercy, and not always able to entertain that true charity which, while it thinketh no evil, is anxious to put the best possible interpretation upon the motives of a fellow worker. It will foster, too, an attitude of generous, friendly rivalry untinged by the yellow peril, jealousy, that is the best preventive of the growth of a bastard scientific spirit-loving seclusion and working in a lock-and-key laboratory, as timorous of light as is a thief.

You have all become brothers in a great society, not apprentices, since that implies a master, and nothing should be further from the attitude of the teacher than much that is meant in that word, used though it be in another sense, particularly by our French brethren in a most delightful way, signifying a bond of intellectual filiation. A fraternal attitude is not easy to cultivate—the chasm between the chair and the bench is difficult to bridge. Two things have helped to put up a cantilever across the gulf. The successful teacher is no longer on a height, pumping knowledge at high pressure into passive receptacles. The new methods have changed all this. He is no longer *Sir Oracle*, perhaps un-

1 Delivered before the medical students of McGill College, Montreal, and the students of the Medical Department of the University of Pennsylvania, Philadelphia.

1 "These views, as usual, pleased some more, others less; some chid and calumniated me and laid it to me as a crime that I had dared to depart from the precepts and opinions of all Anatomists." Chapt. I, De Motu Cordis.

consciously by his very manner antagonizing minds to whose level he cannot possibly descend, but he is a senior student anxious to help his juniors. When a simple, earnest spirit animates a college there is no appreciable interval between the teacher and the taught—both are in the same class, the one a little more advanced than the other. So animated, the student feels that he has joined a family whose honor is his honor, whose welfare is his own, and whose interests should be his first consideration.

The hardest conviction to get into the mind of a beginner is that the education upon which he is engaged is not a college course, not a medical course, but a life course, for which the work of a few years under teachers is but a preparation. Whether you will falter and fail in the race, or whether you will be faithful to the end depends on the training before the start, and on your staying powers, points upon which I need not enlarge. You can all become good students, a few may become great students, and now and again one of you will be found who does easily and well what others cannot do at all, or very badly, which is John Farriar's excellent definition of a genius.

In the hurry and bustle of a business world, which is the life of this continent, it is not easy to train first-class students. Under present conditions it is hard to get the needful seclusion, on which account it is that our educational market is so full of wayside fruit. I have always been much impressed by the advice of St. Chrysostom: "Depart from the highway and transplant thyself in some enclosed ground, for it is hard for a tree which stands by the wayside to keep her fruit till it be ripe." The dilettante is abroad in the land, the man who is always venturing on tasks for which he is imperfectly equipped, a habit of mind fostered by the multiplicity of subjects in the curriculum; and while many things are studied, few are studied thoroughly. Men will not take time to get to the heart of a matter. After all, concentration is the price the modern student pays for success. Thoroughness is the most difficult habit to acquire, but it is the pearl of great price, worth all the worry and trouble of the search. The dilettante lives an easy, butterfly life, knowing nothing of the toil and labor with which the treasures of knowledge are dug out of the past, or wrung by patient research in the laboratories. Take, for example, the early history of this country—how easy for the student of the one type to get a smattering, even a fairly full acquaintance with the events of the French and Spanish settlements. Put an original document before him, and it might as well be Arabic. What we need is the other type, the man who knows the records, who, with a broad outlook and drilled in what may be called the embryology of history, has yet a powerful vision for the minutiæ of life. It is these kitchen and back-stair men who are to be encouraged, the men who know the subject in hand in all possible relationships. Concentration has its drawbacks. It is possible to become so absorbed in the problem of the "enclitic de," or the structure of the flagella of the *Trichomonas*, or of the toes of the prehistoric horse, that the student loses the sense of proportion in his work, and even wastes a lifetime in researches which are valueless because not in touch with current knowledge. You remember poor Cassaubon, in Middlemarch, whose painful scholarship was lost on this account. The best preventive to this is to get denationalized early. The true student is a citizen of the world, the allegiance of whose soul, at any rate, is too precious to be restricted to a single country. The great minds, the great works transcend all limitations of time, of language and of race, and the scholar can never feel initiated into the company of the elect until he can approach all of life's problems from the cosmopolitan standpoint. I care not in what subject he may work, the full knowledge cannot be reached without drawing on supplies from lands other than his own—French, English, German, American, Japanese, Russian, Italian—there must be no discrimination by the loyal student, who should willingly draw from any and every source with an open mind and a stern resolve to render unto all their dues. I care not on what stream of knowledge he may embark, follow up its course, and the rivulets that feed it flow from many lands. If the work is to be effective he must keep in touch with scholars in other countries. How often has it happened that years of precious time have been given to a problem already solved or shown to be insoluble, because of the ignorance of what had been done elsewhere. And it is not only book knowledge and journal knowledge, but man knowledge that is needed. The student will, if possible, see the men in other lands. Travel not only widens the vision and gives certainties in place of vague surmises, but the personal contact with foreign workers enables him to appreciate better the failings or successes in his own line of work, perhaps to look with more charitable eyes on the work of some brother whose limitations and opportunities have been more restricted than his own. Or, in contact with a master-mind, he may take fire, and the glow of the enthusiasm may be the inspiration of his life. Concentration must then be associated with large views on the relation of the problem, and a knowledge of its status elsewhere; otherwise it may land him in the slough of a specialism so narrow that it has depth and no breadth, or he may be led to make what he believes to be important discoveries but which have been long current coin in other lands. It is sad to think that the day of the great polymathic student is at an end; that we may, perhaps, never again see a Soaliger, a Haller, or a Humboldt—men who took the whole field of knowledge for their domain and viewed it as from a pinnacle. And yet a great specializing generalist may arise, who can tell? Some twen-

tieth-century Aristotle may be now tugging at his bottle, as little dreaming, as are his parents or his friends, of a conquest of the mind, beside which the wonderful victories of the Stagirite will look pale. The value of a really great student to the country is equal to half a dozen grain elevators or a new trans-continental railway. He is a commodity singularly fickle and variable, and not to be grown to order. So far as his advent is concerned there is no telling when or where he may arise. The conditions seem to be present even under the most unlikely externals. Some of the greatest students this country has produced have come from small villages and country places. It is impossible to predict from a study of the environment, which a "strong propensity of nature," to quote Milton's phrase again, will easily bend or break.

The student must be allowed full freedom in his work, undisturbed by the utilitarian spirit of the Philistine, who cries *cui bono* and distrusts pure science. The present remarkable position in applied, and industrial trades of all sorts have been made possible by men who did pioneer work in chemistry, in physics, in biology, and in physiology, without a thought of any practical application in their researches. The members of this higher group of productive students are rarely understood by the common spirits, who appreciate as little their unselfish devotion as their unworldly neglect of the practical side of the problems.

Everywhere now the medical student is welcomed as an honored member of the guild. There was a time, I confess, and it is within the memory of some of us, when, like Falstaff, he was given to "taverns and sack and wine and methoglins, and to drinkings and swearings and starings, pribbles and prabbles": but all that has changed with the curriculum, and the "Meds" now roar you as gently as the "Theologs."

What I have said upon the general life and mental attitude of the student applies with tenfold force to you on account of the peculiar character of the subject-matter of your studies. Man, with all his mental and bodily anomalies and diseases—the machine in order, the machine in disorder, and the business yours to put it to rights. Through all the phases of its career this most complicated mechanism of this wonderful world will be the subject of your study and of your care—the naked, new-born infant, the artless child, the lad and the lassie just aware of the tree of knowledge overhead, the strong man in the pride of life, the woman with the benediction of maternity on her brow, and the aged, peaceful in the contemplation of the past. Almost everything has been renewed in the science and in the art of medicine, but all through the long centuries there has been no variableness or shadow of change in the essential features of the life which is our contemplation and our care. The sick love-child of Israel's sweet singer, the plague-stricken hopes of the great Athenian statesman, Elpenor, bereft of his beloved Artemidora, and Tully's daughter mourned so tenderly, are not of any age or any race—they are here with us to-day, with the Hamlets, the Ophelias, and the Lears. Amid an eternal heritage of sorrow and suffering our work is laid, and this eternal note of sadness would be insupportable if the daily tragedies were not relieved by the spectacle of the heroism and devotion displayed by the actors. Nothing will sustain you more potently than the power to recognize in your humdrum routine, as perhaps it may be thought, the true poetry of life—the poetry of the commonplace, of the ordinary man, of the plain, toil-worn woman, with their loves and their joys, their sorrows and their griefs. The comedy, too, of life will be spread before you, and nobody laughs more often than the doctor at the pranks Puck plays upon the Titanias and the Bottoms among his patients. The humorous side is really almost as frequently turned toward him as the tragic. Lift up one hand to heaven and thank your stars if they have given you the proper sense to enable you to appreciate the inconceivably droll situations in which we catch our fellow creatures. Unhappily, this is one of the free gifts of the gods, unevenly distributed, not bestowed on all, or on all in equal portions. In undue measure it is not without risk, and in any case in the doctor it is better appreciated by the eye than expressed on the tongue. Hilarity and good humor, a breezy cheerfulness, a nature sloping toward the southern side, as Lowell has it, help enormously both in the study and in the practice of medicine. To many of a sombre and sour disposition it is hard to maintain good spirits amid the trials and tribulations of the day, and yet it is an unpardonable mistake to go about among patients with a long face.

Divide your attentions equally between books and men. The strength of the student of books is to sit still—two or three hours at a stretch—eating the heart out of a subject with pencil and note-book in hand, determined to master the details and intricacies, focusing all your energies on its difficulties. Get accustomed to test all sorts of book problems and statements for yourself, and take as little as possible on trust. The Hunterian "Do not think, but try" attitude of mind is the important one to cultivate. The question came up one day, when discussing the grooves left on the nails after fever, how long it took for the nail to grow out, from root to edge. A majority of the class had no further interest; a few looked it up in books; two men marked their nails at the root with nitrate of silver, and a few months later had positive knowledge on the subject. They showed the proper spirit. The little points that come up in your reading try to test for yourselves. With one fundamental difficulty many of you will have to contend from the outset—a lack of proper preparation for really hard study. No one can have watched successive groups of young men pass through

the special schools without a profound sympathy for the hap-hazard, fragmentary character of their preliminary education. It does seem too bad that we cannot have a student in his eighteenth year sufficiently grounded in the humanities and in the sciences preliminary to medicine—but this is an educational problem upon which only a Milton or a Locke could discourse with profit. With pertinacity you can overcome the preliminary defects, and once thoroughly interested, the work in books becomes a pastime.

A serious drawback in the student life is the self-consciousness, bred of too close devotion to books. A man gets shy, "dysopic," as old Timothy Bright calls it, and shuns the looks of men, and blushes like a girl. The strength of a student of men is to travel—to study men, their habits, character, mode of life, their behavior under varied conditions, their vices, virtues and peculiarities. Begin with a careful observation of your fellow-students and of your teachers; then, every patient you see is a lesson in much more than the malady with which he suffers. Mix as much as you possibly can with the outside world, and learn its ways. The student societies, the students' union, the gymnasium, and the outside social circle should be cultivated systematically, to enable you to conquer the diffidence which goes with bookishness and which will prove a very serious drawback in after-life. I cannot too earnestly impress upon the earnest and attentive men among you the necessity of overcoming this unfortunate failing in your student days. It is not easy for every one to reach a happy medium, and the distinction between a proper self-confidence and "cheek," particularly in junior students, is not always to be made. The latter is met with chiefly among the student pilgrims who, in traveling down the Delectable mountains, have gone astray and have passed to the left hand, where lieth the country of Conceit, the country in which you remember the brisk lad Ignorance met Christian. I wish we could encourage on this continent the habit of wandering among our best students. I do not know that we are quite prepared for it, as there is still great diversity in the curricula, even among the leading schools, but it is undoubtedly a great advantage to study under different teachers, as the mental horizon is widened and the sympathies enlarged. The practice would do much to lessen that narrow "I am of Paul and I am of Apollos" spirit which is hostile to the best interests of the profession.

There is much that I would like to say on the question of work, but I can only spare a few moments for a word or two. Who will venture to settle upon so simple a matter as the best time for work? One will tell us there is no best time; all are equally good; and truly, all times are the same to a man whose soul is absorbed in some great problem. The other day I asked Edward Martin, the well-known story writer, what time he found best for work. "Not in the evening, and never between meals!" was his answer, which may appeal to some of my hearers. One works best at night; another, in the morning; a majority of the students of the past favor the latter. Erasmus, the great exemplar, says, "Never work at night; it dulls the brain and hurts the health." One day, going with George Ross through Bedlam, Dr. Savage, at that time the physician in charge, remarked upon two great groups of patients—those who were depressed in the morning and those who were cheerful, and he suggested that the spirits rose and fell with the bodily temperature—those with very low morning temperates were depressed, and vice versa. This, I believe, expresses a truth which may explain the extraordinary difference in the habits of students in this matter of the time at which the best work can be done. Outside of the asylum there are also the two great types, the student-lark who loves to see the sun rise, who comes to breakfast with a cheerful morning face, never so "fit" as at 6 A. M. We all know the type. What a contrast to the student-owl with his saturnine morning face, thoroughly unhappy, cheated by the wretched breakfast bell of the two best hours of the day for sleep, no appetite, and permeated with an unspeakable hostility to his *vis-à-vis*, whose morning garrulity and good humor are equally offensive. Only gradually, as the day wears on and his temperature rises, does he become endurable to himself and to others. But see him really awake at 10 P.M.! While the plethoric lark is in hopeless coma over his books, from which it is hard to rouse him sufficiently to get his boots off for bed, our lean owl-friend, Saturn no longer in the ascendant, with bright eyes and cheery face, is ready for four hours of anything you wish—deep study, or

"Heart affluence in discoursive talk,"

and by 2 A.M. he will undertake to unsphere the Spirit of Plato. In neither a virtue, in neither a fault; we must recognize these two types of students, differently constituted and owing possibly—though I have but little evidence for the belief—to thermal peculiarities.

In the days of probation the student life may be lived by each one of you in its fulness and in its joys, but the difficulties arise in the break which follows departure from college and the entrance upon new duties. Much will now depend on the attitude of mind which has been encouraged. If the work has been for your degree, if the diploma has been its sole aim and object, you will rejoice in a freedom from exacting and possibly unpleasant studies, and with your books you will throw away all thoughts of further systematic work. On the other hand, with good habits of observation you may have got deep enough into the subject to feel that there is still much to be learned, and if you have had ground into you the lesson that the collegiate period is only the beginning of the student life, there is a hope that you may enter

upon the useful career of the *student-practitioner*. Five years, at least, of trial await the man after parting from his teachers, and entering upon an independent course, years upon which his future depends and from which his horoscope may be cast with certainty. It is all the same whether he settles in a country village, or goes on with hospital and laboratory work; whether he takes a prolonged trip abroad, or whether he settles down in practice, with a father or a friend,—these five waiting years fix his fate so far as the student life is concerned. Without any strong natural propensity to study, he may feel such a relief after graduation that the effort to take to books is beyond his mental strength, and a weekly journal with an occasional text-book furnish pabulum enough, at least, to keep his mind hibernating. But ten years later he is dead mentally, past any possible hope of galvanizing into life as a student, fit to do a routine practice, often a capable, resourceful man, but without any deep convictions, and probably more interested in stocks or in horses than in diagnosis or therapeutics. But this is not always the fate of the student who finishes his work on Commencement day. There are men full of zeal in practice, and who give good service to their fellow creatures, who have not the capacity or the energy to keep up with the times. While they have lost interest in science, they are loyal members of the profession, and appreciate their responsibilites as such. That fateful first lustrum ruins some of our most likely material. Nothing is more trying to the soldier than inaction, to mark time while the battle is raging all about him; and waiting for practice is a serious strain under which many yield. In the cities it is not so hard to keep up; there is work in the dispensaries and colleges, and the stimulus of the medical societies; but in smaller towns and in the country it takes a strong man to live through the years of waiting without some deterioration. I wish the custom of taking junior men as partners and assistants would grow on this continent. It has become a necessity, and no man in large general practice can do his work efficiently without skilled help. How incalculably better for the seniors; how beneficial to the patients; how helpful in every way if each one of you, for the first five or ten years, was associated with a senior practitioner, doing his night work, his laboratory work, his chores of all sorts. You would, in this way, escape the chilling and killing isolation of the early years, and amid congenial surroundings you could, in time, develop into that flower of our calling—the cultivated general practitioner. May this be the destiny of a large majority of you! Have no higher ambition! You cannot reach any better position in a community; the family doctor is the man behind the gun, who does our effective work. That his life is hard and exacting; that he is underpaid and overworked; that he has but little time for study and less for recreation —these are the blows that may give finer temper to his steel, and bring out the nobler elements in his character. What lot or portion has the general practitioner in the student life? Not, perhaps, the fruitful heritage of Judah or Benjamin, but he may make of it the goodly portion of Ephraim. A man with powers of observation, well trained in the wards, and with the strong natural propensity to which I have so often referred, may live the ideal student life, and even reach the higher levels of scholarship. Adams, of Banchory (a little Aberdeenshire village), was not only a good practitioner and a skilful operator, but he was an excellent naturalist. This is by no means an unusual or remarkable combination, but Adams became, in addition, one of the great scholars of the profession. He had a perfect passion for the classics, and amid a very exacting practice found time to read "almost every Greek work which has come down to us from antiquity, except the ecclesiastical writers." He translated the works of Paulus Æginata, the works of Hippocrates, and the works of Aretæus, all of which are in the Sydenham Society's publications, monuments of the patient skill and erudition of a Scottish village doctor, an incentive to every one of us to make better use of our precious time.

Given the sacred hunger and proper preliminary training, the student-practitioner requires at least three things with which to stimulate and maintain his education, a note-book, a library and a quinquennial brain dusting. I wish I had time to speak of the value of note-taking. You can do nothing as a student in practice without it. Carry a small note-book which will fit into your waistcoat pocket, and never ask a new patient a question without note-book and pencil in hand. After the examination of a pneumonia case two minutes will suffice to record the essentials in the daily progress. Routine and system, when once made a habit, facilitate work, and the busier you are the more time you will have to make observations after examining a patient. Jot a comment at the end of the notes; "clear case," "case illustrating obscurity of symptoms," "error in diagnosis," etc. The making of observations may become the exercise of a jackdaw-like trick, like the craze which so many of us have to collect articles of all sorts. The study of the cases, the relation they bear to each other and to the cases in literature—here comes in the difficulty. Begin early to make a threefold category—clear cases, doubtful cases, mistakes. And learn to play the game fair, no self-deception, no shrinking from the truth; mercy and consideration for the other man, but none for yourself, upon whom you have to keep an incessant watch. You remember Lincoln's famous *not* about the impossibility of fooling all of the people all of the time. It does not hold good for the individual who can fool himself to his heart's content all of the time. If necessary, be cruel; use the knife and the cautery

to cure the intumescence and moral necrosis which you will feel in the posterior parietal region, in Gall and Spurzheim's center of self-esteem, and where you will find a sore spot after you have made a mistake in diagnosis. It is only by getting your cases grouped in this way that you can make any real progress in your post-collegiate education; only in this way can you gain wisdom with experience. It is a common error to think that the more a doctor sees the greater his experience and the more he knows. No one ever drew a more skilful distinction than Cowper in his oft-quoted lines, which I am never tired of repeating in a medical audience:

"Knowledge and wisdom, far from being one,
Have ofttimes no connection. Knowledge dwells
In heads replete with thoughts of other men;
Wisdom in minds attentive to their own.
Knowledge is proud that he has learned so much;
Wisdom is humble that he knows no more."

What we call sense or wisdom is knowledge, ready for use, made effective, and bears the same relation to knowledge itself that bread does to wheat. The full knowledge of the parts of a steam engine and the theory of its action may be possessed by a man who could not be trusted to pull the string to its throttle. It is only by collecting data and using them that you can get sense. One of the most delightful sayings of antiquity is the remark of Heraclitus upon his predecessors—that they had much knowledge, but no sense, which indicates that the noble old Ephesian had a keen appreciation of their difference; and the distinction, too, is well drawn by Tennyson in the oft-quoted line:

"Knowledge comes, but Wisdom lingers."

Of the three well-stocked rooms which it should be the ambition of every young doctor to have in his house, the library, the laboratory and the nursery—books, balances and bairns—as he may not achieve all three, I would urge him to start at any rate with the books and the balances. A good weekly and a good monthly journal to begin with, and read them. Then, for a systematic course of study, supplement your college text-books with the larger systems—Allbutt or Nothnagel—a system of surgery, and, as your practice increases, make a habit of buying a few special monographs every year. Read with two objects; first, to acquaint yourself with the current knowledge on a subject and the steps by which it has been reached, and secondly, and more important, read to understand and analyse your cases. To this line of work we should direct the attention of the student before he leaves the medical school, pointing in specific cases just where the best articles are to be found, sending him to the index catalogue—that marvelous storehouse, every page of which is interesting and the very titles instructive. Early learn to appreciate the differences between the descriptions of disease and the manifestations of that disease in an individual—the difference between the composite portrait and one of the component pictures. By exercise of a little judgment you can collect at moderate cost a good working library. Try, in the waiting years, to get a clear idea of the history of medicine. Read Foster's Lectures on the History of Physiology, Baas's History of Medicine. Get the Masters of Medicine series, and subscribe to the *Library and Historical Journal.*[1]

Every day do some reading or work apart from your profession. I fully realize, no one more so, how absorbing is the profession of medicine; how applicable to it is what Michel Angelo says, "There are sciences which demand the whole of a man, without leaving the least portion of his spirit free for other distractions"; but you will be a better man and not a worse practitioner for an avocation. I care not what it may be, gardening or farming, literature or history or bibliography, any one of which will bring you in contact with books. (I wish that time permitted me to speak of the other two rooms which are really of equal importance with the library, but which are more difficult to equip, though of coordinate value in the education of his head, his heart and his hand.) The third essential for the practitioner as a student is the quinquennial brain dusting, and this will often seem to him the hardest task to carry out. Every fifth year, back to the hospital, back to the laboratory, for renovation, rehabilitation, rejuvenation, reintegration, resuscitation, etc. Do not forget to take the note-books with you, or the sheets, in three separate bundles, to work over. From the very start begin to save for the trip. Deny yourself all luxuries for it; shut up the room you meant for the nursery,—have the definite determination to get your education thoroughly well started: if you are successful you may, perhaps, have enough saved at the end of three years to spend six weeks in special study; or in five years you may be able to spend six months. Hearken not to the voice of old "Dr. Hayseed" who tells you it will ruin your prospects, and that he "never heard of such a thing" as a young man, not yet five years in practice, taking three months' holiday. To him it seems preposterous. Watch him wince when you say it is a speculation in the only gold mine in which the physician should invest—*Grey Cortex!* What about the wife and babies if you have them—leave them! Heavy as are your responsibilities to those nearest and dearest, they are outweighed by the responsibilities to yourself, to the profession and to the public. Like Isaphaena, the story of whose husband—ardent, earnest soul, peace to his ashes!—I have told in the little sketch of "An Alabama Student," your wife will be glad to bear her share in the sacrifice you make.

With good health and good habits the end of the second lustrum should find you thoroughly established—all three rooms well furnished, a good stable, a good garden, no mining stock, but a life insurance and, perhaps, a mort-

[1] Brooklyn. Price, $2 per annum.

gage or two on neighboring farms. Year by year you have dealt honestly with yourself; you have put faithfully the notes of each case into its proper place, and you will be gratified to find that, though the doubtful cases and mistakes still make a rather formidable pile, it has grown relatively smaller. You literally "own" the country-side, as the expression is. All the serious and dubious cases come to you, and you have been so honest in the frank acknowledgment of your own mistakes, and so charitable in the contemplation of theirs, that neighboring doctors, old and young, are glad to seek your advice. The work which has been very heavy is now lightened by a good assistant, one of your own students, who becomes in a year or so your partner. This is not an overdrawn picture, and it is one which may be seen in many places, except, I am sorry to say, in the particular as to the partners. This is the type of man we need in the country districts and the smaller towns. He is not a whit too good to look after the sick, not a whit too highly educated—impossible! And with an optimistic temperament and a good digestion he is the very best product of our profession, and may do more to stop quackery and humbuggery, inside and outside of the ranks, than could a dozen prosecuting county attorneys. Nay, more! such a doctor may be a daily benediction in the community—a strong, sensible, whole-souled man, living a life often of great self-denial, always of tender sympathy, worried neither by the vagaries of the well nor the testy waywardness of the sick, and to him, if to any, may come (even when he knows it not) the true spiritual blessing—that "blessing which maketh rich and addeth no sorrow."

The danger in such a man's life comes with prosperity. He is safe in the hard-working day, when he is climbing the hill, but once success is reached, with it come the temptations to which many succumb. Politics has been the ruin of many country doctors, and often of the very best, of just such a good fellow of whom I have been speaking. He is popular; he has a little money; and he, if anybody, can save the seat for the party! When the committee leaves you, take the offer under consideration, and if in the ten or twelve years you have kept on intimate terms with those friends of your student days, Montaigne and Plutarch, you will know what answer to return. If you live in a large town, resist the temptation to open a sanatorium. It is not the work for a general practitioner, and there are risks that you may sacrifice your independence and much else besides. And, thirdly, resist the temptation to move into a larger place. In a good agricultural district, or in a small town, if you handle your resources aright, taking good care of your education, of your habits and of your money, and devoting part of your energies to the support of the societies, etc., you may reach a position in the community, of which any man may be proud. There are country practitioners among my friends with whom I would rather change places than with any in our ranks, men whose stability of character and devotion to duty make one proud of the profession.

Curiously enough, the student practitioner may find studiousness to be a stumbling-block in his career. A bookish man may never succeed; deep-versed in books, he may not be able to use his knowledge to practical effect; or, more likely, his failure is not because he has studied books much, but because he has not studied men more. He has never got over that shyness, that diffidence against which I have warned you. I have known instances in which this malady was incurable; in others I have known a cure effected not by the public, but by the man's professional brethren, who, appreciating his work, have insisted upon utilizing his mental treasures. It is very hard to carry student habits into a large city practice; only zeal, a fiery passion, keeps the flame alive, smothered as it is so apt to be by the dust and ashes of the daily routine. A man may be a good student who reads only the book of nature. Such an one[1] I remember in the early days of my residence in Montreal—a man whose devotion to patients and whose kindness and skill quickly brought him an enormous practice. Reading in his carriage and by lamplight at Lucina's bedside, he was able to keep well informed; but he had an insatiable desire to know the true inwardness of a disease, and it was in this way I came into contact with him. Hard pushed day and night, yet he was never too busy to spend a couple of hours with me searching for data which had not been forthcoming during life, or helping to unravel the mysteries of a new disease, such as pernicious anemia.

The *student specialist* has to walk warily, as with two advantages there are two great dangers against which he has constantly to be on guard. In the bewildering complexity of modern medicine it is a relief to limit the work of a life to a comparatively narrow field which can be thoroughly tilled. To many men there is a feeling of great satisfaction in the mastery of a small department, particularly one in which technical skill is required. How much we have benefited from this concentration of effort in dermatology, laryngology, ophthalmology, and in gynecology! Then, as a rule, the specialist is a freeman, with leisure or, at any rate, with some leisure; not the slave of the public, with the incessant demands upon him of the general practitioner. He may live a more rational life, and has time to cultivate his mind, and he is able to devote himself to public interests and to the welfare of his professional brethren, on whose suffrages he so largely depends. How much we are indebted in the larger cities to the disinterested labors of this favored class, the records of our libraries and medical societies bear witness. The dangers do not come to the strong man in a specialty, but to the weak brother who seeks in it an easier field in which specious garrulity and mechanical

[1] The late John Bell.

dexterity may take the place of solid knowledge. All goes well when the man is larger than his specialty and controls it, but when the specialty runs away with the man there is disaster, and a topsy-turvy condition which, in every branch, has done incalculable injury. Next to the danger from small men is the serious risk of the loss of perspective in prolonged and concentrated effort in a narrow field. Against this there is but one safeguard—the cultivation of the sciences upon which the specialty is based. The student specialist may have a wide vision—no student wider—if he gets away from the mechanical side of the art, and keeps in touch with the physiology and pathology upon which his art depends. More than any other of us, he needs the lessons of the laboratory, and wide contact with men in other departments may serve to correct the inevitable tendency to a narrow and perverted vision, in which the life of the ant-hill is mistaken for the world at large.

Of the *student-teacher* every faculty affords examples in varying degrees. It goes without saying that no man can teach successfully, who is not at the same time a student. Routine, killing routine, saps the vitality of many who start with high aims, and who, for years, strive with all their energies against the degeneration which it is so prone to entail. In the smaller schools isolation, the absence of congenial spirits working at the same subject, favors stagnation, and after a few years the fires of early enthusiasm no longer glow in the perfunctory lectures. In many teachers the ever-increasing demands of practice leave less and less time for study, and a first-class man may lose touch with his subject through no fault of his own, but through an entanglement in outside affairs which he cannot control, yet deeply regrets. To his five natural senses the student teacher must add two more—the sense of responsibility and the sense of proportion. Most of us start with a highly developed sense of the importance of the work and with a desire to live up to the responsibilities intrusted to us. Punctuality, the class first, always and at all times, the best that a man has in him, nothing less; the best the profession has on the subject, nothing less; fresh energies and enthusiasm in dealing with dry details; animated, unselfish devotion to all alike; tender consideration for his assistants —these are some of the fruits of a keen sense of responsibility in a good teacher. The sense of proportion is not so easy to acquire, and much depends on the training and on the natural disposition. There are men who never possess it; to others it seems to come naturally. In the most careful ones it needs constant cultivation—*nothing over much* should be the motto of every teacher. In my early days I became under the influence of an ideal student teacher, the late Palmer Howard, of Montreal. If you ask what manner of man he was, read Matthew Arnold's noble tribute to his father in his well-known poem, *Rugby Chapel*. When young, Dr. Howard had chosen a path—" path to a clear-purposed goal," and he pursued it with unswerving devotion. With him the study and the teaching of medicine were an absorbing passion, the ardor of which neither the incessant and ever-increasing demands upon his time nor the growing years could quench. When I first, as a senior student, came into intimate contact with him in the summer of 1871, the problem of tuberculosis was under discussion, stirred up by the epoch-making work of Villemin and the radical views of Niemeyer. Every lung lesion at the Montreal General Hospital had to be shown to him, and I got my first-hand introduction to Laennec, to Graves and to Stokes, and became familiar with their works. No matter what the hour, and it usually was after 10 P.M., I was welcome with my bag, and if Wilks and Moxon, Virchow, or Rokitanski, gave us no help, there were the Transactions of the Pathological Society and the big *Dictionnaire* of Dechambre. An ideal teacher because a student, ever alert to the new problems, an indomitable energy enabled him in the midst of an exacting practice to maintain an ardent enthusiasm, still to keep bright the fires which he had lighted in his youth. Since those days I have seen many teachers and I have had many colleagues, but I have never known one in whom were more happily combined a stern sense of duty with the mental freshness of youth.

But as I speak from out the memory of the past, there rises before me a shadowy group, a long line of students whom I have taught and loved, and who have died prematurely—mentally, morally, or bodily. To the successful we are all willing and anxious to bring the tribute of praise, but none so poor to give recognition to the failures. From one cause or another, perhaps because, when not absorbed in the present, my thoughts are chiefly in the past, I have cherished the memory of many young men whom I have loved and lost. *Io victis!* let us sometimes sing of the vanquished. Let us sometimes think of those who have fallen in the battle of life, who have striven and failed, who have failed even without the strife. How many have I lost from the student band by mental death, and from so many causes—some still-born from college, others dead within the first year of infantile marasmus, while mental rickets, teething, tabes and fits have carried off many of the most promising minds! From improper feeding within the first five fateful years scurvy and rickets head the mental mortality bills of students. To the teacher-nurse it is a sore disappointment to find at the end of ten years so few minds with the full stature, of which the early days gave promise. Still, so widespread is mental death that we scarcely comment upon it in our friends. The real tragedy is the moral death which, in different forms, overtakes so many good fellows who fall away from the pure, honorable and righteous service of Minerva into the idolatry of Bacchus, of Venus or of Circe. Against the background of the past these trage-

dies stand out, lurid and dark, and as the names and faces of my old boys recur (some of them my special pride), I shudder to think of the blighted hopes and wrecked lives, and I force my memory back to those happy days when they were as you are now, joyous and free from care, and I think of them on the benches, in the laboratories and in the wards—and there I leave them. Less painful to dwell upon, though associated with a more poignant grief, is the fate of those whom physical death has snatched away in the bud or blossom of the student life. These are among the tender memories of the teacher's life, of which he does not often care to speak, feeling with Longfellow that the surest pledge of their remembrance is "the silent homage of thoughts unspoken." As I look back it seems now as if the best of us had died, that the brightest and the keenest had been taken, and the more commonplace among us had been spared. An old mother, a devoted sister, a loving brother, in some cases a broken-hearted wife, still pay the tribute of tears for the untimely ending of their high hopes, and in loving remembrance I would mingle mine with theirs. What a loss to our profession have been the deaths of such true disciples as Zimmerman, of Toronto; of Jack Cline and of R. L. MacDonnell, of Montreal; of Fred. Packard and of Kirkbride, of Philadelphia; of Oppenheimer and of Oehner, in Baltimore—cut off with their leaves still in the green, to the inconsolable grief of their friends!

To each one of you the practice of medicine will be very much as you make it—to one a worry, a care, a perpetual annoyance; to another, a daily joy and a life of as much happiness and usefulness as can well fall to the lot of man. In the student spirit you can best fulfil the high mission of our noble calling—in his *humility*, conscious of weakness, while seeking strength; in his *confidence*, knowing the power, while recognizing the limitations of his art; in his *pride* in the glorious heritage from which the greatest gifts to man have been derived; and in his sure and certain hope that the future holds for us still richer blessings than the past.

TWO EXPERIMENTS IN ARTIFICIAL IMMUNITY AGAINST TUBERCULOSIS.

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

As the papers which have just been read relate to the difference of the pathological lesions produced in animals immunized against tuberculosis by attenuated living cultures, also to the value of agglutination in the various degrees of tuberculous infection and to the opsonic power of the blood of immunized compared with unimmunized animals, I am glad to avail myself of the privilege accorded me by your Chairman of describing to you two experiments recently made by me which bear on artificial immunity against tuberculosis in small animals.

Many of you who have followed carefully the continued but apparently hopeless efforts to produce artificial immunity against this disease, in which clinically no acquired immunity seems to exist, and where one attack apparently does not protect from another, and who remember the many failures which have followed attempts at producing an antitoxic serum for tuberculosis or immunity against the disease by tuberculin or other products of the germ, may nevertheless have been struck with the fact that rather better results have been claimed at intervals during the past thirteen years by a certain class of experimenters.

I refer principally to the work done by de Schweinitz, Pearson and Gilliland, and Trudeau, in this country, that of MacFadyean in England, and of Behring, Neufeld, Baumgarten, and also Möller and Friedmann, in Germany. The distinctive feature of their work is that the immunity claimed, whatever its degree, is produced not by a toxin but by a preventive inoculation made with living but attenuated bacilli. These bacilli may depend for their attenuation either on the selection of a race of tubercle bacilli not naturally virulent for the animals to be protected, or on prolonged cultivation on artificial media which produces attenuation of virulence in the same variety of tubercle bacillus naturally virulent for the animal sought to be protected.

Marmorek and Maragliano still claim to produce antitoxic and bacteriolytic serums which are effectual when employed in the treatment of human tuberculosis, but sufficient time has not elapsed to establish the validity of their claims. In my own work the best results I have obtained in producing a relative but demonstrable degree of immunity, or at least increased resistance in small animals, have been brought about by the previous inoculations of living but attenuated cultures, and have been published at long intervals since 1893.

Rabbits and guinea-pigs, which I have always made use of, are by no means ideal animals for immunization, the guinea-pig being almost too susceptible, so that nothing more than relative immunity can be obtained with these animals; the rabbit, on the other hand, recovering very readily after a time from even intravenous inoculations of human tubercle bacilli, unless these be very virulent or the amount injected very large, so that the controls have a disagreeable way of making relative if not complete recoveries.

It having been demonstrated by de Schweinitz and myself that a human culture by prolonged cultivation lost its virulence for even such susceptible animals as guinea-pigs, and that its injection gave these animals a relative degree of immunity, I began over a year ago experiments

[1] Part of the Discussion at the Bacteriological and Pathological Section of the Meeting of the National Association for the Study and Prevention of Tuberculosis, May 18 to 19, 1905.

to try to throw more light on the nature of this very apparent protection. The first experiment I made was with a view to determining whether a living bacillus was necessary to the production of the highest degree of immunity attainable, or whether dead bacilli would be equally effective. Was the immunity a result of the struggle between the living bacillus and the cell, or was it merely the chemical products of the germ which were essential to success, living or dead? Was the immunity simply a toxin immunity, or was it a bacteriolytic or isopathic immunity which could be induced only by the substances resulting from the struggle between the living cells and the living but attenuated germs? The conditions of the experiment were as follows:

Guinea-pigs of the same weight were chosen. Twelve were injected in the left groin with one-half milligram attenuated, actively growing, human culture (R 1). The culture was then put in the steam sterilizer for fifteen minutes, and twelve more guinea-pigs were similarly inoculated. In a month they received one milligram of the same attenuated culture (living and dead) intraperitoneally. A month after the first vaccination the pigs injected with the living bacilli showed slight enlargement of inguinal glands, but nothing more. Those injected with the dead bacilli showed no evidence whatever of the inoculation. A month after the last protective inoculation they were all injected in the right groin, along with eight control animals of the same size, with one milligram virulent human tubercle bacilli. The last of the controls died in ninety days with gross and advanced cheesy lesions in glands, spleen, liver and lungs. At that time (ninety days) four of the pigs vaccinated with dead tubercle bacilli had died, and none of those vaccinated with living. One of the animals from each of the two lots of vaccinated pigs was then killed in order to compare their lesions with those of the controls. As you see in the painted photographs I show you, the lesions of the controls and those of the animals vaccinated with dead tubercle bacilli differ but little. They both have cheesy nodes, enormous cheesy spleens and livers, and the lungs are extensively invaded with cheesy tubercle. The difference in the gross appearance of the organs of the animal vaccinated with the living culture is, however, apparent at a glance; namely, though the nodes are enlarged, and the spleen moderately so, there is as yet no evidence of caseation recognizable to the naked eye. In other words, the animal is tuberculous, and would, like the rest of those in the same lot, have died ultimately of tuberculosis as they all do, but the living vaccination had a very decided and easily demonstrable influence in arresting the progress of the disease; an influence which proved to be undemonstrable in the animal vaccinated with the same culture previously killed by heat, but which nevertheless is found to be present, though to a less degree, when the duration of life in a larger number of animals is considered.

The test inoculation in this particular lot of animals was more virulent and much larger than is best to use in order to demonstrate the immunity conferred by the vaccination, but that some slight protection is afforded even by the dead bacilli, under so severe a test, is apparent when the duration of all the animals' lives is considered. Thus the controls' average life was 70⅔ days; the average life of the animals vaccinated with dead bacilli 99 days, and with living bacilli 155 days. It would seem that a very marked protection is afforded by the living bacilli, and a very slight but still appreciable degree of increased resistance by the dead bacilli. Such evidence is important in its bearing on the treatment of tuberculosis by Bacillen Emulsion, some observers still maintaining that good results are obtainable from this treatment in the human being, though no very marked immunity is produced.

This experiment is no doubt open to the criticism that in killing the cultures by heat their chemical constituents may have been altered, and that if they could be killed by some method that would not in any way change their delicate chemical composition the dead bacilli would protect as well as the living. To obtain some evidence on this point another experiment was undertaken. Small amounts, one-tenth milligram, of dead bacilli killed by three hours' exposure to sunlight were injected at short intervals in pulverized form, and the protection afforded was less marked than where the heat-killed cultures were employed in two massive injections. Average life for nine controls, 87.4 days. Average life for twelve vaccinated, 95 days. The next experiment also gives some evidence rather tending to disprove this hypothesis.

During the past year Möller, and later, Friedmann, have used bacilli derived from or passed through cold-blooded animals as a protective inoculation, and have claimed marked results from these vaccinations in guinea-pigs and rabbits, much better results, it seems to me, than I was able to obtain with my attenuated tubercle bacilli of human origin. Möller used a tubercle bacillus culture which was derived from the frog, and one which had been passed through the blind worm. Both these cultures grew freely on glycerin peptone agar at room temperature, and Möller claimed that as they would not grow at the temperature of the human body, they were perfectly safe to use as a vaccine, an advantage which could not be said to be possessed by the bacillus of human origin and growing at the temperature of warm-blooded animals, only, no matter how attenuated it might have become by prolonged cultivation on artificial media in the thermostat.

These two varieties of cultures, the frog and the slow worm, Dr. Baldwin was enabled to

obtain from Dr. Möller, and they were grown in our laboratory at room temperature. I determined to make an experiment that would be likely to shed light, (1) on the degree of protection afforded by cultures of warm-blooded origin but attenuated by prolonged growth, as compared with that conferred by bacilli derived from cold-blooded creatures and which apparently die at once when introduced into warm-blooded animals. (2) To determine whether the degree of attenuation obtained by prolonged growth bears any relation to the degree of protection afforded; that is, whether a culture of human origin grown for over twenty years on artificial media, which produces now little or no appreciable local lesion and never tends to generalize itself, will protect as well as one also of human origin which has been cultivated for over fourteen years, and which still produces in all the guinea-pigs slightly enlarged inguinal nodes near the site of inoculation, and occasionally even—that is, in about one in ten animals—brings about a little caseation in such a node, with a tendency to become generalized only to the extent that bacilli in a few instances reach as far as the spleen. The former culture is designated K 1, and is one of the original cultures which Dr. Koch separated in his first work on tuberculosis. The second is my old R 1 culture, which I obtained from the human subject, and has grown, principally on glycerin peptone bouillon, about fifteen years.

On February 27, 1905, 48 guinea-pigs of the same size were separated into four groups, and each group received respectively, in the left groin, one-half a milligram of each of the following vigorously growing agar cultures: Lot I, human, R 1 culture; Lot II, human K 1 culture; Lot III, cold-blooded (frog), and Lot IV, cold-blooded (blind worm) culture. A month later one of each group was killed. Blind worm and frog guinea-pigs showed absolutely no lesion. K 1 animals show enlarged nodes, no caseation or tubercle bacilli. R 1, one or two enlarged nodes, slight caseation and a few tubercle bacilli. No other lesions anywhere. The animals were all tested with tuberculin, and only the Lot I, human culture R 1 pigs, gave any reaction indicating the presence of a slight tuberculous process.

March 27, thirty-three days after vaccination, all the vaccinated animals, together with twelve controls, were injected subcutaneously in right groin with one-tenth milligram virulent human tubercle bacilli culture. All the 55 animals were killed at the same time, May 10, or 44 days after the virulent inoculation, and having been divided in five lots, were laid out side by side for comparison. The animals of each lot were quite uniform in the character and extent of their lesions.

Lot I, Vaccinated R 1 Human, show enlarged and, occasionally, cheesy nodes, slightly enlarged spleen, abundant perirenal fat. No other macroscopical lesions are visible, no tubercles or caseation.

Lot II, Vaccinated with K 1 Human, show caseous nodes and much larger spleen (over twice as large as Lot I); absence of perirenal fat marked in nearly half the animals, but no caseous tubercles, though a few gray tubercles could be seen in liver and lung in about one-third of the animals.

Lots III and IV, vaccinated with cultures from cold-blooded animals (frog and blind worm), as well as the controls, all show to about the same degree the usual picture of well-advanced generalized tuberculosis in the guinea-pig. Spleens about three times the size of Lot II, riddled with gray caseating tubercle. Entire absence of perirenal and lumbar fat, cheesy areas in liver, and gray tubercle in the lungs.

The controls and animals of Lots III and IV were in no way distinguishable, while any one of the animals, Lot I and Lot II, could have been picked out easily if thrown among controls, or victims vaccinated with cultures from cold-blooded animals.

This experiment seems to offer some interesting evidence. First, there is evidently a relation between the degree of protection and the attenuation of the culture used as a vaccine. The R 1 human, which from its production of local effects, enlargement of neighboring nodes containing bacilli, and slight tendency to generalization (bacilli having been found occasionally in the spleens of animals injected with this attenuated culture), protects better against subsequent virulent inoculation than the K 1 culture, which produced hardly any appreciable and purely localized effect, no bacilli being found to have penetrated even the inguinal glands near the inoculation spot.

The frog and blind worm bacillus, which causes no local disturbance at all, seemed to have no effect in protecting the vaccinated animals, for the lesions of these exactly resembled those of the controls. The conclusions to be drawn from both of these experiments would therefore seem to be, (1) that dead tubercle bacilli increase, though to a very slight degree, the animal's resistance to subsequent inoculation; (2) that the living attenuated bacillus gives a stronger degree of immunity than the same baccillus killed by heat: (3) that the degree of attenuation of the bacillus used as vaccine bears a distinct relation to the degree of protection it affords in guinea-pigs to subsequent inoculation with virulent human cultures. That a culture still capable of producing a very small amount of cell destruction, and of spreading to the neighboring inguinal nodes, gives better protection than one which produces hardly any appreciable and purely localized tissue changes; (4) that cultures derived from cold-blooded animals and which grow only at room temperature, as used above, have brought about no ap-

preciable degree of immunity. (5) the chemical changes produced in killing the bacilli by heat in the first experiment cannot wholly explain the lack of protective power of the vaccination with dead bacilli, for the K 1 human bacilli used in the second experiment, though they had not been killed by heat, failed to give as good protection as the R 1 human culture, which differed from it only in the degree of its virulence.

The evidence here presented would seem to be in keeping with what we know of the artificial immunizations. Toxin immunity, or immunity brought about with dead germs, is never as strong or as lasting as that produced through the medium of a living virus (passive and active immunity). Furthermore, the degree of the attenuation of the virus greatly influences the degree of immunity obtained.

My acknowledgments are due to Dr. E. R. Baldwin, Dr. Hugh Kinghorn, and Dr. A. H. Allen, who carried out these experiments for me.

STUDIES ON IMMUNITY IN TUBERCULOSIS: THE PROPERTIES OF THE SERUM OF IMMUNIZED RABBITS.

BY E. R. BALDWIN, M.D., H. M. KINGHORN, M.D., AND A. H. ALLEN, M.D.
OF SARANAC LAKE, N. Y.

Part I.

The following experiments were undertaken largely as a continuation of the work presented by Dr. Trudeau in 1903 before the Association of American Physicians.[1] It was desired to obtain if possible a closer insight into the mechanism of the specifically acquired resistance to a virulent human tuberculous infection produced in rabbits by previous intravenous inoculation with bacilli of weak virulence.

Briefly described, the observations previously made were that an intense and prolonged inflammatory reaction, both general and local, occurred in the vaccinated animals immediately following the virulent inoculation. This was not noted in the controls. Gradually this tuberculin-like reaction subsided and in many favorable cases the ultimate result was an almost complete absorption of the tuberculous foci and disappearance of the bacilli, while in the meantime the controls became progressively worse until a condition of chronic tuberculosis ensued.

The importance of an intimate knowledge of this immunity reaction is at once obvious to us. It might explain some phases of the clinical course of human tuberculosis in its relapses and pneumonic forms, and even furnish new viewpoints for a rational therapy. Furthermore as this vaccination has already been found useful in the bovine, one may not be skeptical of its possibilities in human application.

1 Trans. Association of American Physicians, Vol. XVIII, 1903.

The first step naturally suggested was to follow from day to day the different stages of the reaction in comparison with control animals killed simultaneously. For this purpose 23 Belgian hares were first selected as nearly the same color and size as possible, and 13 were vaccinated by the inoculation of .0001 gm. from a broth culture (R1 human) intravenously. No apparent loss of health usually follows this dose unless the animals are already the subjects of some other infection such as coccidiosis, or septicemia (snuffles). Of this series one died from the effects of fighting. The virulent inoculation followed in two months. Two c.c. (.00235 gm.) of virulent human (H33) from nine days' serum cultures was given in the same way to 11 vaccinated and 10 controls, one of the former being reserved without inoculation. The animals were etherized and bled to death in pairs, from the first to the thirtieth day at intervals of several days. Later a second lot of 30 hares and rabbits were vaccinated and 25 inoculated in the same maner together with 20 controls. This series was killed from the fourteenth to the sixty-first day so that a fairly complete review of the pathological processes was obtained (see the paper by Dr. J. L. Nichols, Part II). In addition to the above a further series of five pairs was used, more especially for the study of the serum reactions.

Daily observations of the temperature for a month after the virulent inoculation were made on 10 pairs of the first series, the result of which indicated an average higher temperature for the vaccinated animals during the first ten days, but higher for the controls during the second ten days, after which both subsided: thus it coincided with the course of the inflammatory reaction as described in the pathological report.

Agglutination Tests.—The examination of the serums was made either on the day of the bleeding or within twenty-four hours. Various emulsions and extracts of tubercle bacilli were employed to test their agglutinating and precipitating powers, but the preparation employed mostly was an emulsion of pulverized bacilli, as described by Koch, but without the addition of phenol.

The lack of uniformity in successive emulsions of the homogeneous culture of Arloing and Courmont made the results with this method useless for comparison. Moreover, the serums showing most activity in sedimenting Koch's emulsion frequently failed to agglutinate the Courmont cultures and *vice versa.*

The pulverized bacillus emulsion was prepared by diluting one part of 1-1,000 Koch emulsion to three volumes with .85 per cent. NaCl, which made a weak opalescence. The tests were made in dilutions of 1 in 5; 1-10; 1-15; 1-20, or higher, when the serum proved active. Each tube contained a total volume of 1 c.c. and a small drop of toluol.

The readings were taken after twenty-four

hours in the incubator and only sedimentation with clearing was regarded as a positive reaction.

Weak emulsions of the homogeneous culture "A" obtained from Prof. Courmont as well as one of our own ("K") were made by diluting the one month broth cultures about four times with .85 per cent. NaCl. Observations were taken after two and five hours, the tubes being kept at room temperature.

The results of precipitation tests with filtered extracts of tubercule bacilli were uniformly negative.

Normal saline—NaCl .85 per cent.—and $NaHCO_3$ 0.5 per cent. extracts of washed cultures from broth were prepared by digesting the bacilli for twenty-four hours at 45° C., and filtering through the Berkefeld bougie.

The sedimentation produced in Koch's emulsion was, however, quite markel in most of the vaccinated serums from the third to the thirtieth day after the virulent inoculation, reaching a maximum of 1 in 50 dilution in two serums and apparently higher and more constant between the fifth and twelfth days. All were negative before inoculation and during the first two days, and after the thirtieth day following inoculation. Only 9 controls out of 26 gave any agglutinations, the highest being 1 in 20 on the ninth day.

A curious fact may here be noted in passing that of these nine controls reacting positively, six were found to have more or less coccidiosis of the liver and revealed very slight and unprogressive tuberculous lesions.[1] Because of the complications these animals may be excluded in comparison, and in general it may be stated that the controls were negative to the Koch agglutination test, although more frequently positive to the Courmont test. It would appear that the agglutinin in the coccidiosis animals was less specific, or a so-called "partial agglutinin" since its genesis depended upon the presence of the coccidiosis. This view is strengthened by the fact that no congestion was evident about the tubercles in these animals.[2] On comparison of the lung sections with the results of the serum tests we noted a correspondence of the stronger serum reactions with the more intense and extensive inflammatory appearances in the vaccinated animals.

The significance of this undoubted development of agglutinin in the vaccinated animals, far in excess of the controls, is obvious as an evidence of a specific reaction-product. Whether we must also regard it as having some important function in combating the infection is less certain at present.

Phagocytosis.—The publicaton of Wright and Douglas's [2] work on the so-called "opsonin" in the tuberculosis serums naturally gave us the incentive to study the phagocytosis of tubercle bacilli as influenced by the serums of immunized and control rabbits before and after inoculation. According to Wright and Douglas, who worked exclusively with human serums, an increase of the number of living or dead tubercle bacilli, taken up by polynuclear leucocytes, could be demonstrated by counting the bacilli according to Leishman's method in the stained specimens, where the patient was undergoing a successful tuberculin treatment.

The technic was somewhat lengthy and difficult, and we found the rabbits' blood less adapted to the process than the human. After numerous trials we came to the conclusion that this method of determining comparatively the opsonic power of serum was of little value in rabbits unless considerable differences were found in the strength of the serums. When the serums were nearly the same, or even moderately variable in strength, the counts were very wide in their variation. The above tests were made with twenty animals of the second series.

The method of Leishman was first tried with blood taken directly from the ear vein during life and incubated fifteen minutes at 38.5° C. in a moist chamber on slides, with an equal volume of tubercle bacilli emulsion. The smears were then immediately dried and fixed, stained with aniline fuchsin fifteen minutes at 38° C.; decolorized with acid alcohol (0.5 per cent. HCl, alcohol 50 per cent.), and stained with Wright's blood stain. Counts of the tubercle bacilli in 20 to 80 polynuclear leucocytes were then made and averaged.

When the animals were killed the serum method was employed as described by Wright,[1] using washed leucocytes obtained sometimes from a healthy rabbit, but frequently from one of the inoculated animals. Two volumes of leucocytes suspended in normal NaCl, two volumes of centrifugalized serum and one of a standard emulsion of tubercle bacilli in 1 per cent. NaCl were measured in capillary pipettes and incubated 20 minutes at 40° C. The greatest difficulty was experienced in preparing uniform emulsions of tubercle bacilli on successive days. The most satisfactory method was found to be the use of homogeneous cultures grown on potato eight days, sterilized by boiling the entire tubes, and taking a large standard loopful of the moist growth which was rubbed up in 1.5 c.c. one per cent NaCl, and centrifugalized fifteen minutes in small tubes. These emulsions were generally free from clumps; others were not, nor could the same emulsion be used on successive days, even if it stirred up and recentrifugalized without weakening it and thus making any comparison from day to day quite useless. At the best, the spontaneous clumping of the emulsions and the varying agglutinating powers of the serums made the counts of doubtful value for comparison on the same day. An

1 This apparent insusceptibility or restraining influence in animals suffering from coccidiosis has often been noted by us, and has recently been mentioned by Libbertz and Ruppel in connection with other diseases in guinea pigs. Such animals appear to emaciate and die with but few apparent tuberculous foci, but often reveal extensive atrophy of the liver. Deutsch med. Woch., No. 4, Jan. 26, 1905.

2 Lancet, Oct. 24, 1904.

1 Wright and Douglas, London Lancet, Oct. 22, 1904.

inevitable variability in the number of leucocytes present and active is another source of fallacy.

By modifying the technic somewhat we were able to study the opsonic power of the serum of five immunized and four control animals whose blood was taken almost daily for four days preceding, and twenty days after, the virulent inoculation. Besides the latter, three healthy animals were used from time to time for comparison; agglutination tests were also made each day.

In this series about 1 c.c. of blood was drawn each day from the ear vein and the serum used within two hours.

Instead of incubating the specimens in the measuring pipettes, as described by Wright, we found it more convenient and the results better by employing miniature tubes into which the mixture was transferred after measuring. These "mixers" were placed in holes of a wooden block during incubation, like cribbage counters.

No marked difference was noted between vaccinated and control serums before and immediately after the virulent inoculation. Both sets showed considerable individual variations from day to day, but all were weaker on the first two days following infection. The vaccinated serums were usually below the controls in opsonic power from the beginning, and two pairs which had shown the greatest variation, when bled to death, revealed the typical differences elsewhere described between the lungs of the vaccinated and controls to a marked degree; one pair was killed on the sixteenth day, the other on the twentieth day. Both vaccinated serums sedimented Koch's emulsion 1-40 and 1-20, respectively; the controls were negative. If the intense reactive infiltration is regarded as an active phagocytosis, which it appears to be in part, the lower opsonic power of the serums may be accounted for by its exhaustion, though evolved in excess of that in the controls. On the other hand the higher opsonic value of the control serum and the excess of the agglutinin, simultaneously with lower opsonin in the vaccinated, are phenomena that need explanation.

No coincidence was noted in our experiments between the agglutination of Koch's emulsion and opsonic power, although the phagocytosis was generally more complete when the serum agglutinated the bacilli. Studies on the relations between the agglutinins and opsonic power are in progress.

As a final observation we may state that the intense reaction seen in vaccinated rabbits was observed only in the lungs, where doubtless most of the bacilli lodge; and in a few animals the reaction was evidently followed by such lowered resistance that instead of absorption large caseous areas developed, much more extensively than in the controls. Thus one cannot say that the method of vaccination always succeeds at last in destroying the bacilli and removing the tubercles, though it must be remembered that these inoculations are extremely severe conditions for animals to withstand. Moreover, the absorption of foci in the controls was occasionally observed to nearly the same degree, and the presumption is that the mechanism is the same, but delayed and less active in unvaccinated animals.

STUDIES ON IMMUNITY IN TUBERCULOSIS: AN HISTOLOGICAL STUDY OF THE LESIONS OF IMMUNIZED RABBITS.

BY JOSEPH L. NICHOLS, M.D.,
OF SARANAC LAKE, N. Y.

Part II.

The following examination was conducted for the purpose of demonstrating the histological differences in the formation and further progress of tubercles in previously vaccinated and in unvaccinated animals already described in Part I.

In former experiments by Dr. Trudeau[1] the great value of previous vaccination was shown by the survival, or greatly prolonged lifetime, of the vaccinated animals, and by the death of nearly all the unvaccinated. In those experiments a number of animals in each series were killed on the twenty-second day after the virulent inoculation, and microscopical examination made by Dr. Eugene Hodenpyl[2] showed a marked difference between the lungs of the vaccinated animals and those of the controls. The former were densely infiltrated and more congested than the controls, while vaccinated animals, killed some months later, revealed a remarkable absence of tuberculous foci and bacilli in the lungs, thus indicating an extensive absorption of the infiltration.

In order to try to follow the successive stages of this reaction the present experiment was conducted on the same lines, with the difference that one of each set of animals, *i.e.*, vaccinated and unvaccinated, was killed at certain intervals after the virulent inoculation, varying from twenty-four hours to thirty days. The blood serum was tested for agglutinins by Dr. Baldwin, while the internal organs were given to me for microscopical examination.

The two sets of animals reacted differently to the virulent inoculation, the vaccinated showing for the first three or four days a distinctly higher temperature and greater general disorder. In the ensuing week, however, the condition was gradually reversed, the vaccinated animals

1 Transactions Association of American Physicians, Vol. XVIII, 1903.

2 Sections from some of these rabbits were made and examined by Dr. Hodenpyl with the following results, which agree substantially with my own:

a. Vaccinated rabbits; no virulent inoculation. Killed after eighty days; no trace of inoculation.

b. Control; killed twenty-two days after virulent inoculation: Many tubercle bacilli; little general reaction.

c. Vaccinated; killed twenty-two days after virulent inoculation; greater reaction; air cells full of exudate and epithelioid cells; less definite arrangement as tubercles; some caseation; numbers of tubercle bacilli.

d. Vaccinated; killed 110 days after virulent inoculation (controls had all died tuberculous); a few very minute scattered tubercles composed of few epithelioid cells and single layered capsule; a few larger tubercles with caseated centers; no tubercle bacilli; rest of lung tissue apparently completely restored to normal.

returning to a normal appearance without having lost flesh, while the unvaccinated began to decline.

This difference in reaction of the two sets of animals was still more marked on examination of the internal organs. For this purpose one of each set, selecting animals as nearly alike as possible, was killed, every twenty-four hours for the first three days; then on the fifth and eighth days; and thereafter, up to the thirtieth day, at intervals of about four days. The animals were killed by bleeding and the autopsy performed at once. Small selected pieces were taken from the lungs, liver, spleen, and kidneys, hardened in Orth's fluid, embedded in celloidin, and the sections stained; some in hematoxylin and eosin, others by the Ziehl-Neilsen method for tubercle bacilli.

Attention may be drawn to the fact that because these animals were killed at regular progressive intervals, it does not necessarily follow that the lesions will be found in exactly the same proportionate advance. We must allow for differences in the individual resistance, and some variation in the dose no matter how carefully given. However, the periods between each killing have been sufficiently long to allow some definite advance over the preceding ones in each succeeding set.

The following description will be confined to the lungs: I shall take up first a description of the general reaction in each case, and discuss afterward any difference in the specific elements of tubercle formation.

At the end of twenty-four hours, there is a difference between the lungs of the vaccinated and control, evident to the naked eye. The latter appear unchanged. The former are congested and somewhat denser than normal, and scattered through the tissues, or just beneath the pleura, are small punctate hemorrhagic spots. On distention of the lung with fluid these spots for the most part disappear.

Under the microscope we find in both sets of animals the bacilli of the virulent inoculation pretty evenly scattered through the section as small clumps in the capillaries, forming a thrombus composed of bacilli, fibrin and many leucocytes. In the control the reaction has extended little further than this. In the vaccinated animal, however, the way seems to have been prepared for an immediate and powerful reaction. All capillaries throughout the section are greatly congested, and contain many leucocytes. About the foci of bacilli the congestion is very intense, and at some points small hemorrhages have occurred. There is already some exudate containing a number of "epithelioid" cells; *i.e.*, cells with large, clear vesicular nuclei; and similar cells may be seen in the alveoli adjoining the tubercle. These latter are probably in part desquamated epithelium.

In the vaccinated animals, during the next two days, the number of these characteristically formed tubercles has materially increased, as well as their size. The "epithelioid" cells in the center of the tubercle contain numbers of tubercle bacilli. Occasionally these cells containing tubercle bacilli are seen in a neighboring alveolus, or capillary. The bacilli are thus more or less scattered, and are beginning to lose their brilliant stain and regular contour. There is also some evidence of nuclear fragmentation, and a clearer zone in the center of the tubercle, but no sign of necrosis.

In many places the newly formed cells have either coalesced, or their protoplasm has not divided, and we find giant cells made up of a large mass of protoplasm containing several more or less centrally placed, large, vesicular nuclei, and sometimes a number of tubercle bacilli.

At the end of the fifth day we find the lungs of the vaccinated animal very voluminous (not collapsible), very much congested, and speckled with large and small hemorrhagic spots, one or two as large as a pea. Numbers of minute, translucent tubercles can be plainly seen with the naked eye. Under the microscope these differ from an ordinary tubercle of the same size in the unusual amount of exudate and epithelioid cells; in the apparent degeneration of the bacilli in the center of each, and in the spread of exudate and number of "epithelioid" cells to the intervening septa and alveoli. The margins of these tubercles are intensely injected with blood, which, in many places, has escaped from the capillaries.

Where several tubercles are adjacent this congestion and extravasation cover quite a large area and become visible to the naked eye as the hemorrhagic spots already spoken of.

So far the controls have remained much the same as on the first day. The control of this date, the fifth day, shows only slightly greater congestion and density of the lungs than normal. There are no tubercles visible to the naked eye. Under the microscope numerous small tubercles can be made out, varying greatly from the vaccinated in that they are much smaller, contain little exudate, almost no cells of the epithelioid type, and many brightly staining tubercle bacilli, showing no signs of degeneration or inclusion in phagocytes. There is little or no reaction in the intervening septa.

It was thought the hemorrhagic spots spoken of might be due to the remains of the previous vaccination, as they were noticed only in the vaccinated animals, and were so pronounced and constantly present. Therefore, an extra vaccinated animal, which had received no virulent inoculation, was injected with 50 mg. tuberculin, at the same time as an unvaccinated animal which had received a test intravenous inoculation of the virulent culture three weeks previously. Both were killed on the following day. The former showed no reaction to the tuberculin; the latter, a slight one. On section the lungs of the vac-

cinated showed no hemorrhagic spots, and under the microscope no trace of the original vaccination could be found, except one or two very minute clumps of newly formed connective tissue cells, enclosing a couple of old, degenerate-looking tubercle bacilli, all that had remained of the vaccination at the end of sixty-eight days. The lungs of the second animal contained easily visible tubercles, well circumscribed, and with beginning caseation and numerous tubercle bacilli in the center, and a zone of hypercongestion about the periphery, perhaps due to the tuberculin. The hemorrhagic spots, therefore, are evidently a part of the intense reaction produced in the vaccinated animals by the injection of the virulent organism, and not due to any remains of the original vaccination.

The ensuing six pairs of animals were killed at intervals of about four days, and are especially interesting, as this period, from the fifth to the thirtieth day, seems to complete the mastery of the infection by the vaccinated animals and to usher in the final stage to complete absorption of all these inflammatory products, while in the unvaccinated animals the infection progresses gradually to the formation of chronic tuberculous lesions.

If we examine the lungs of the first of these vaccinated animals killed nine days after the virulent inoculation, we are struck by their great alteration, and would be inclined to conclude that the animal was under the influence of a very severe infection. The lungs are very dense and voluminous, do not collapse, are mottled, dusky pink in color, with here and there very dark red hemorrhagic spots. The surface is very irregular, where numerous, sometimes coalescing tuberculous nodules protrude. On carefully examining these they are seen to be of a somewhat more translucent, opalescent appearance than in the control. The lungs of the control of this date present very little alteration to the naked eye. They collapse a good deal, and are only slightly more congested than normal lungs. On careful examination minute, dense, gray-looking tuberculous nodules, scarcely perceptible to the touch, are visible to the naked eye, scattered through the lung tissue. On examining the lungs of the vaccinated animals under the microscope we find the large, opalescent, irregular nodules to be composed of several small, well-defined tubercles, bound together by a mass of exudate, epithelioid and desquamated cells, which fill up the adjoining alveoli and septa, the whole surrounded and permeated by extravasated blood, and highly congested capillaries, which are also packed with leucocytes. The whole has more the appearance of a pneumonia than the gradual, newly forming connective tissue of an ordinary tuberculous process of the same extent. The individual tubercles are filled with large epithelioid cells, with pale vesicular nuclei, with some polymorphonuclears, loosely held together by a plentiful homogeneous exudate. In the center of these is some nuclear fragmentation, but no appearance of beginning caseation. In this portion only are tubercle bacilli to be found, and there are very few indeed, and nearly all fragmented and degenerate-looking. All through these small nodules of exudate, cells and minute tubercles are seen many karyokinetic figures, and giant cells of the type spoken of above, evidences of great cell activity. All sizes and shapes of nuclei are to be seen. The tubercles in the control of this date are much like the previous one, and consist mainly of conglomerate small areas of leucocytic infiltration, containing little exudate, and few epithelioid cells, but many brightly staining, clearly defined bacilli.

The next two succeeding vaccinated animals, killed on the twelfth and seventeenth days, resemble very closely the preceding one. There is, however, a marked diminution in the number of tubercle bacilli, and in the latter one they are exceedingly hard to find. On the twenty-second day the gross appearance has little changed, but on microscopical examination we find a slight clearing up of the cellular exudate in the intermediate tissue, and that the tubercle bacilli have apparently disappeared. The small tubercles are often sharply circumscribed by a single layer of epithelioid cells, and there is, as before, much extravasation of blood within and surrounding them. All these last three animals showed a good deal of cellular detritus in the smaller bronchioles, and occasionally tubercle bacilli could be seen within some of these cells.

In the remaining two vaccinated animals a remarkable change has taken place in the absorption of the cellular exudate from the septa and alveoli lying between the small tubercles, so that this portion of the lung has nearly returned to its normal appearance. The tubercles themselves seem to be breaking up, the central portion dissolving out, while the peripheral capillary ring is reduced to slightly congested vessels, and a number of darkly staining leucocytes. Many of these tubercles have been reduced to nothing more than a few large, pale vesicular cells, surrounded by a small capillary ring whose limits are somewhat emphasized by a greater number of nuclei than normal.

As to the controls, it will be remembered that those up to the seventeenth day showed no very marked reaction. At this date, however, there is a marked advance. In gross appearance they are denser, grayer-looking than in the vaccinated; they are smaller and more sharply marked off from the surrounding tissue. Under the microscope these nodules are composed, like the vaccinated, of several small tubercles joined together by a cell infiltration. Their character, however, differs somewhat. There is less exudate, fewer epithelioid cells, more deeper staining leucocytes, and more cells resembling new connective tissue corpuscles. These last are especially marked in the intervening substance, which thus has a firmer, less succulent appearance. There is also

some karyokinesis. What is of more importance, there are, in the central portion of the individual tubercles, considerable fragmentation and necrosis, and numerous brightly staining tubercle bacilli. Few of these are within cells. In the next succeeding control, killed twenty-five days after inoculation, there is more fragmentation in this portion, with beginning caseation and many bacilli. In the intervening tissue are found numerous fibrous tissue corpuscles, and many giant cells of the small darkly staining eccentric nuclei type generally seen in beginning fibrous tuberculous tissue. In the last control a similar condition exists, though some of the tissue in between these conglomerate tubercles has cleared up, and rarely we may find a small tubercle undergoing resolution. The bacilli are still present in large numbers. It is to be regretted that more animals were not used in this experiment, so that the virulent infection could have been followed in its further stages.[1]

As an ultimate result then, at the end of thirty days, the lungs of the vaccinated are practically free from tubercle bacilli, and nearly entirely cleared of all signs of their invasion; in the controls, on the other hand, the great majority of the tubercles are still progressing, undergoing fragmentation and caseation, and containing many tubercle bacilli in their centers, while their periphery and intervening substance are apparently undergoing a change into more durable fibrous tissue.

Of the elements more or less specific of tubercle formation, I will consider, before closing the giant cells, the "epithelioid" cells and, lastly, the tubercle bacilli.

From the foregoing it will already have been noticed that giant cells of the type represented by a mass of protoplasm containing two or more nuclei, more or less centrally placed, appear in the vaccinated as early as the third day, and continue until the twenty-fifth, reaching their maximum in the seventeenth day, when also some giant cells of more eccentric type accompany them, and a good deal of evidence of cell division. In the controls, on the other hand, giant cells do not make their appearance until the twenty-fifth day, and are then nearly all of the type with eccentric dark staining nuclei seen in fibrous tuberculous tissue. It seems probable that the presence and numbers of giant cells of the vesicular nuclei type, like the nuclei of the "epithelioid" cells, have some dependence on the rapid appearance of large numbers of these cells at the foci of disease in the vaccinated animals.

These epithelioid cells, which appear in the earliest specimens of the vaccinated animals have a good deal of protoplasm, and large vesicular nuclei. It seems hardly likely that they are produced so quickly and in such large numbers from local elements. It is more likely that they come with the excessive exudate from the blood, containing vast numbers of leucocytes. These "epithelioid" cells possess great phagocytic power. From as early as the second day, many may be seen containing four or more tubercle bacilli, mostly in the tubercles, sometimes in an adjacent capillary or alveolus, and later in the smaller bronchioles. This is also true of the giant cells of this type.

The tubercle bacilli show early signs of degeneration in the vaccinated animals, and rapidly diminish between the fifth and ninth days, to disappear almost entirely by the thirtieth day. In a few sections, however, of the vaccinated animals, in spite of the care with which the emulsion was made, a very large clump of tubercle bacilli had lodged, making a more resistant focus, and out of all comparison with the surrounding process. These can be disregarded.

In the controls, on the other hand, although some tubercle bacilli are undoubtedly taken up and destroyed, they are still present in all the specimens in considerable numbers, and in the thirtieth day may be found, apparently little diminished in numbers and virulence, about the fragmentation and caseation which has begun to make its appearance.

In conclusion, then, it may be said about this manner of vaccination, that, within a given time at least, it prepared the way for an immediate and powerful reaction. Apart from the speed and intensity with which it develops, and the proportionate excess of exudate, and of epithelioid elements, this tubercle does not differ in cellular character from the tubercle of the control. It does differ, however, in its ultimate result in that it effects the death of the tubercle bacilli within it, and ends by being completely absorbed. It does not go on to caseation nor the formation of chronic tuberculous tissue. The reason for this must be sought in an increased bactericidal power of the exudate; in the increased capacity or numbers of the phagocytes, the "epithelioid" cells, or, as recent work has shown, a combination of both of these elements.

In these sections it was very difficult to determine the exact boundaries of the cells, and whether the bacilli were actually within or without them, so that a definite difference in phagocytosis between the vaccinated and controls was difficult to determine. Certainly there were much earlier definite evidences of it in the vaccinated, and it was easier to find cells that evidently contained bacilli in those specimens.

[1] The study of the stages up to the sixty-first day was made later on with the second series (See Part I), and in some animals absorption was still in progress on the fiftieth day; otherwise nothing new was developed.

Effect of Digitalis on the Normal Heart.—If medicinal doses of digitalis or strophanthus are given to normal individuals, a distinct slowing of the pulse will be obtained quite regularly, yet the blood-pressure remains within normal limits. A. FRAENKEL (*Münch. med. Woch.*, Aug. 8, 1905) finds however, that the blood-pressure will rise above the normal if the drug is given with atropine. It follows that the slowing of the pulse is the factor which acts against a rise in pressure.

THE VITALITY OF TUBERCLE BACILLI IN SPUTUM.

BY DAVID C. TWICHELL, M.D.,
OF SARANAC LAKE, N. Y.;
ASSISTANT RESIDENT PHYSICIAN OF THE ADIRONDACK COTTAGE SANITARIUM.

This experiment was undertaken to prove how long the tubercle bacillus would live in sputum under natural conditions, it being of interest to know for how long a period the tubercle bacillus in sputum, in articles such as handkerchiefs or in rooms or public places, may retain its vitality, and relative to the question as to the danger of sputum as a cause of infection.

Villemin[1] found that dried sputum preserved its virulence after several weeks. Experiments of Koch,[2] Schill,[3] Fischer and others, have shown that the bacilli retained their vitality in desiccated sputem for several months (nine to ten, De Thoma[4]) but they are said to undergo a gradual diminuation in pathogenic virulence, which is more rapid when the desiccated material is kept at a temperature of 30° to 40° C. Koch dried sputum at the temperature of the laboratory for four to eight weeks and found it still would produce tuberculosis in animals.[5] In his address before the Tenth International Medical Congress, Berlin, 1890, he stated that when exposed to direct sunlight the tubercle bacilli are killed in from a few minutes to several hours, according to the thickness of the layer. He also stated that they are destroyed by diffuse daylight in from five to seven days when placed near a window.

Malassez and Vignal[6] found that sputum alternately dried and moistened for twelve days was yet virulent. Sawizky [7] found that sputum, subjected to the ordinary conditions of the floors of a dwelling house preserved its virulence for a period of two to two and one-half months, and that there was no difference between the sputum obtained from dark corners and that which had been exposed to the sun's rays.

Migneco [8] found that sputum dried on handkerchiefs in the sunlight preserved its virulence for eighteen hours, whereas dried on woolen cloth in sunlight preserved its virulence for thirty hours.

Dr. Arthur Ransom [9] and Mr. Sheridan Delepine, in a series of experiments, found that sputum exposed to light and air for forty-five days in June and July did not produce tuberculosis when inoculated into rabbits; that sputum exposed in an air shaft at dusk during the same season produced slight tuberculosis; that the same sputum exposed at the same time to light and air produced no tubercle in a guinea-pig. The same methods employed, only at dusk, produced advanced tuberculosis. Another sputum exposed in April for sixteen days to little or no air in darkness, produced well-marked tuberculosis. Sputum dried on paper for twenty-four hours and placed in a dark, close cupboard for one day produced well-marked tuberculosis. Sputum kept under the same conditions and exposed to a little air for thirty-five days produced distinct local tuberculosis. Sputum placed in the air shaft of a draught-closet in a dim light, pure air passing through it for three days at ordinary temperature, caused well-marked tuberculosis. Sputum exposed to light for three days, with an hour of sunshine, good ventilation, and a maximum temperature of 50° F., produced no tuberculosis. Other sputum exposed to light for seven days, with fifteen hours of sunshine and brisk ventilation, did not cause tuberculosis. Again, sputum exposed to the light for two days after having been kept dried for four weeks (there had not been much exposure to sunshine and ventilation had been slight) produced no tuberculosis.

Cornet [10] says, "After about six months expectorated material contains not a single germ capable of further development."

The material used in our experiment was obtained by mixing in equal proportions the sputum of two patients, in whom the disease was actively progressing, so as to make reasonably sure of obtaining a virulent, strongly growing organism.

The number of bacilli present in the sputums used showed from vii to viii on Gaffky's scale.

The sputum from each patient was first tested by injecting 0.5 c.c. into the groins of two guinea-pigs. Ninety-one days later the first pig was killed. The pig was emaciated and showed a large open ulcer in the right groin. Tubercle bacilli were obtained from the ulcer. The inguinal glands were enlarged and caseated, and the spleen showed tubercles. After one hundred days the second pig was killed. On autopsy it showed generalized tuberculosis.

The following are the conditions in which the sputum was placed:

First.—Sputum deposited in sterilized, corked and paraffined white glass bottles (the bottles were 3 cm. in diameter and a depth of about 1 cm. of the mixed sputum was placed in each bottle); A, in a dark moist box; B, in a dark closet; C, in the diffuse light of an ordinary room; D, in the sunlight on glass plates (a fairly thin layer of sputum on a Petri dish); E, in the thermostat.

Second.—Sputum deposited in sterilized white glass bottles stoppered with cotton; A, in a dark, moist box; B, in a dark closet; C, in the diffuse light of an ordinary room; D, in the thermostat.

Third.—Sputum deposited in sand in sterilized white glass bottles: A, in a dark, moist box; B, in a dark closet; C, in the diffuse light of an ordinary room. Bottle corked and paraffined. D, in the diffuse light of an ordinary room. Bottle not sealed. E, in the thermostat. Bottle not sealed. F, in the thermostat. Bottle corked and paraffined.

Fourth.—Sputum deposited under ordinary room conditions on: A, handkerchief (folded); B, carpet; C, wood; D, woolen blanket (folded).

Fifth.—Sputum deposited in the open air during the winter months, in open, white glass bottles.

Sixth.—Sputum deposited in sterilized, white glass bottles, corked and paraffined; buried in the ground.

Seventh.—Sputum deposited in sterilized, white glass bottles, packed with ice, corked and paraffined, frozen in blocks of ice.

In the experiment with sputum exposed to sunlight, the specimens when not actually exposed to the sun's rays were kept in a dark box.

The experiment with the sputum placed in sand was not satisfactory. Many pigs died early of septicemia. The sand was not sterilized, and the reclaiming of the sputum from the sand was not certain.

The experiment with the sputum placed in blocks of ice was not entirely satisfactory, as it was not possible to keep the bottles frozen solid. At stated intervals, the sputum under these various conditions was tested by subcutaneous injection into the groins of guinea-pigs. 0.25 c.c. of the sputum was injected into both groins of each pig, and was introduced by a glass hypodermic syringe. The site of injection was washed with five per cent. carbolic acid, and the syringe was carefully boiled between each injection.

One pig was inoculated with each sample of sputum to be tested. If at the end of two to three weeks there was no enlargement of glands, a second pig was inoculated with the same material. After a certain length of time, usually from a month to six weeks, pigs, if still living, were killed. At autopsy, smears from glands and tubercles were made and examined under the microscope.

The following tables show the results of our experiments on the vitality of the tubercle bacillus in sputum under the various conditions as heretofore detailed:

Results were negative in the following instances. With the sputum in glass bottles, stoppered with cotton, placed in the diffuse light of an ordinary room (II*c*), the pigs inoculated at the end of 88 and 100 days died of unknown cause a few days after the injection. With the sputum in glass bottles stoppered with cotton, placed in the thermostat (II*d*), no pig was inoculated between 21 days and 101 days, so that experiment was of no use as a comparison with the other specimens of that set. None of the results with the sputum in sand (III) was entirely satisfactory, owing to the death of many pigs from septic infection a few days after inoculation.

The results were negative in the case of the sputum buried (VI). The pig inoculated after 102 days died at the end of two weeks with no sign of tuberculosis

This inoculation could not be repeated, as the specimen was destroyed by mistake.

Summary.—(I*a*) The tubercle bacilli in the sputum in paraffined bottles placed in a dark, moist box, were alive and produced a tuberculous lesion in a guinea-pig at the end of 170 days. No tuberculous lesion was produced after 188 days.

(I*b*) With the sputum in paraffined bottles, placed in a dark closet, a lesion resulted after 160 days, but not after 188 days.

(II*a*) With the sputum in bottles stoppered with cotton, placed in a dark, moist box, a lesion resulted after 157 days, but not after 172 days.

Ic) With the sputum in paraffined bottles, placed in the diffuse light of an ordinary room, a lesion resulted after 124 days, but not after 175 days.

(VII) With the sputum in ice a lesion resulted after 102 days, but not after 153 days.

(III*c*) with the sputum in sand, in a moist, light place, a lesion resulted after 123 days, but not after 148 days.

(II*b*) With the sputum in bottles stoppered with cotton in a dark closet, a lesion resulted after 100 days, but not after 141 days.

(V) With the sputum in open bottles, placed out of doors in the winter months, a lesion resulted after 110 days, but not after 132 days.

(IV*a*) With the sputum in a handkerchief, a lesion resulted after 70 days, but not after 110 days.

(IV*d*) With the sputum in a woolen blanket, a lesion resulted after 70 days, but not after 110 days.

(IV*c*) With the sputum on wood, a lesion resulted after 70 days, but not after 110 days.

(I*c*) With the sputum in paraffined bottles, in the thermostat, a lesion resulted after 33 days, but not after 100 days.

(IV*b*) With the sputum on carpet, a lesion resulted after 39 days, but not after 70 days.

(III*d*) With the sputum in sand, in a dry, light place, a lesion resulted after 30 days, but not after 70 days.

(I*d*) With the sputum exposed to direct sun rays, a lesion resulted after one hour, but not after seven hours.

It appears that the conditions most conducive to the prolonged life of the tubercle bacillus in sputum are darkness and moisture. In our experiment, the bacilli under these conditions were alive at the end of five and a half months. Dryness hastens their destruction. A temperature of about 37° C. is less favorable for them than ordinary room temperature. A temperature near the freezing point is less favorable for them than ordinary room temperature. The direct sun rays kill them in a few hours.

My acknowledgments are due to Dr. E. L. Trudeau for the opportunity to try this experiment, to Dr. Lawrason Brown for suggesting it, and to Mr. Edgar J. Higgins and Dr. A. M. Forster for their kind assistance.

THE SERUM DIAGNOSIS OF TUBERCULOSIS.[1]

BY HUGH M. KINGHORN, M.D.,
OF SARANAC LAKE, N. Y.

AFTER it was found that the serum of animals that had been injected with bacteria possessed agglutinating power over the same bacteria, and that the serum of man agglutinates typhoid, cholera, and plague if he suffers from typhoid, cholera, and plague, it was suggestive that the blood of tuberculous individuals would agglutinate tubercle bacilli. But tubercle bacilli offer a great obstacle to such an investigation, because they form in their cultures compact masses, which are already, to some extent, in an agglutinated condition.

Arloing overcame this difficulty by cultivating the bacilli for a considerable time on potatoes, till the cultures obtained a smooth appearance. He then transferred them to the beef broth with six per cent. glycerin. In this way he finally obtained a culture that grew evenly distributed throughout the liquid; that is to say, the culture became homogeneous.

Together with Paul Courmont, he found that homogeneous tuberculous cultures can be agglutinated by the serum of several kinds of animals, when these animals are inoculated by tuberculin or by attenuated cultures of tubercle bacilli. They also found that the normal blood serum of certain animals is able to agglutinate the homogeneous cultures, but with much less activity than when these animals are infected with the tubercle bacillus, or injected with its products.

A sufficient number of tests were made on human beings to convince them that the serum agglutination can be used in the diagnosis of tuberculosis, and they regard the test of equal value to Koch's tuberculin.

Many scientists of various nationalities have made publications absolutely confirmative and based on a large number of cases. Other investigators, and particularly in Germany, have obtained very different results. At the present time, however, the serum-agglutination test for tuberculosis is still in doubt.

The chief objections to the test are due to the following facts; namely, that the serums of quite a number of healthy individuals and of patients with other diseases are able to agglutinate homogeneous tuberculous cultures, and also that in some patients with well-marked symptoms of tuberculosis in the incipient or advanced stages the reaction is wanting.

In spite of these contradictory results Arloing and Courmont still firmly maintain that an individual whose blood serum agglutinates a homogeneous tuberculous culture at 1 to 5 is tuberculous, and if at 1 to 10 he is tuberculous without a doubt; and that the serum reaction reaches its highest grade of intensity when the lesions are slight.

The contradictory results are partly due to the differences in the cases tested. The general condition of the patient, and the stage and severity of the disease have great influence on the agglutination. The reaction can also vary during the course of the disease. In five far-advanced cases, four fail to react, while in thirty-eight patients which included healed, incipient, and advanced cases, five failed to react. In giving percentages, therefore, it seems fair to exclude the far-advanced cases, in which the diagnosis is plain without other means of help.

The chief reason for the difference in the results rests with the test culture used. In spite of the clear directions given by Arloing and Courmont, the preparation of the culture is extremely difficult, and it is very hard to have always on hand a culture at standard strength. In order to avoid this difficulty, Koch and Romberg have modified the method of Arloing and Courmont, and used emulsions of dead bacilli instead of living homogeneous cultures. These emulsions are much more easily prepared, and the results are much more uniform.

1 From the Saranac Lake Laboratory,

In the following tests the "A" homogeneous culture of Arloing and Courmont was the one used. It was kindly given by Dr. Paul Courmont during his recent visit to America. The tests were all made with cultures which were standardized as accurately as possible. Where there was any doubt that the culture was at standard strength the test was not counted.

The culture was grown in the following medium:

Peptone (Witte	20
Sodium chloride	10
Glycerin	40
Water	1000

This was neutralized with normal soda solution. This is the formula given by Dr. Paul Courmont, with the exception that Witte's peptone was used instead of Dufresne's (French peptone). The standard serum was obtained from a normal sheep, whose serum was found to constantly agglutinate at 1-25. Clear fresh human serum was used to make the tests. It was obtained either from the lobe of the ear or from a vein in the arm.

With each serum, mixtures of different strengths were prepared at 1 to 5, 1 to 10, 1 to 15, and so on; that is, to one drop of serum five drops of culture are added, etc. Or, else, it was done by adding to—

.2 of serum	.8 of culture (1-5)
.1 of serum	.9 of culture (1-10)
.06 of serum	.94 of culture (1-15) etc.
.04 of serum	.96 of culture (1-25)

Comparative tests were made with these methods, and as they were the same, the latter one was used. The former, however, is simpler, and can be used with better advantage when one has a small amount of serum.

When agglutination took place in a dilution of 1 to 5, the reaction was considered positive. The time limit given to the reaction was five hours, —not more. A well-developed, actively growing culture of a month's growth was removed from the incubator and placed in the ice chest. It was used for a month, or as long as it was agglutinated by the standard serum up to the proper dilution. The necessary quantities of culture were taken and diluted with normal salt solution (0.8 per cent.) until the mixture became slightly milky.

Agglutination was observed by the naked eye up to five hours. Results were considered positive only in those tubes which showed well-marked flocculi easily visible to the eye, and with subsequent sedimentation and clearing.

Results.—One hundred and twenty-four serums were tested. I found later, however, that the culture was not at standard strength in sixty-two of these, and they were excluded. Sixty-two, therefore, remain to be reported on.

Of these 62 cases, 43 were tuberculous, 12 were apparently in robust health, and 7 were more or less suspicious as having tuberculous disease. In these 7 there was no positive evidence of tuberculosis, and they were not tested with tuberculin. Of the 43 tuberculous cases 34 reacted and 9 failed; of the 12 healthy cases, 9 reacted and 3 failed; of the 7 *suspicious* cases, 7 reacted and none failed.

Of the tuberculous cases there were, 2 healed patients; 1 reacted and 1 failed; 3 patients that reacted to the tuberculin test, 3 reacted; 9 incipient cases, 8 reacted and 1 failed; 24 advanced cases, 21 reacted and 3 failed; 5 far advanced cases, 1 reacted and 4 failed.

It is thus seen that nearly all the more favorable cases gave positive reaction (*i.e.*, 86.8 per cent.), and that only one of 5 far advanced cases reacted.

The average agglutinating power of the tuberculous serums that reacted was 1 to 10, whereas the average agglutinating power of the healthy serums that reacted was 1 to 23.

Conclusions.—1. In far advanced cases with very extensive or virulent lesions the serum reaction is generally absent.

2. The reaction seems to appear most often with the most favorable cases.

3. A certain number of favorable cases with well-marked signs of disease fail to show any agglutination.

4. Nine out of 12 persons in robust health reacted to the test. Six of the 9 were in close contact with tuberculous patients.

5. In the tuberculous cases the average agglutinating power was 1 to 10; in the healthy cases the average agglutinating power was 1 to 23.

6. Up to the present time I do not rely on the serum test as being a sure and reliable one for the presence or absence of clinical tuberculosis.

MEDICAL PROGRESS.

SURGERY.

Scopolamine-Morphine Anesthesia.—M. G. Seelig (*St. Louis Med. Rev.*, Aug. 12, 1905) reports a series of sixty-five cases in which general anesthesia was preceded by the administration of scopolamine hydrobromate, grain 1-100, and morphine, grain 1-6, hypodermically. The general anesthesia was induced by means of the ethyl chloride-ether sequence. The series included the following range of cases: Abdominal hysterectomy, 8; vaginal hysterectomy, 6; hernia, 5; plastic operations, 8; operations on the tubes and ovaries, 11; uterine fixations, 6; curetterments, 6; hemorrhoids, 3; fistula in ano, 2; thyroidectomy, craniectomy, orchidectomy, appendicectomycostectomy, nephropexy, tumor of the breast, cyst of neck, pelvic abscess, exploratory laparotomy, one each. The author claims that as a result of his experience with this method, that he has never seen such good results with other methods. Of these sixty-five cases only one patient vomited or retched while on the operating table. Seventy-seven per cent. of the patients did not vomit at at all. One-third of the patients that did vomit, did so only once, and then only from two drams to one ounce of clear mucous. Nausea was never pronounced, except in two cases, and vomiting never occurred earlier than two hours after the operation. The quantity of anesthetic necessary was markedly lessened. After the administration of scopolamine-morphine the patients are in a peace-

ful state of mind, and go under the influence of the general anesthetic without passing through the usual state of excitement. Salivation is almost invariably absent, thus adding another safeguard against aspiration pneumonia. After their return to bed the patients lie absolutely quiet and awaken without the slightest excitation. The first twenty-four hours following the operation is attended by much less pain and discomfort than in cases where the scopolamine is not administered.

Parietal Motor Nerves in Abdominal Section.—The apparent lack of attention that is paid by the majority of operators to the trunks or distribution of nerves supplying the abdominal region is commented upon by V. P. BLAIR (*Interstate Med. Jour.*, August, 1905) who carefully considers the subject and who gives the best methods of incisions so as to avoid cutting these nerve supplies. The author states that in the severance of motor nerves of the abdominal wall, that large areas of the abdominal parietes are deprived of their contractile power, thus causing the unparalized portions to bring about compensation by extra effort. When this compensation is defective there will be a tax on the involuntary muscles, which, if too great, will result in exhaustion, imperfect function and neurosis. All motor nerves and their distributions should be carefully considered in making abdominal incisions. The least harmful is that made in the median line and in the linæ semilunares. In other incisions, especially when they have to be lengthened, the author lays great stress upon the fact that they should be enlarged by tearing by means of hooks on the fingers and not cut.

Ligature of the Innominate Artery.—In reporting a case of aneurism of the innominate successfully treated by ligaturing WILLIAM SHEEN (*Annal. of Surg.*, July, 1905) thoroughly reviews the subject. Seven times only has this operation been successful. The author's operation was as follows: Median incision from cricoid to one inch below sternal notch; the carotid and innominate exposed and freed; then a double floss silk ligature carried around the innominate distally and tied with Balance's "stay knot." Pulsation ceased, but later reappeared. A second similar operation also failed. The third operation was performed through a five-inch transverse incision above the clavicle. The artery was ligated twice proximally. Recovery uneventful. Abstracts of previous recorded cases are given. In 36 cases ligature has been accomplished; mortality 78 per cent. Of fatal cases 24 were due to sepsis and hemorrhage combined; 3 to sepsis alone; 3 to cerebral lesions; 1 to acute pericarditis; 1 to pus kidney and 1 to bronchopneumonia. Of recoveries only one occurred during the preantiseptic period. Conclusions drawn are: (1) in properly selected cases the operation is reasonably safe; (2) suitable cases are those of the globular and circumscribed variety; (3) the maintenance of asepsis is the chief factor for success; (4) the incision should be central with horizontal and vertical division of the manubrium, if necessary; (5) the carotid be tied also; (6) the ligature should be silk; (7) some injury of the inner coats is probably necessary to insure occlusion; (8) two ligatures, if possible, be placed; (9) drainage is inadvisable; (10) cerebral lesions stand next to sepsis as cause of death; (11) "Valsalvan" methods prior to operation are inadvisable.

Surgical Treatment of Colitis.—Following some preliminary remarks upon the classification of colitis and the physiology of the appendix and cecum J. E. SUMMERS, JR., says (*Annal. of Surg.*, July, 1905) physiologists are beginning to recognize the necessarily important part the appendix, cecum, and ascending colon take in digestion. The fad of the day seems to be that the whole colon is simply a sewer canal, but its importance in digestion is proven by its glandular structure. Any interference of function reacts, producing either appendicitis or colitis. An interesting and important topic is the observation by means of the X-rays and bismuth impregnated food that antiperistalsis is a constant factor in the digestive process of the large intestine. This admits of thorough mixing and absorption of the contents. Also experiments on the disposition of nutrient enemata, similarly conducted, demonstrated that these were ultimately carried to the cecum, absorption taking place chiefly above the descending colon. Anything which disturbs the antiperistalsis is apt to induce an inflamation of the colon. Surgically, colitis is divided into three classes; primary bacterial, secondary bacterial, and that induced by mechanical interference. Upon these causes hinges the surgical treatment, and if carried out intelligently, will be successful. It will not do to confine all cases to a right inguinal colostomy. This was first selected for bacteriological cases, but even here Gibson's operation has many advantages. In the appendicular forms of colitis removal of the appendix is all that is required in the explosive form. Whereas in the neurasthenic type of Deaver not only should the appendix be removed, but Gibson's fistula ought to be established. If this does not produce a return to health then some operation for exclusion must be done.

Thyroidectomy for Exophthalmic Goiter.—In a contribution comparing the surgical treatment of exophthalmic goiter, F. HARTLEY (*Annal. of Surg.*, July, 1905) reports 15 cases of partial throidectomy with 93.4 per cent. cures. In the literature there are five instances where symptoms have returned after operation. Tetany and sudden death have been known to occur during or just after operation. Medicinal treatment should precede surgical interference, because of undoubted cures, but should not be continued too long, since the disease tends to diminish the vital resistance and exhaust the nerve centers. Early operation is indicated in all cases as soon as medicinal treatment fails, and especially so where the disease is engrafted upon colloid goiter. The anesthetic used in this series was ether or gas and ether. The extirpation of the greater part of the growing gland is made in all cases. The method employed was Kocher's. Fourteen of these patients seen postoperatively are in good health; anxiety, nervousness and muscular tremor all gone, and in all but three cases the exophthalmos has disappeared. One patient died during operation; mortality, 6.6 per cent. Partial thyroidectomy is compared with sympathectomy; statistics given. Results are shown to be about equal, but with the advantage in favor of thyroidectomy, both as regards mortality and cures.

Tuberculous Lymph-Nodes.—The surgical treatment of tuberculous lymph-nodes, with a study of one hundred cases, is presented (*Annal. of Surg.*, July, 1905) by CHARLES N. DOWD. Three generalizations are important. (1) The disease is serious. (2) Thorough extirpation is better than partial removal or palliative measures. In 692 cases treated constitutionally, 29.2 per cent. later developed tuberculosis in other parts. (3) The prognosis is better in children than in adults. The disease usually begins insidiously. A majority of the patients live in unsanitary surroundings. The throat is the most common portal of infection. There is abundant evi-

dence that the bacilli can go through mucous membrane and infect lymphatics without leaving visible evidence of their transit. The diagnosis is not always easy. Syphilitic enlargement and simple hyperplasia often offer difficulties. The anatomical arrangement is considered with drawings. The operation is described under the following headings: (1) Incisions. (2) Structures to be removed and avoided. (3) Details as to time and wound treatment. The incisions are important. Disfiguring scars are and usually can be avoided. Longitudinal scars stretch and frequently thicken. Transverse scars following the neck-creases do not stretch, and after a short time are almost invisible. Description of incisions and accessible glands are given. The nodes are to be removed with as little surrounding tissue as possible. Structures to be avoided are the internal jugular vein, the spinal accessory nerve, and the lower fibers of the facial nerve. It is not often necessary to divide the sternomastoid muscle. Injury of the thoracic duct has been recorded. Plenty of time should be given to the operation, but it should not be unduly prolonged. For a child under twelve years it is seldom wise to continue longer than one hour at a time. Irrigation is desirable, and as a routine drainage is advised. The dressings should be bulky and changed daily. In this series there was no mortality; freedom from recurrence in 75 per cent., and ultimate recovery in 90 per cent. of the cases.

X-Ray in Malignant Disease.—W. B. Coley, basing his observations upon the result of over three years' tireless investigation, discusses (*Annal. of Surg.*, August, 1905) the value of the X-ray in the treatment of cancer, including sarcoma. During the time specified 176 patients were treated, as follows: 68 cases of sarcoma; 36 of carcinoma of the breast; 44 of epithelioma of the head, face and neck, including tongue; 14 of deep-seated abdominal growths, probably carcinoma; 5 not classified; 3 of tuberculous glands of the neck; 3 of Hodgkin's disease; 3 of lupus. In five cases of sarcoma there was complete disappearance of the growth, but in all it recurred a few months later. In two of these the recurrent growth disappeared under combined X-ray and toxin treatment, the patients remaining well to date. The 36 cases of carcinoma of the breast furnished nearly every variety of this disease. The treatment was almost wholly negative. In only one patient did the tumor disappear, and in this case the diagnosis was in doubt. Of the 44 cases of epithelioma of the head, face and neck, in only four did the disease disappear entirely. In every case in which there was glandular involvement, no improvement whatever was noticed, and the rays had little, if any, effect in retarding the disease. One patient suffering with Hodgkin's disease improved markedly at first, but later died suddenly. No autopsy. There was complete disappearance of lupus in two patients, and improvement in the third. In one patient tuberculous glands of the neck decreased in size; in one they disappeared, and in the third there was slight involvement. Reports from several other series of observations agree fully with this. Of late the X-ray as a preoperative measure has been advocated, the reason given being that the operative field is thus cleared. The fallacy of such reasoning is twofold: (1) It presupposes that the agent is curative, and (2) it takes for granted that no harm can come to the patient by reason of delay. Both of these arguments are pernicious.

PATHOLOGY AND BACTERIOLOGY.

Laryngeal Diphtheria Complicating Cerebrospinal Meningitis.—W. K. Simpson (*Med. Rec.*, Sept. 16, 1905) reports this case to demonstrate that cerebrospinal meningitis and true diphtheria may coexist in the same patient, and that the respective germs are not necessarily antagonistic. The patient, a married woman, aged twenty-seven years, was taken down with a classical attack of cerebrospinal meningitis. Twenty-one days later and while in the midst of her cerebrospinal symptoms she gave evidence of hoarseness, a croupy cough, and beginning laryngeal dyspnea. Examination of the larynx revealed the entire lumen filled with a distinct thick membrane. Intubation became necessary and subsequently large pieces of membrane were expelled through the tube, from which a pure culture of the Klebs-Löffler bacillus was obtained, confirming the diagnosis. During a period of nine days 30,000 units of antitoxin was administered, and since this case occurred at the time when the use of antidiphtheria serum was being advocated in the treatment of cerebrospinal meningitis, the effect was carefully noted. No appreciable influence was observed upon the course of the meningitis. Once during and twice after the period of serum treatment, lumbar puncture was performed, and in each instance there was found the characteristic *Meningococcus intracellularis*. It is possible to suppose that if diphtheritic antitoxin was in any way antagonistic to cerebrospinal meningitis its administration would show effect in the destruction of these cocci.

The Trichocephalus in Typhoid Fever.—Following up the observations of Gujart, Giuseppe Spezia reports (*Med. Rec.*, Sept. 16, 1905) nineteen cases of typhoid fever, in seventeen of which the eggs of the *Trichocephalus* were noted in the stools. The presence of the eggs seemed to have no special relation to the day of the disease or to the physical character of the feces. In other diseases, especially of the gastro-intestinal tract, these eggs are rarely seen. These observations lead to the conclusion that this intestinal parasite, from its ability to wound the intestinal mucosa, plays an important rôle as a predisposing etiological factor to typhoid infection. That the development of the *Trichocephalus* is not a natural consequence of this disease is disproved by the fact that the growth of the parasite from the egg in the stomach to its adult stage covers a month and more; whereas the eggs are found in typhoid stools during the first few days.

Etiology of Syphilis.—In order to become acquainted with the appearance of the *Cytorrhyctes luis*, J. Siegel (*Münch. med. Woch.*, July 11, 1905) states that it is absolutely necessary to become familiar first with the artefacts which are liable to be found in normal blood. If a drop of normal blood be examined under a cover-glass with a high power, small, movable granules and filaments will soon separate out owing to the breaking down of the cells. In syphilis the structures have a more definite shape and size, and are much more refractile. The more characteristic forms are distinctly flattened and pear-shaped and possess a rapid, jerky motion owing to the presence of flagellæ. This motion will at once cease if a small amount of chloral hydrate is added to the blood. On permitting the blood to dry out under the cover-glass, a distinct nucleus with 2 to 16 refractile granules will be evident. The organisms are most numerous in

the blood during the second and third week of the disease, and are particularly abundant in the secretion of the primary sore. The staining is rather difficult, but the nuclei are brought out well by a combination of hematoxylin and azur, while the flagellæ are rendered prominent by the older method of Giemsa for plasmodia. Proof that the organisms stand in definite relation to syphilis is to be found in the fact that they occur in large numbers in the blood of apes which have been inoculated with syphilitic virus. Some further notes on the *Spirochæta pallida* are to be found in an article by C. THESING (*Münch. med. Woch.*, July 11, 1905). This author denies all etiological relation, and states that in many cases the spirilla are not derived from the interior of the lesions, but from the surface of the skin or from the stain, which harbors many organisms unless boiled shortly before use. Structures corresponding in every way to the organisms described by Schaudinn and Hoffmann were also found in the smegma of absolutely healthy individuals.

Blood-Pressure Observations for the Practising Physician.—CLINTON E. BRUSH (*Am. Med.*, July 15, 1905) speaks of the importance of using a cuff at least 12 cm. wide, as the error in cuffs that wide or wider may be disregarded. The importance of obtaining both diastolis and systolic pressures is emphasized—the method of Strassburger for determining diastolic pressures being deemed sufficiently accurate for ordinary work. He concludes (1) both systolic and diastolic pressures should be taken. (2) The cuff on the instrument should be at least 12 cm. wide. (3) With the wide cuff the normal systolic blood-pressure for the healthy adult male is nearer 110 mm. Hg. than it is 130 mm. Hg. (4) The chief value of blood-pressure observations lies in the lead they give in regard to indications for and results of treatment. (5) In a few conditions they are of diagnostic value. (6) In many conditions blood-pressure observations are of no practical value.

Pathogenesis of Myelogenous Leucemia.—Myelogenous leucemia is characterized by A. JOUSSET (*Arch. de Méd. Exper.*, July, 1905) as a chronic septicemia whose infective agent causes definitive lesions in the hemapoietic organs, lesions which survive the infection and which imprint their special seal upon the syndrome. The author has isolated a number of germs in this condition, but does not believe that they are specific. What is really specific is the mode of reaction of the tissues.

Effect of Experimental Cholemia in the Cardiac Ganglia.—It is well known that bradycardia frequently results from icterus; the question presented itself to R. MALATESTA (*Arch. de Méd. Exper.*, July, 1905) whether this condition might not be due to pathological changes in the cardiac ganglia. With the object of deciding this question he experimented in rabbits, producing an icterus by means of ligatine of the common duct. Examination of the cardiac ganglia revealed a peripheral chromatolysis, which gradually extended throughout the entire cell body, a coloration of the achromatic substance, a vacuolization of the cell-body and a production of a homogeneous condition of the nucleus. In some cases the cardiac ganglia are not affected. The author does not believe that the bradycardia is due to the pathological changes in the ganglia. These changes are found likewise in other parts of the nervous system, and so far as they affect the cardiac ganglia, they are not severe. Similar changes have been found in intoxications that result in a rapid pulse.

Bacteriology of Bronchitis.—The sputum of bronchitis, secondary to heart disease or emphysema, has never been found absolutely sterile by J. KARCHER (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 3 and 4), but as a rule the germs present were scant in number and of diminished vitality. Streptococci and staphylococci were most numerous, less often pneumococci were encountered. In acute and subacute processes, the bacteria were more abundant, but as a rule the same varieties predominated.

Influence of the Roentgen Rays on Leucemia.—In order to study the effects of the Roentgen rays on leucemia, J. LOSSEN and P. MORAWITZ (*Deutsch. Arch. f. klin. Med.*, Vol. 83, Nos. 3 and 4) studied the blood, urine and wherever possible the organs. Thus in a case of myelogenous leucemia the leucocytes had returned to the normal number and the excess of uric acid in the urine disappeared, so that the white cells were probably formed less abundantly in the hematopoietic organs. In other cases, however, where an extreme leucopenia resulted, the percentage of uric acid remained unaltered. Under the influence of the X-rays the proportion of the different forms of leucocytes may return to the normal or, on the other hand, an aplastic leucyemia may result. The organs very often show a decided hypoplasia.

Pathogenesis of Icterus.—S. ABRAMOW (*Virchow's Archiv*, Vol. 181, No. 2) has applied special staining methods which have enabled him to trace the course of the finer bile capillaries in the liver in various pathological processes accompanied with jaundice. Normally, the epithelium of the capilliaries is soon replaced by a mere cuticle border. The capillary itself courses in the axis of the acinus and constantly anastomoses with neighboring capillaries. Small branches are given off throughout the entire interacinous course, which enter the cells and often end blindly near the nucleus. Wherever the flow of the bile is impeded owing to the presence of a stone or a tumor involving the biliary ducts, extreme dilatation of these blind ends will occur so that they extend to the vascular border of the cell. Eventually rupture takes place, so that the bile has free access to the perivascular, lymphatic spaces. It has been found, however, that an obstructive jaundice is also possible if the thoracic duct is ligated; this is explained by the fact that the dilated capillaries will exert pressure upon the accompanying blood vessels and erode their walls. The icterus of cirrhosis of the liver is due to compression of the finer bile-capillaries by connective tissue while the icterus of heart disease is partly explained by connective tissue, partly by the formation of thrombi of inspissated bile, which impede the flow downward. In destructive processes in the liver, such as accompany tumors, it is evident that the walls of the bile-capillaries may be eroded and that the bile may find free access to the perivascular spaces. Lastly, jaundice may be a symptom of pure functional disturbance of the liver, as in infectious diseases and in icterus neonatorum. In these cases it is likely that the cells themselves are at fault and that there is an increased production of bile with possibly a diminished pressure in the capillaries.

Staining Leucocytes in the Counting-Chamber.—In order to obviate the examination of a smear to obtain a differential leucocyte count, W. RIEBES (*Münch. med. Woch.* Aug 1, 1905) employs the

following solutions: (1) Methylene blue, 0.05; formalin, 1.0; distilled water, 100.0, to which are added three drops of formalin. (2) Eosin, 0.05; formalin, 1.0; distilled water, 100.0. The first solution is sucked up five times to the mark 1 of the pipette and once to the mark 0.5, then blown into a clean glass dish. The blood is then sucked into the pipette up to the desired height, then diluted with the above amount of methylene blue solution, and finally with the eosin solution up to the mark 101. By allowing the first solution to act before the second, a satisfactory staining of all the elements in the blood will always be obtained.

EYE, EAR, NOSE AND THROAT.

Voluntary Iris.—J. W. SHERER, *Journal A. M. A.*, May 6, 1905) reports a case of this rather rare condition. It was first noticed at the age of nine, when the child developed the power of voluntary rotating the eyeballs independently. After that it became a matter of common observation that the iris could be dilated at will, almost to the disappearing point. At puberty the right iris was for awhile twice the size of the other, but later they became equal again. The power to stimulate convergent strabismus is possessed by the woman to a remarkable degree. Vigorous exercise of the iris movements seem to cause slight aching of the eyes, but no other inconvenient symptoms are reported.

Cause of Progressive Myopia.—Myopia is a result of deficiency of the posterior half of the sclerotic generally due to absence or poor development of the elastic fibers, which normally are very abundant. The lateral pressure, exerted by the external muscles of the eye, will causee a bulging of the posterior pole, as a result of which the sagittal axis will become longer. The thickness of the sclerotic is also of importance, since a thin layer will hasten, a thick one retard, the process. The stretching of the sclerotic at the posterior pole will also cause tension of the internal tunics, hence diminished visual acuity. This tension may, however, be also due to deficiency of the circular portion of the ciliary muscle. In this case, the longitudinal fibers will cause tension during accommodation. According to G. SEGGEL (*Münch. med. Woch.*, May 2, 1905) all three defects (absence of elastic fibers, thin sclerotic, deficiency of circular muscle fibers) are congenital and inherited, and all three, or the first and second, are responsible for progressive myopia. Proper glasses will not prevent, but may inhibit, the process.

Importance of Lumbar Puncture in Ear Complications.—Before the popularization of lumbar punctures, there has often been considerable doubt in the minds of ear specialists whether in the presence of certain symptoms an operation was indicated or whether a meningitis was already present. C. GRÜNERT (*Münch. med. Woch.*, June 20, 1905) states that it is the duty of all ear specialists to familiarize themselves perfectly with the simple technic of withdrawing lumbar fluid. A clear fluid, evacuated drop by drop, will argue directly against a meningitis and may urgently demand an operation since the symptoms may be due to a brain abscess or other circumscribed suppuration, and the patient may thus be saved. On the other hand, a turbidity, even if very slight, almost always means the death warrant for the patient; since, however, a few cases have been known to recover, it is always best to identify the bacteria present. Streptococci and tubercule bacilli are always more serious than pneumococci. Since the bacteria often stain poorly in the fluid, it is best to employ the dyes for at least half an hour. Occasionally it may be necessary to resort to culture methods or to inject animals. The only bad after-effects ever observed are due to hemorrhage and to the sudden fall of intracerebray pressure. As a rule they are not severe and rapidly disappear.

Traumatic Lesions of the Eye.—F. W. MILLER (*Journal A. M. A.*, Aug. 5) remarks on the various possible traumatic injuries of the eye and their causes, and the necessary classification into recent and old cases, according to whether they are seen before or after the exudates of plastic lymph during the first few hours. The chief danger in these cases, he states, is infection, though hemorrhage is often troublesome and may be very destructive. In non-penetrating and recent cases only can an expectant attitude be assumed. Every penetrating wound must be considered as probably infected and treated as such, so far as possible. The vigorous measures used in general surgery are unfortunately not all applicable to the delicate structures of the eye. Miller speaks very highly of the subconjunctival use of cyanide of mercury, according to Darier's suggestion, in these cases. It should be used early, and not merely as a last resort. Another remedy which he considers exceedingly valuable is dionin, not only for its analgesic properties, but also for its ability to clear up exudates and opacities. Individual treatment and conservatism are necessary as a rule. The question of enucleation arises in severe injuries, and great care and judgment should be used in its decision, especially in case of children whose orbital development may be affected. In case of burns, special effort should be made to prevent disastrous cicatrices and adhesions. In all doubtful cases consultations are desirable and prognosis must always be most guarded.

PRESCRIPTION HINTS.

Non-Operative Treatment of Nevus.— NEUMANN (*Deutsche med. Woch.*, No. 20, 1905) uses an emulsion of pure and dried chloride of zinc (5 to 10 per cent.) in elastic collodion. This is painted with a camel's-hair brush over the nevus, the surrounding skin being protected by strapping. When the collodion is dry, a bandage is applied, which remains on for eight days. The scab is then found to be shed. Any remains of the nevus are covered with gauze, on which has been spread the following ointment:

R Acidi Arsenici, Sulphur depur aa 3i
Ung. cerae 3iii

This is kept on for three days and the necrosed tissues scraped away with a sharp spoon. This is repeated until the nevus has disappeared.

Nervous and Reflex Vomiting.—

R Bismuthi subnit. 3i
Cerii Oxalat. 3ss
Glycerit ac. carbol. (1-4) mxx
Ips. chloroformi, Tinct. cardamom. comp. aa f 3i ss
Aquae menthae pip. f 3iv
Aquae calcis q. s. ad f 3ii

M. Sig. Teaspoonful in a tablespoonful of water every hour till relieved. (Reed.)

Acute Otitis Media.—

R Stovaine gr. iii
Resorcin gr. ii
Glycerin 3ii

M. et Sig. Pour seven or eight drops into the ear every two hours. (G. Laurens.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor.
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	8.00

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, SEPTEMBER 30, 1905.

THE STUDENT LIFE.

To stand upon a mountain above the plain of life and to see one's possessions narrow toward the vanishing point of human perspective makes a philosopher of the meanest of us. And the more often we mount above our daily level the more clearly do we see our relations to our fellow men and theirs to each other. The man who knows these sensations of clear vision and secure wisdom which sweep over him when he sees the world of river and plain as it really lies, will perceive an analogous pleasure in standing for a moment with Dr. Osler as he takes a last look at his once familiar surroundings in Canada and the United States.

In reading his farewell address to Canadian and American medical students, printed in this issue of the MEDICAL NEWS, we feel a thrill of comprehension as he points out one by one the various kinds of lives that lie before the medical profession, and outlines the possibilities of extending the boundaries of one's narrow lot by study. What has already been done lies clearly mapped out at our feet, and as he points to the type of student that has blazed the path and laid the first foundations in the crude soil, we are tempted to think that there is no undiscovered country for the genius to open up. But so familiar is he with the mountain-top, so keenly observant of the march of affairs, that when he indicates in what direction the newest developments lie we are eager to follow his guidance.

It is to the country practitioner that Dr. Osler draws attention. The small town and the country-side has sent its best men to the city, hoping often in vain for their return. And when they have come back their enthusiasm has not been able to stand the strain of the years of waiting. With the student habits which he advises, with the books and laboratories which it is possible to possess even with a limited income, and with the fervent spirit of inquiring, studying and testing every case that comes along, the young practitioners in small towns and country places could, in the course of a generation, change the whole face of medicine in the country.

THE ETIOLOGY OF YELLOW FEVER.

THE recent publication of a "preliminary report on cells found in yellow fever blood, with reference to their etiologic and diagnostic significance," by Drs. Pothier, Hume, Watson and Couret, of New Orleans (*Journ. Am. Med. Assoc.*, Sept. 23, 1905), calls for more than passing comment in view particularly of the wide publicity accorded the report by the activities of the Associated Press.

The belief that the cause of yellow fever has definitely been hunted to the ground, fostered by the specific assertions of the press notices, rests as yet on very insecure foundations.

In the report alluded to the authors state that a careful study of the blood of patients with yellow fever shows certain cells, heretofore undescribed, which undergo developmental changes and which can further be demonstrated in the stomach of a recently infected *Stegomyia*. These parasites are described as extracellular, groups in twos or more, approaching in size from twice the diameter of a pneumococcus to one-fourth the diameter of a red blood cell. They are ovoidal or spherical in shape and are composed of a highly neutrophile granular protoplasm with one or more chromatin staining nuclear masses. A capsule is observed particularly in what are assumed to be older forms. The authors describe four types varying in some minor technical details as to shape, size and staining qualities.

Since the classical filtration experiments of Reed and Carroll (*Am. Med.*, Feb. 22, 1902)

there is little escape from the conviction that the blood in yellow fever contains an infectious parasite which can pass through a Berkefeld filter capable of holding back the minute *Staphylococcus aureus.* This does not à priorily negative our present findings, however, since it may be possible that the newly described organisms may in some stages of their growth be sufficiently small to pass through. Certainly the comparatively large organism described could not pass through the filter test as devised by Reed and Carroll.

It may be recalled that in the report of Working Party Number 1 of the Yellow Fever Institute, Drs. Pothier, Parker and Beyer (Yellow Fever Institute *Bulletin* No. 13, March, 1903) claimed to have found a minute body, which they termed the *Myxococcidium stegomyiæ,* and which was held by them to stand in etiological relationship to the disease, having been found in the blood and in the stomach of the *Stegomyia.* We cannot escape the conviction that the present discovery is a rehabilitation of the claims of one of the members of this working party at least, although this preliminary report does not make any specific mention of the *Myxococcidium.* The description of the organisms is very similar, however.

The claims regarding the *Myxococcidium* have been fairly well sifted and found wanting, both by Working Party Number 2 and by the French Commission headed by Marchoux (*Bulletin* 14, Yellow Fever Institute, 1905, and *Ann. de L'Inst. Pasteur,* Nov., 1903). Both of these groups of investigators found the bodies described, but they were practically unanimous in showing that so far as the organism in the mosquito body was concerned the *Myxococcidium* was probably a commensal yeast, the *Saccharomyces apiculatus,* a very common growth in many mosquitoes. Further, if Schaudinn's suggestion is correct (*Arb. a. d. k. Gesundheitsamte,* 1904), that the inflammation of mosquito bite is largely due to the development of these same yeasts in the human skin it is not impossible that the *Saccharomyces apiculatus* may be the organism recently described as the etiological factor. Certainly the description as recorded by Drs. Pothier, Hume, Watson and Couret are remarkably like those of certain forms of wild yeast.

When the further evidence is borne in mind that scores of investigators have studied the blood smears by modern technical methods, it does not seem probable that so potent an organism as the one described would have slipped by unnoted. We prefer to reserve our judgment and wait for confirmation of the recent findings.

"TIT TAT TO."

California is certainly one of the most prolific states in the Union. Exuberant in her growths and redundant in her productions it is hardly to be wondered at that lavish nature should at times overstep the bounds of conventional habit and become forgetful of her accustomed limitations.

This is all the more natural when we remember that even in the effete East she is at times guilty of a playful hyperplasia that is evinced by the production of the race of double-toed cats which is indigenous to the stern and rock-bound coast of New England, while the appearance of an occasional and superfluously extra finger on the infantile hand of the far North is an event that demands little more than the registration of the fact in the local news of the country paper.

Remembering these facts, therefore, we are not surprised by the announcement in the columns of the *Oakland Clarion* that Miss Isabelle Lefevre, of 661 Madison Street, Oakland, Cal., is the proud and undisputed possessor of three tonsils. Whether she was born with them, whether she achieved them, or whether they were thrust on her, the report does not state. As three of a kind, however, are better than a pair, particularly in California, the late Mr. Jack Hamlin, or Mr. John Oakhurst, would probably claim that she obtained them in the "draw." The fact, however, remains, according to the story of our esteemed lay contemporary, that Miss Lefevre has reached the age of fifteen years and that she not only still holds them, but that their possession has caused her to become a "stand-patter" of the most uncompromising type.

The indictment against Miss Isabelle, which is brief, is as follows: "Miss Lefevre has three tonsils; she stays out nights with undesirable companions. She is wayward in practice and will not go to school." As to the number of tonsils, we are, as we say, with certain reservations, willing to accept it, but we do not quite see the connection between the third tonsil and the habit of nocturnal ramblings with undesirable companions, nor do we know what the standard of desirability of "gentlemen friends" for girls

of fifteen years to "stay out nights" with is. Whether the good people of this California resort gauge it by age, sex or previous condition does not appear in the report, and there is no mention of the time at which Miss Lefevre was accustomed to return. It seems evident, however, that curfew does not ring at Oakland.

As to the third and last count, that she is wayward in practice and will not go to school, the charge is luckily more explicit, for were it not for this it might have been easily imagined that she was merely a truant bird who thought her home a cage, while it is in the evidence that Judge Hall had, because of her behavior, seen fit to put her under the care of the probation officer. Meanwhile Miss Helen Swett, one of the vice-presidents of the Associated Charities, imbued with the idea that practice might prove more efficacious than preaching, took the girl to one Dr. Louise M. Tenny, who found that "she was suffering from an adenoid growth or third tonsil at the upper end of the pharyngeal cavity behind the palate." This the good doctor has "watched most carefully," and is now convinced that the patient's waywardness is due to the abnormal growth in the throat. For, it is explained, "the third tonsil hinders the flow of blood to the brain. In this view starvation of the brain affects moral responsibility, and the observance of the Ten Commandments depends in large measure on this physical condition."

And it is right here that we draw the line. We can readily understand that a girl who is wayward in practice and who has a penchant for "staying out nights" with questionable companions might easily break one of the Ten Commandments. Nay, we will go even farther, and if Dr. Tenny is such an insatiate archer that one would not suffice, we must admit for the sake of argument that she might knock the corners off of even another, but that the adenoid would cause a total disregard for the observance of the entire *ten* seems to us to be stretching the matter of tonsils a little too far.

As, however, Dr. Tenny seems possessed of some of the earmarks of an authority on the subject, it may be that the tonsil of the West differs in magnitude from the tonsil of the East. All flesh is not the same flesh, and the glory of the California adenoid may be terrestrial and sown in corruption. For Dr. Tenny explains that its removal almost invariably has an extraordinary influence on the mentality and morals of those on whom the operation is made. Children with vicious, wayward tendencies, on recovering from it, frequently show an entirely different and much improved disposition. "The reason for this," she thinks, "is more physiological than psychological. It removes a drain on the vitality; it eases and destroys what has always been a source of irritation. The brain, as well as the whole system, is, of course, better nourished as a result of the removal of the abnormal growth."

All this seems reasonable when applied to a large tumor, or to one that is exerting pressure, but that an extra tonsil in the pharynx will give rise to reflex action in the brain sufficient to cause a patient to run amuck with the whole series of the Commandments seems to be of the nature of a very tall oak grown from a very little acorn. Then, too, it is most easy to understand that any child of fifteen years would much prefer to take her doll clothes and "play" with companions of her own age, no matter how objectionable, than to be either mothered by the "probation officer" or fathered by Miss Swett or the Associated Charities. There is no evidence of total depravity in this, so that, taking one consideration with another, remembering the ordinary symptoms of adenoid trouble, and bearing in mind the enormities that this girl is charged with, we feel that we must look deeper for some more plausible etiology.

Far be it from us to question the professional acumen of a sister practitioner, or to cast aspersions on her diagnostic ability. But in view of the peculiar manifestations of this case, the indifference to the Mosaic law and the propensity to "stay out nights," is it not possible that when the case was presented to Dr. Tenny, that the gentle Louise touched the harp lightly on the absence of some inward spiritual grace, while she bore, with an all too heavy hand, on the outward visible sign of the three little tonsils "all in a row?"

ECHOES AND NEWS.

NEW YORK.

The Herter Lectures.—The Herter Lectures, established by Dr. C. A. Herter at the New York University and Bellevue Hospital Medical College, will be given this year by Prof. Carl von Noorden, Chief of the City Hospital of Frankfort-a. M., Germany. His subject will be Diabetes. The lectures, six in number, will be given in English in the large auditorium of the Carnegie Laboratory, 338 East Twenty-sixth Street, from Monday, October 9, to Saturday, October 14, inclusive, at 4 o'clock in the

afternoon. Visitors are welcome to these lectures. Reserved seats to be had on application to the college.

Convention of Homeopathic Medical Society.—The twenty-ninth semi-annual convention of the Homeopathic Medical Society of the State of New York opened at Syracuse, September 26, with a large attendance. A special committee made a report which favored action against "scare" advertisements, inducing persons to believe they suffer from disease, many of which the committee regarded as immoral. The matter of health qualifications for marriage was not taken up, Secretary H. Worthington Page, of New York, stating that it was impossible to get desirable legislation to the end sought, and nothing would be done.

A Weather Guessing Contest.—T. R. Fast, a lawyer, of this city, writes: "As an amateur farmer I am interested in the weather. I have gathered meteorological data for years, but as yet have not found the slightest basis on which to ascertain the state of the weather even twelve hours ahead. The Government weather predictions are very faulty; and as many laymen claim they can predict the weather more accurately than the weather bureau, without any of the elaborate apparatus of the Government, I hereby appeal to all the weather prophets of this country to enter a thirty-day contest for a cash prize of $100, which I will give to whoever predicts the weather most accurately, and will tell for the benefit of the public by what methods he arrived at his conclusions.

Society of Sanitary Prophylaxis.—The program of the October meeting of the Society of Sanitary and Moral Prophylaxis will be as follows: (1) Should the youth of the country be educated in a knowledge of sexual physiology and hygiene? (2) What should be the nature and scope of this education? (3) At what age should this instruction be given, and should it be progressive according to the age of the individual? (4) Through what agencies should this instruction be given—through parents, physicians or teachers? Should our educational centers—high schools, colleges and universities—be utilized for this purpose? (5) Should the teaching of sexual physiology be incorporated in our textbooks of elementary hygiene? As the educational feature of the society's work is an important one, the Executive Committee would be glad to have a general expression of opinion from the medical profession as to the availability and practical value of this proposed education. Physicians who have given serious thought to the subject are invited to send to the Secretary their views upon any or all of the questions submitted for discussion. Such communications will be analyzed and tabulated and form the subject of a report by the Committee on Education.

Harvey Society.—This new society for the diffusion of the knowledge of the medical sciences offers the following as its first course of lectures for 1905-1906, which are to be given under the patronage of the New York Academy of Medicine: Oct. 7, Prof. Hans Meyer, "Die Theorie der Narcose" (in German); Oct. 14, Prof. Carl von Noorden, "Modern Problems of Metabolism;" Nov. 4, Prof. F. G. Novy, "Trypanosomes;" Nov. 18, Dr. P. A. Levene, "Autolysis;" Jan. 20, Prof. W. H. Park, "A Critical Study of Serum Therapy;" Jan. 27, Prof. Lewellys F. Barker, "The Neurones;" Feb. 2, Prof. F. S. Lee, "Fatigue;" Feb. 9, Prof. L. B. Mendel, "The Formation of Uric Acid;" Feb. 16, Prof. T. H. Morgan, "The Extent and Limitations of the Power to Regenerate in Man and Other Vertebrates;" Feb. 23, Prof. Charles S. Minot, "On the Nature and Cause of Old Age;" March 2, Prof. J. C. Webster, "Modern Views Regarding Placentation;" March 9, Prof. Theobald Smith, "Some Phases of Tuberculosis;" March 16, Prof. W. H. Howell, "The Cause of the Heart-beat." The lectures will be held in the Academy of Medicine at half-past eight on the above Saturday evenings during the winter. In the Sorbonne at Paris courses of lectures by distinguished Frenchmen and men of other lands are given with the object of bringing science before those engaged in practice and art of various pursuits. The aim of the Harvey Society is similar in character. The Harvey Society invites all interested to attend this course. Dr. Graham Lusk is the President of the new society.

Conference of Sanitary Officers of the State of New York.—The fifth annual conference will be held in the Capitol at Albany, October 4 and 5, 1905. The following program has been arranged: Opening session, Wednesday, October 4, address of welcome by Hon. F. W. Higgins, Governor of the State of New York; address by Dr. Eugene H. Porter, State Commissioner of Health; address by Hon. Julius M. Mayer, Attorney General of the State of New York.

Evening session, October 4. "State Assistance in the Local and Institutional Control of Contagious Diseases," by Dr. F. F. Westbrook, Director Laboratory, State Board of Health, Minneapolis, Minn., President American Public Health Association. "Pathology of Diphtheria" (illustrated with lantern slides), by Dr. Richard M. Pearce, Director Bender Hygienic Laboratory, Albany, N. Y. Discussion.

October 5, morning session. "Statistical Studies of Pneumonia and Typhoid Fever," by Dr. John S. Fulton, Secretary, State Board of Health of Maryland, Baltimore, Md. "Status of Pneumonia and Cerebrospinal Meningitis as Contagious Diseases," by Dr. William H. Park, Director Bacteriological Laboratory, Department of Health, New York City. "Some Isolated Outbreaks of Cerebrospinal Meningitis in New York State," by H. D. Pease, Director of Antitoxin Laboratory, State Department of Health, Albany, N. Y. Discussion opened by Daniel Lewis, M.D. In the afternoon of October 5, at one o'clock, the guests and members of the conference will take a special train at the Union Station and proceed direct to the new sewage disposal plant of the village of Saratoga Springs, as guests of the State Department of Health. "The Pollution of Streams and the Natural Agencies of Purification" (illustrated), by Mr. George C. Whipple, New York City. "The Purification of Public Water Supplies" (illustrated), by Mr. Robert Spurr Weston, Boston, Mass. "Water Resources of this State Available for Potable Water Supplies," by Prof. O. H. Landreth, Consulting Engineer, State Department of Health. "Description of Methods for the Collection of Samples of Water for Chemical and for Bacteriological Analysis," by Dr. Willis G. Tucker and Dr. R. M. Pearce.

PHILADELPHIA.

Medical Ethics.—At a stated meeting of the Philadelphia County Medical Society, held June 21, 1905, a resolution was adopted conveying a request that all medical schools furnish their senior class with a special course of lectures or addresses upon the subjects of Medical Ethics and the Business Aspect of

the Practice of Medicine, and including the recommendation that graduates promptly join the local County Medical Society.

To Take Charge of the Research Work at Wistar Institute.—During the months of January, February and March Dr. Henry H. Donaldson, professor of neurology at the University of Chicago, will have charge and will conduct the entire work at the Wistar Institute. The appointment of Dr. Donaldson was made upon the recommendation of the Advisory Board, which is composed of some of the most eminent anatomists of this country.

Debarred From the Use of the Mail.—The postoffice authorities at Washington, D. C., have instructed Postmaster McMichael to prevent certain "drug and remedy" companies from using the mail. The order is based upon the results of the investigation of the postal inspectors, who have determined that the business of these so-called "drug and remedy" companies is of an illegitimate and fraudulent nature. S. Regan, of 217 Drexel Avenue, Atlantic City, is denied the same privilege.

Meeting of the Pathological Society of Philadelphia.—The Pathological Society of Philadelphia held its regular meeting Thursday evening, September 28, where the scientific program was offered by Dr. B. Nisbit, who showed sections from the washings of the stomach. Dr. A. J. Smith reported a case of Multiple Tumors. Dr. A. Stengel exhibited (1) specimens of cirrhosis of the liver, (2) "Chronic Fibrous Myocarditis." Dr. C. Y. White presented card specimens. The nominations for officers for the ensuing year were made.

Hospital Receives State Charter.—The Roosevelt Hospital, a new institution in the northeastern section of the city has received a charter from the State. The Roosevelt was established in 1894 by Dr. Franklin Brady as a private concern at 1833 Chestnut Street, but finally charitable patients were admitted, the demands of which became so great that the above step was thought necessary. Temporary quarters have now been established at 1815 Frankford Avenue, but recently a new site has been acquired, where a modern building will be erected.

Work at the Maternity Hospital.—At a recent meeting of the Board of Directors of the Maternity Hospital the reports of this institution showed that in the three months ending August 31, 1905, 182 patients, including 19 remaining from May, were cared for in the hospital proper; 25 infants were born in the obstetric service, necessitating 152 visits from physicians; 447 patients visited the various clinics, and 417 prescriptions were compounded. These reports are very satisfactory to the board, and they believe the work can constantly and gradually be extended.

Convention of Homeopathists.—Last week saw the beginning and the end of the forty-second annual meeting of the Homeopathic Medical Society of Pennsylvania. One of the papers that commanded considerable attention was that of Dr. E. R. Gregg, who read of the "Scopolamine-Morphine Combination as a General Anesthetic." He treated 28 patients of all ages in the Pittsburg Homeopathic Hospital by this method. A paper on the "Present Status of the Consumptive" was read by Dr. F. W. Boyer, of Pottsville. Dr. C. O. W. Bartine, of Philadelphia, read a paper on "Milk as a Factor in the Causation and Spread of Infectious Diseases." Another paper which commanded a great deal of attention was read by Dr. J. D. Boileau, of Philadelphia, upon "Cause and Prevention of Yellow Fever." He took the ground that the mosquito was alone responsible for the spread of the disease. Dr. August Korndörfer, of Philadelphia, read an interesting paper on the "Work and Life of Hahnemann."

Report of the County Medical Committee.—At the regular meeting of the Philadelphia County Medical Society the committee composed of Drs. Francis M. Perkins, Charles W. Burr and Henry W. Cattell, and named at the meeting of the society April 20, 1905, for the purpose of acting in conjunction with the Coroner, the Director of Public Safety and with the District Attorney in securing evidence against and in prosecuting individuals guilty of performing criminal abortions, have handed in the following report: "Your committee begs leave to report that it has investigated over thirty persons making a practice of performing criminal abortions in the city of Philadelphia, and that at the present time each one of these has either left the city, is under police surveillance (6), is a fugitive from justice (7), is awaiting trial (7), or is in prison serving time (8). Your committee in its entirety or individually has paid frequent visits to Coroner Dugan, District Attorney Bell, Director Smyth, and Director Potter, and have been most courteously received by these gentlemen, and believe the support of the society in assisting them in the performance of their duties has been much appreciated. As an additional example of what has been done may be cited the case of one of the Philadelphia newspapers which formerly carried in its Sunday edition ten to seventeen advertisements of criminal abortionists, and which now no longer prints the objectionable kind of matter. So much having been accomplished, it is hoped that the County Medical Society will never permit this nefarious business again to assume such vast proportions in Philadelphia as was the case in the early part of 1904. It would seem to the committee that the only way to prevent this now that the city is largely freed from criminal abortionists, is to have the matter taken up by the State Medical Society and the American Medical Association, so that when the abortionists are driven from one city they will not immediately go to another place and carry on work of a similar nature. Thus several years ago an earnest endeavor was made to drive this class of persons out of Boston, and as a result Philadelphia received several of the worst specimens with which the authorities have had to deal. Then, too, it is so easy to live in New York or New Jersey and to come over to Philadelphia a certain number of days each week. If a central committee of the American Medical Association could be established with affiliating committees in the various large centers, your committee believes in the various large centers, accomplished thereby."

Brain and Arm Bequeathed to Wistar Institute.—General Wistar, who recently died at Claymont, Del., left the following will: "I, Isaac J. Wistar, of Philadelphia, widower, do make and publish my last will in manner following, to wit: I bequeath to the Wistar Institute of Anatomy and Biology my right arm, said to be a desirable specimen of gunshot anchylosis, and also my brain, both to be removed by said institute promptly after my death, and I direct my executor, before performing any other act of administration, to cause the remainder of my body to be cremated with all convenient dis-

patch, without ostentation or unnecessary expense, and to deposit the ashes thereof in an urn or other small vessel of inexpensive character, to be marked and sealed up in the mural crypt or recess prepared for that purpose in the main hall of the said Wistar Institute's museum building. The details of these dispositions may, if my executor so choose, be entrusted to my friends, the director and assistant director of the said institute, who know my wishes and will not refuse me that last service. I give and devise to the said Wistar Institute, and request it to preserve and maintain it in such plain and reasonable good order as it now is, my lot in Laurel Hill Cemetery, known as section 4, No. 114, which I inherited from my father, in which my deceased wife is interred, and in which my brother Thomas, but no other person, is to have the right of burial. Also my original share in the Library Company of Philadelphia, with the framed certificate authenticating the payment for any registry thereof, over the signature of B. Franklin, which descended to me from my great-grandfather, Richard Wistar, an original subscriber. Also the dress sword presented to me by the citizens of Philadelphia, with the correspondence relating thereto, my general officer's service sword worn by me in many celebrated engagements; my colonel's service sword worn at Ball's Bluff, Antietam and other actions, the scabbard of which was lost when I was wounded at the latter place; my epaulettes and all weapons, flags and trophies of war used or captured by me in the Civil War; my several military and other commissions from the State of Pennsylvania and the United States; the portrait of myself, all my books, my military, official, personal and other manuscripts, correspondence, orders and papers. All my clocks, oil portrait of my mother, all the movable furniture of my library and such other pieces of my household furniture as I may hereafter designate, or as the said Wistar Institute shall desire to have for permanent use in its buildings, all my pictures, photographs and engravings, and my personal recollections in two bound volumes of manuscripts, which, however, shall not be published, if at all, until at least five years after my death. After the payments of all the said several legacies, and of the taxes, repairs, insurance, maintenance and restoration, and all other necessary and lawful charges and expense that may be required for the protection and maintenance of my estate, I direct that all the rest, residue and remainder of my estate shall be transferred and paid over to the person, natural or corporate, who shall then be the trustee, lawfully holding the trust estate which was granted and settled by me for the perpetual use and benefit of the Wistar Institute of Anatomy and Biology, a charitable corporation of the State of Pennsylvania, which trustee is at the present time the Girard Trust Company, of Philadelphia, to be held upon the trusts and for the uses and subject to the terms, conditions, stipulations and limitations which are in the deed or declaration of trust, and shall thereafter be and constitute an inseparable part of the said trust estate for the sole and perpetual use and benefit of the said The Wistar Institute of Anatomy and Biology, as is in and by the said deed declared and limited to all the provisions, stipulations, conditions, limitations and remainders which are in and by the said deed settled, limited and declared. It is my intention that all the devises, bequests, legacies, annuities and benefits conferred by this my will, are given to the said several beneficiaries on the express condition that no such beneficiary shall directly or indirectly dispute or contend concerning any clause or direction of my will, and in case of any contention or litigation I direct that the bequest, devise or legacy, and every other right or claim to any part of my estate of the beneficiary or of any other person so contending, disputing or litigating shall forthwith lapse, and become part of my residuary estate, to be disposed of as I have provided, or may provide, concerning such estate. And I hereby declare that I have no intention of dying intestate as respects any portion of my estate, and if any of the directions or disposition of this my will shall be declared invalid by any competent tribunal, in whole or in part, then the result thereof, so far as any change or modification may be thereby caused, shall inure to the advantage of the Wistar Institute of Anatomy and Biology, as the ultimate beneficiary, as herein provided and intended."

CHICAGO.

Contagious Diseases.—Except for a continued spread of diphtheria in South Chicago, the contagious diseases are steadily declining. No death from measles or scarlet fever occurred during the week, and there were marked reductions in the deaths from typhoid fever and whooping-cough.

Resignation of Dr. George F. Butler.—Dr. George F. Butler, author of Butler's Materia Medica and Therapeutics, has resigned from the College of Physicians and Surgeons, Chicago, where for nearly twelve years he held the Chair of Materia Medica, Therapeutics and Clinical Medicine.

Dedication of Hinsdale Sanitarium.—This sanitarium was dedicated September 20. The Hon. R. A. Childs, of Hinsdale, Ill., presided, and the dedicatory address, entitled "The Sanitarium Idea," was delivered by Dr. J. H. Kellogg, head of the Battle Creek Sanitarium. Other addresses were given by Judge Orrin N. Carter, Mr. Hastings H. Hart, and Dr. Homer M. Thomas.

CANADA.

The Army Medical Corps.—The permanent army medical corps of Canada is to consist of 150, all ranks. Nine will be stationed at London, ten at Toronto, eleven at Kingston, nine at Montreal, nine at Fredericton, twenty at Halifax and ten at Winnipeg. The remainder will be located in the west at places not yet stated.

Winnipeg General Hospital.—During the month of August, 1905, 613 patients were treated in the Winnipeg General Hospital, as against 512 in the same month in the previous year. The number of patients treated from January 1 to August 31, 1905, was 2,904, as against 2,412 for August in 1904. The outpatients treated in August were 395, as against 292 for August of the previous year.

Dr. R. A. Reeve, Toronto, Elected President of the British Medical Association.—On September 10 the physicians of Toronto had a meeting in the Ontario Medical Library to discuss the arrangements for holding the annual meeting of the British Medical Association in Toronto in 1906. A special committee was appointed to select another committee to advise with the local branch of the British Medical Association in Toronto as to the arrangements. Following this the local branch of the Association held a meeting. Dr. I. H. Cameron occupied the chair, and Dr. W. B. Thistle, the secretary

of the local branch, acted in that capacity. Dr. R. A. Reeve, Dean of the Medical Faculty of Toronto University, was unanimously elected President, and it was decided to have the meeting divide into twelve sections, the chairmen and secretaries of each being selected. It was also decided to have the meeting take place during the week preceding the Canadian National Exhibition, so that it may be expected to be held in the third week in August. A committee of arrangements will be appointed in the near future.

Montreal General Hospital.—During the week ending September 23 the regular quarterly meeting of the Montreal General Hospital was held in that city. Dr. Craik, formerly Dean of the Medical Faculty of McGill University, gave some interesting items regarding the growth of the institution. He stated that in 1854, fifty-one years ago, he was a house surgeon in the Montreal General Hospital, as was Dr. Ault, who was also present at the meeting. At that time there was a staff of eight or ten nurses, and the patients numbered between eighty and ninety in the year. He also gave an interesting account of the epidemic of Asiatic cholera in Montreal in 1854. During the quarter ending June 30, 1905, there had been treated to a conclusion in the wards no less than 803 patients. There had been in that quarter 55 deaths, 28 of which occurred within three days of their admission, giving a mortality rate of 3.34 per cent. In the out-door department there were 10,850 consultations, as compared with 9,072 for the corresponding quarter in 1904. The income for the quarter had been $18,975 and the expenditure $23,858. Dr. R. P. Campbell was appointed medical superintendent for another year. Owing to the increase in work in the out-door department it has been found necessary to make an addition to the staff as follows: Out-patient physicians, Drs. A. W. Gordon, B. W. D. Gillies and A. C. P. Howard; out-patient surgeons, Drs. E. M. von Eberts, A. T. Bazin, A. R. Pennoyer, C. A. Peters. The governors are asking wealthy citizens to donate funds to the extent of $500,000 for an endowment.

The Management of the Ontario Provincial Hospital.—For the first time in the history of the province of Ontario the medical superintendents of the various provincial hospitals for the insane gathered in convention in the city of Toronto. This took place September 20, and was summoned at the call of the Hon. the Provincial Secretary, under whose department lies the administration of these institutions. It is the first of what will hereafter be a series of meetings on the part of those engaged in this department of medicine. Dr. G. A. MacCallum, Superintendent of the London Provincial Hospital, was chairman of the conference, while Dr. Beemer, the superintendent of the Mimico Provincial Hospital, discharged the duties of secretary. Dr. W. N. Barnhardt, of Toronto, contributed a paper, in which he advocated pathological work in these institutions, stating that we in Ontario were about ten years behind similar institutions in the United States. He thought that excellent work might be done by the present staff if they were relieved of some of their non-medical duties. In the discussion that followed this paper the general opinion was that there was lots of room for improvement in this direction. Dr. D. Campbell Meyers, Toronto, contributed a paper dealing with the prevention of insanity, and held that the first step in prevention was for the providing of better facilities for instruction of a clinical character for the medical student in functional nervous diseases. Having this end in view, he advocated the establishment of wards or separate pavilions in connection with the general hospitals of the province for the treatment of the early acute cases of insanity. Following the reading of this paper, the chairman of the Board of Trustees of the Toronto General Hospital, stated that the Toronto General Hospital was prepared to undertake this class of work and would provide for the residence of the former superintendent, Dr. Charles O'Reilly, being used for this very purpose. The plan advocated by Dr. Meyers was endorsed by the meeting. There was a long discussion on the question: "Under what conditions should the insane be committed to jails?" Satisfaction was expressed that there are now fewer insane in jails in Ontario than formerly, but there yet remained room for considerable improvement, particularly with regard to the committment of lunatics to jail by warrant. A resolution was adopted recommending that the system of committing lunatics to jails by warrant be simplified, and that magistrates be instructed against committing alleged insane persons to jail when application for the admsision of sane to the asylums has not been made.

GENERAL.

Quarantine at Annapolis.—On account of the prevalence of typhoid fever and diphtheria at the Naval Academy, a rigid quarantine has been established. No midshipmen are allowed to leave the grounds.

National Purity Conference.—The National Purity Conference will be held at La Crosse, Wis., October 17 to 19. Delegates will be present from all of the United States and Canada. The purpose of the conference is to consider and discuss rescue work, law enforcement, divorce, race suicide and State toleration of the social evil.

New Orleans Fever Report.—With September practically gone, the yellow fever situation is under control in New Orleans, and as the days grow cooler the number of mosquitoes is expected to decrease. There is a steady inpour of people from all sections of the country. The most favorable feature of the report for the last twenty-four hours is the small number of persons now under treatment here. They number 288, the smallest list since August 8.

Hospital Superintendents' Conference.—A four-days meeting, the seventh annual conference, of the Association of Hospital Superintendents of the United States was opened at the Hotel Vendome, Boston, September 26. Among those who were expected to read papers was Sir Henry C. Burdett, K.C.B., of London, whose subject was to be "The Hospital World." Dr. George H. M. Rowe, of the Boston City Hospital, is president of the association.

Cholera Epidemic Checked.—Ambassador Tower cabled the State Department from Berlin as follows: "It is announced officially by the German Government that the cholera has been checked, and that any epidemic is entirely unlikely." This statement will be communicated by the Department of State to the Public Health and Marine Hospital Service, through the Treasury Department, in order that it may modify, if it sees fit, the restrictions which it has been obliged to impose upon emigration through German ports.

Public Health Association.—Physicians, surgeons and bacteriologists from all parts of the United States and from Canada and Mexico met in Boston last Monday to attend the thirty-third annual meeting of the American Public Health Association, which opened

Monday, September 25, and continued until Friday night. Subjects for discussion touching the preservation of public health have been prepared, covering a wide range. Section meetings were held Monday at the medical library in the Fenway. The convention proper opened its sessions Tuesday, September 26.

Vermont's Senator Donates a Tuberculosis Sanitarium.—Senator Redfield Proctor, of Vermont, in a letter to Dr. W. N. Bryan, of Ludlow, Secretary of the Vermont State Tuberculosis Commission, announces that he will purchase a site and erect a sanitarium at a cost of about $50,000 in this State for treatment in incipient cases of tuberculosis. The building will accommodate from twenty-five to thirty patients. In addition the Senator says he will give $100,000 as endowment for the institution. He suggests that a board representing all sections of the State, headed by the Governor, be selected to have charge of the sanatorium and to provide that if the State at any time wishes to assume the charge and maintenance of the institution it may, in the discretion of the trustees, be turned over to the State with all its property and funds. The site has not been announced, but will be selected soon. The Senator says he makes the gift at the request of his children.

Military Surgeons Meet.—With a gathering of 150 delegates representing the armies or navies of Japan, China, Mexico, Great Britain, the Dominion of Canada, Guatemala, France, and the United States, and the National Guard of many of the States in this country, the fourteenth annual meeting of the Association of Military Surgeons of the United States opened in Detroit, Sept. 26. Reports from officers and committees were read at the morning session. Surgeon-General Walter Wyman of the Marine Hospital Service, president of the association, was unable to be present, and Col. A. M. Briggs, of Buffalo, the vice-president, read his report. The report of the secretary, Major J. E. Pilcher, of Carlisle, Pa., noted an increase of membership from 1,800 to 2,000. A report from the legislation committee indorsed the army bill which provides for increasing the number of medical officers in the army and the establishment of a medical reserve. Major Jefferson Randolph Kean, U. S. A., of Washington, D. C., was announced as the winner of the Seaman prize for 1905. This is a prize of $500 offered for the best essay on "The Prevention of Disease in the Army and the Best Method of Accomplishing that Result."

The Army Canteen.—It is not to be denied, writes the *New York Times*, that the experience of the army canteen furnishes a serious argument against female suffrage. It is quite notorious that it has been by the efforts of the W. C. T. U. that the judgment, the practically unanimous judgment, of the officers of the United States Army with respect to the best means of promoting temperance in the army has been nullified. This year, it appears, once again, has that judgment been expressed, again with practical unanimity, by the reports of all the department commanders. They are the only expert witnesses. And they corroborate one another from their widely different stations and points of view. In any question in which sentiment was not allowed to play a disproportionate part, such a consensus would be conclusive. But it seems that members of Congress allow the sentiment of persons who know nothing about the matter in hand to outweigh the opinions of those who know all about it. There is grave doubt whether, in spite of all this consensus, the most practicable expedient for promoting temperance in the army will be again adopted. Mr. Rudyard Kipling, in the character of a Prince of India, once wrote a fierce satire upon the British legislation which similarly went counter to the facts of the case, as these were certified by the most competent witnesses. The Indian Prince declared that it was the "barren women," meaning the women who had nothing more important to do than to regulate affairs of which they were grossly ignorant, who dictated the legislation of Great Britain. If Secretary Taft has the courage of what must be his convictions on the subject of the army canteen, the subject will again be pressed upon the attention of Congress. It will once more be brought to proof whether the testimony of expert witnesses shall or shall be allowed to weigh against what one must call the combined ignorance and impudence of those who know nothing at all about the matter in question.

International Surgical Society.—At the first Congress of the International Surgical Society, held last week at Brussels, the subject of the treatment of general peritonitis was formally introduced by six "Rapporteurs" from various countries. These were: Dr. P. L. Friedrich (Leipzig), Dr. A. Krögius (Helsingfors), Dr. M. K. G. Lennander (Upsala), Dr. F. Lejers (Paris), Dr. A. J. McCosh (New York) and Dr. E. de Ista (Madrid). On a few points there was more or less difference of opinion as to the best methods of treatment; on others all were agreed as on the value of salt infusions during and after operation. The points in dispute were the questions of (1) Invariable operation (except in moribund cases). Four of the speakers approved of immediate operation in all cases. Two doubted the universality of this rule. (2) Anesthesia. The speakers were about equally divided as to the respective advantages of local and general anesthesia. (3) Incision. A long median incision, with secondary openings, was advocated by two speakers; a moderate by three, and a short single by one. Irrigation in a thorough manner was recommended by two speakers; in a modified manner by two, whereas dry sponging in cleansing was preferred by two. Salt solution was universally advised. All antiseptics discountenanced. Evisceration of intestines was rather discountenanced by all the speakers. Drainage, with extensive packing by means of gauze tampons, was advocated by two speakers. Very scant drainage by two, and two were rather doubtful which plan was most advisable. Also two were in favor of multiple openings for drainage. Entire absence of drainage was opposed by all. Enterostomy. This subject received the fullest discussion. The formation of one or more intestinal fistulæ was warmly advocated by three. The other three were in doubt as to the advisability of this procedure, at least in the great majority of cases. Fowler's position was advocated by three. A general discussion followed the reading of the six papers.

Harvard Medical School.—The Harvard Medical School opens on October 1 this year with certain very marked change in its curriculum. Beginning with the year 1900 the so-called concentration system was adopted; *i.e.*, for the first half of the first year Anatomy and Histology were the only subjects taken up; during the second half students devoted all their time to Physiology and Physiological and Pathological Chemistry; in the first half of the next year Pathology and Bacteriology were studied, while during the second half of the same year a wider variety of subjects was taken up, preparing the student for the clinical work of the last two years. The work of these last two years was practically all prescribed. This year under the new system while the first two years remain the same, the greater part of the prescribed work is put into the third year, and the fourth is purely elective. One thousand hours

is the minimum requirement for each fourth-year student; this time, under certain supervision, he may divide among as large number of electives as he chooses. For the convenience of the students these electives are arranged in groups, a certain group being recommended for the man who intends to go into general practice, and another for those men especially interested in surgery. Men desiring to take up work along special lines, scientific medicine or otherwise, may select their electives with this end in view, providing they include the necessary one thousand hours of work and meet with the approval of the Advisory Board. This change makes the third year, in the past always the hardest, decidedly more so, giving the student fifteen to eighteen examinations in the spring of that year; the success of the fourth year depends much on the intelligence of the student in the selection of his electives; this factor, now that a college degree or its equivalent is required for admission to the school, is not such an altogether doubtful quantity as when the high-school graduate went directly into the study of medicine. The new buildings will be ready for occupation in the spring of 1906. The exterior of all is now practically completed, and the beautiful white marble group is rapidly becoming a sight very worth while going out of one's way to see. It is hoped that a broad boulevard can be made leading from the city directly out to what is to become a great educational center; the building of this avenue is, however, as yet very uncertain.

The Senators Who Smirched a State's Fair Name.—Georgia, writes *Charities*, has again furnished the annual demonstration of the truth that her civilization stands somewhat lower than that of England a century ago. Georgia has once more cast her annual vote against affording any protection whatever to the tiny children in her cotton mills. For another year it will remain legal for little girls five and six years of age to work throughout the night, eleven hours, whenever it may prove profitable to the mills to work night shifts. Year after year Georgia rejects a bill which would, if enacted, prohibit all work in cotton mills to children under the age of ten years. Sir Robert Peel's bill of 1802 is still in advance of public opinion in Georgia. Lord Shaftesbury's bill of 1842 is still too merciful for the people of that State. Compared with Georgia, Alabama (where little girls may work in mills eight hours at night on reaching the thirteenth birthday) is a modern and enlightened State. Compared with Georgia, South Carolina (where children of ten years may work in mills in the summer provided that some time during the year they have attended some school throughout four months) appears well forward in the ranks of the enlightened. Compared with Georgia, Russia (where no child under age of twelve years may be employed in any mill) appears tender in its care of childhood. This action of Georgia is deliberate. It is taken, year after year, at the close of long debates in the Senate. It is by the vote of twenty-three senators that the year 1905 is placed in the black list of years in which Georgia advisedly sacrifices her little boys and girls to the greed of her manufacturers. The list of enemies of the children of Georgia as published in the Atlanta *News* is as follows: Adams, Alsobrook, Bennett, Blalock, Bond, Bunn, Carithers, Copelan, Fitzgerald, Foy, Graybill, Hamby, Hand, Lumsden, McAllister, Odum, Parker, Peyton, Phillips, Rose, Sirmans, Wheatley, Williams. Many northern corporations have branches in Georgia. The writer has seen the splendid, modern equipment of the Merrimac mills, the Massachusetts mills, and the beautiful village of the New York mills at Aragon. Are these northern corporations guiltless of influencing the votes of the twenty-three enemies of the little white children of Georgia? The disfranchised black men of Georgia may well feel a certain satisfaction that it is only the white children who are employed in the cotton mills; and that all these senators are white men. Thinking citizens of this republic, however, must recognize the sinister fact that progress in legislation in all States in which the cotton industry thrives is hampered by the competition of manufacturers in Georgia whose cruel privilege of wearing out and destroying little white children has thus been extended a year by the twenty-three senators of Georgia whose names should be familiar in every home in the nation.

A Medical Estimate of Prayer.—At the recent annual meeting of the British Medical Association a testimony was given to the therapeutic value of prayer which, says *The Outlook*, should be recorded over against the skeptical views of some scientists. Dr. Theodore B. Hyslop, Superintendent of Bethlem Royal Hospital, has a reputation as a specialist in neurology and in the treatment of mental disease which adds weight to his words: "As an alienist and one whose whole life has been concerned with the sufferings of the mind, I would state that of all hygienic measures to counteract disturbed sleep, depressed spirits and all the miserable sequels of a distressed mind, I would undoubtedly give the first place to the simple habit of prayer." It matters not, in Dr. Hyslop's view, what are ones' theological conceptions—anthropomorphic or rationalistic—of the infinite environment with which prayer attempts to commune; the effect is the same: "Let there but be a habit of nightly communion, not as a mendicant or repeater of words more adapted to the tongue of a sage, but as a humble individual who submerges or asserts his individuality as an integral part of a greater whole. Such a habit does more to clean the spirit and strengthen the soul to overcome mere incidental emotionalism than any other therapeutic agent known to me." Mediæval superstition, connecting medical art with magic supposed to be learned from evil spirits, used the proverb, *"Ubi duo medici, tres athei."* In some quarters this stigma is not yet entirely effaced and medical men are perhaps not fully free of responsibility for whatever of it lingers.' On the background of such a history Dr. Hyslop's testimony before an audience of specialists is highly significant of the trend of scientific thought away from materialistic conceptions of mind and of religion. "I believe it," said he, "to be our object, as teachers and physicians, to fight against all those influences which tend to produce either religious intemperance or indifference, and to subscribe, as best we may, to that form of religious belief, so far as we can find it practically embodied or effective, which believes in 'the larger hope,' though it condemns unreservedly the demonstrable superstition and sentimentality which impede its progress." Not many years ago Professor Tyndall's challenge of the religious world to try a prayer-test on a selected number of hospital patients was deemed by many, upon its being declined, to have refuted the claim of a healing power in prayer. As a physicist, Tyndall was, on this subject, not within his own province, as Hyslop, a psychologist, is. Religious men, to be sure, have made extravagant claims, and scientific men also have shot beyond the mark. But Dr. Hyslop's competence to speak in the name of science is unquestionable, and what he affirms as a discovery of medical science is identical with the immemorial faith of religion, that there is a place for prayer in the very nature of things. Not only does he find this place to be foremost among restorative agents. Of the religious enthusiasm which the nature of prayer

is to feed and sustain he affirms that it "embodies the most healthy and preservative development of our social forces." Among the many notable utterances in which science is now evincing herself to be the handmaid of religion, these, the most recent, are as memorable as any.

Atlanta (Ga.) School of Medicine.—This school has just been organized. It will be open on October 3, 1905. Ample accommodations for the coming winter have been secured in the new and elegant Masons' Annuity Building, corner Edgewood Avenue and Ivy Street. Quarters for dissection consist of the first floor of the Masons' Annuity Building. This comprises an office; two lecture rooms, one with a seating capacity of two hundred and the other of one hundred; an operating room with sterilizing and anesthesia rooms adjoining; a private room for professors. A waiting room and adjoining rooms in the basement for the examination and treatment of outdoor patients. A large, well-lighted laboratory equipped with an abundance of chemical apparatus on the third floor; also on the same floor a laboratory for histological, pathological and bacteriological work well stocked with the finest Bausch & Lomb microscopes and other apparatus such as these laboratories need. No medical students in Georgia will be more abundantly supplied with dissecting material. Dissecting will be done outside the building proper, a half block away. Operations on cadavers will be made a special feature of the session's work. Most of the men whose names appear as members of the faculty are already well known to the profession. They have entered into the project with full knowledge of ample financial backing for the future. They have further entered upon the task before them with the specific intention of building up an institution of high grade rather than a necessarily large one. It is intended, just as soon as possible, to qualify for membership in the Association of American Medical Colleges. No College south of Richmond and Louisville belongs to that Association. There has been developing for quite a while a sentiment that there ought to be in the South a medical school whose diploma would entitle one to practise medicine in any part of the United States. Students need therefore have no fear whatever about their certificates, etc., being recognized by other regular medical colleges. This school is not organized to fight any other school. A mistake made by most medical colleges in the South is that they are run to make money. This institution is not run for that purpose Advanced standing of one year will be given students holding degrees from Literary colleges and to graduates in Dentistry and Pharmacy. One or more previous courses in any regular medical college will be recognized and the student advanced accordingly. The first and second years will be devoted to Anatomy, Physiology, Chemistry, Materia Medica and Histology; the third and fourth to such subjects as are usually taught in these years in other medical colleges. The fees for the coming session will be forty dollars whether the student be in the first, second, third or fourth year. No other fees of any kind will be charged, except a graduation fee of twenty-five dollars. As the expense of erecting a building has not been incurred, the expenditures for the coming winter will be small and the tuition can be placed thus at a low figure. Dr. Edward G. Jones particularly desires it to be known that any past promises made to students by him as late Registrar of the Atlanta College of Physicians and Surgeons will be redeemed in the Atlanta School of Medicine. The Proctor, or his representative, will be at the college building, corner Edgewood Avenue and Ivy Street, to matriculate students and look after all other duties in connection with the school. Students are advised to register as soon as they reach the city. Good boarding-houses are abundant near the college. Address all communications to Dr. Geo. H. Noble, Dean, or Dr. Edward G. Jones, Proctor, Atlanta School of Medicine, corner Edgewood Avenue and Ivy Street, Atlanta, Ga.

OBITUARY.

Dr. C. ALFRED GRYMES, formerly a member of the Stock Exchange firm of Henry G. Stebbins & Sons, died of heart disease at his home, 38 Union Square East, New York, last week. Dr. Grymes was a graduate of Harvard University and the College of Physicians and Surgeons in Philadelphia. Dr. Grymes entered his father-in-law's firm after practising medicine four years.

Dr. F. A. BALDWIN died last week at his home, 129 West Seventy-seventh Street, New York. He was born in New York in 1846, and was graduated in 1881 from Bellevue Medical College. He served in the Eastern Dispensary until 1886, and from 1884 until 1895 he was attending surgeon to the outdoor department of Bellevue Hospital. From 1885 to 1889 he was assistant to the late Dr. Alexander B. Mott, who held the chair of clinical surgery in the Medical College. He was a member of the American Medical Association, of the New York Medical Association and of the New York County Medical Society.

CORRESPONDENCE.

A NEW BROOM SWEEPS CLEAN.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Delight in character study is the excuse for presenting what follows; even at the risk arising from the use of an awkward expression for a title, whose like Lord Chesterfield has condemned so much. The search for sterile materials for the surgeon's use leads along a devious path. Thus, sinews from a rat's tail and a heron's legs are some of the latest suggestions. The employment of wire taken from a new broom, as incidentally mentioned in the present instance, is along the same line.

The wife of a financially successful artist, engaged with him in living out that erratic sort of career which society styles Bohemian, related to me sometime since an original method employed by her to restrict the size of her family. Always regular in her menstrual periods, save for the interruptions of pregnancy, the woman, now past forty, possessed of an attractive personality, high spirits and seeming robust health, is the mother of three grown children. After experiencing the pleasure of mothering two children early in her married life and becoming pregnant a third time, a young practitioner suggested to her the error of sacrificing good looks to a numerous progeny. Showing the woman an ordinary uterine sound, the doctor instructed her how it might be used, and explained that while he could not perform such an operation himself, would gladly lend her the implement. Declining to carry out the abortion under such circumstances, the woman's fear was overcome a few weeks later by a sharpened wit. By unwinding she secured the wire which binds the splint bundles to the handle of a broom and with scissors cut out a length of about twenty inches of the bright interior. Doubled at the middle a flexible blunt-pointed implement was secured, of which she had no fear to use, and after some further preparation by scrubbing the wires with soap and water, passed the instrument along her vaginal tract into the uterus with a prompt, uncomplicated re-

suit. Subsequent experiences taught the woman that about the second month was the best time for interrupting her pregnancies, and that a new broom supplied the cleanest wire. During a period spread over twenty-five years of married life this lady has successfully produced by the means described fifteen consecutive, with one exception, abortions. The break in the mortality rate of this auto-operator shows another phase of the woman's character. Controlled by a vivid dream when about making up her mind to commit the depredation, the thought became fixed that the present occupant of her womb would become a daughter, beautiful as herself and with a mind to match. Her hand thus stayed, the birth of a daughter at term fulfilled the first part of the prophesy. The rest is borne out in the individual herself, who now, grown to womanhood, bears a striking likeness to the mother. Her mind will probably never get the stimulation which her mother's has experienced, for she is married to a man many years her senior, and who, possessed of wealth, is controlled by her slightest wish. Those who accept the theory manifest the glib phrase of the Christian Scientists, namely, control of mind over matter will not scoff at the instance which leads one into the occult sciences, just given.

For the unbelievers it may be stated that the woman had nothing but her own whim to control her regarding the number of children she should have. Furthermore, she has not had a similar dream since, but she has had twelve abortions. Regarding acceptance of the truth of the whole story, the woman's eldest daughter was present when he mother gave me her sexual history; she, having been present upon several occasions, was able to corroborate the details. This impressed me not only with the truth of her statements, but of the happy relationship of perfect confidence existing between mother and daughter. This daughter, as well as her brother, it might be remarked, are as commonplace as the younger sister is brilliant. The woman, who is now about in her menopause, viewing a case of spear and dagger-like implements used by the French laity for producing abortion, and collected by me several years ago in Paris, passed them with the comment that "those French women would run any risk."

To set forth the depth and gradual dissemination throughout society of the question of production of children, the following case has but just passed from my notice. A Russian Jewess, the wife of a poor painter of the same nationality, is the mother of nine children, and has been a resident in America some five or six years. Under cocaine anesthesia I operated upon her toe for ingrowing nail. When about to be discharged, after the completion of treatment, the reason for her wish and change, which she effected, from being a patient in a public clinic to a private one, became apparent. Feeling herself to be pregnant, the woman desired to be relieved of the product of conception. Unable to gratify her request, she announced to me "that not for twenty thousand dollars would she bear another child," and left me with fixed determination to find the way to gain her wish.

FREDERICK GRIFFITH

Tested Eyes Before Fight.—Surgeon-General S. Suzuki, of the Imperial Japanese Navy, addressing the convention of military surgeons in session in Detroit, told how the Japanese surgeons before every engagement carefully inspected the eyes of all gunners on the warships. They were all tested with reference to refractive errors in particular.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighteenth Annual Meeting, held Sept. 19, 20 and 21, 1905.

The President, Howard W. Longyear, M.D., of Detroit, Mich., in the Chair.

(Continued from Page 621.)

Indications for Hysterectomy in Puerperal Septicemia.—Dr. Charles Green Cumston, of Boston, stated that hysterectomy applied to the treatment of acute puerperal infection is as yet a mooted question as far as its indications are concerned, and it would be quite as illogical to advise this inference in all serious cases as it would be systematically to condemn it. All surgeons seem to be in accord as to the great difficulty of formulating the indications for this operation, and especially the time when these become formal. To come to a conclusion all clinical methods of examination and those of the laboratory must be employed. The latter, however, are far from being of equal value, as no positive result can be obtained from a bacteriological examination of the lochia or blood. Cytological examination of the blood will give excellent data as far as the prognosis of the type of infection is concerned. Clinically, there is no one valuable sign, but taken altogether the symptoms obtained by careful intrauterine examination may indicate the necessity of surgical intervention when all other therapeutic procedures have failed. Septicemia occurring at once after labor cannot derive benefit from surgery, but, on the other hand, it would appear that hysterectomy is indicated in cases of secondary septicemia with a slow evolution, or those taking on a pyemic type proceeding by successive stages, without visceral metastases, in which case surgical treatment would be a method of exception.

Abdominal Hysterectomy for Multiple Fibroids Complicated by Pregnancy.—Dr. J. Henry Carstens, of Detroit, Mich., reported the case of a woman, forty-two years old, who was never pregnant before. A tumor was noticed for five or six years, but not accompanied by hemorrhage. Menstruation was regular until May; there was a slight show in June and July. He operated in the middle of August. The growth became rapid during the last three months. Patient recovered from the operation for the removal of the tumors.

These cases are not uncommon, still they are sufficiently rare to warrant reporting them. In nearly all cases the women are sterile; the growth develops, and after some years they become pregnant, which makes one suspect that there was some abnormal condition of the uterus, perhaps some malposition which prevented impregnation, but as the result of the growth the uterus was pulled up or shoved over in one direction or another in such a way that the ova could pass into the uterus and pregnancy occur. This seems to him the correct explanation of the occurrence of pregnancy in sterile women after the development of fibroid tumors.

In reference to general rules for these cases, the cases vary so much that no definite rule can be laid down to govern all cases, but on general principles he thinks cases of fibroids complicated by pregnancy can be left alone if they are subperitoneal and located at the upper half of the uterus. Fibroids

located in the lower half of the uterus or in the broad ligament should be removed. Fibroids adherent or complicated with other pelvic diseases should be removed by enucleation, or in some cases an abdominal hysterectomy should be performed.

Personal Experiences in Myofibroma of the Uterus.—Dr. Miles F. Porter, of Fort Wayne, Ind., presented some of the more important facts gained from the treatment and observation of over 125 cases of myofibroma of the uterus. The earlier cases having been seen during a rather exacting general practice, and many of them operated away from home, in private houses, without adequate assistance, accounted for the fact that the records of this part of his work were imperfect. Of the 125 cases, more than 100 were subjected to supravaginal hysterectomy. Two vaginal hysterectomies were done, and in a few cases the tumors were removed per vaginam without opening the peritoneal cavity. No vaginal myomectomies were done in which the abdomen was entered. Myomectomy through the abdomen was done six or eight times only, except cases in which small fibroids were removed during celiotomy for other causes, and these were not considered. Hemorrhage was not so prominent a symptom as was generally thought. In two cases this was the immediate cause of operation, and in one it manifested itself first after establishment of the menopause. Pain, especially during the menstrual period, had been the most common symptom. Only one case of pyosalpinx as a complication was seen. In one an eight and one-quarter-pound tumor was removed from a four and one-half months' pregnant uterus. Normal labor at term followed, and one child had been born to the mother since without accident. In one case the pregnant uterus was removed for pain, on the theory, which the specimen proved correct, that the woman could neither miscarry nor carry the child to term. The third was operated because of mild sepsis due to retained fetus. Both recovered. Women with fibroids were peculiarly liable to infection following labor, miscarriage or menstrual flow. In several cases this danger was the chief indication for operation. Three cases were reported to support this opinion. Rapid growth of fibroids during pregnancy was believed to be more apparent than real. Partial or complete sterility was common in fibroid patients. But one case of malignant degeneration was seen. But one case died. This was due to the breaking-down of a large vaginal tumor, coexisting with a large abdominal tumor. Both were removed through the abdomen. Removal of the vaginal tumor per vaginam by morcellation, and an abdominal hysterectomy later would probably have saved the patient, who died from the effect of the sepsis from which she was suffering at the time of the operation, combined with the effect of the shock and loss of blood. One case of dermoid of the ovary with multiple fibroids was met with, one practically a pure myoma, and one fibroid of the ovary complicating fibroid of the uterus. Oophorectomy for fibroids was not a justifiable operation, as it neither stopped the hemorrhage nor the growth of the tumor. The ideal operation for myofibroma would leave the genital tract intact, or as nearly so as possible within reason. The tubes should always be removed when operation rendered pregnancy impossible. Healthy ovaries should be left, as should healthy cervices. Whether to operate through the vagina or through the abdomen might be determined before the operation began, but the details of the technic should be developed as the operation proceeded. In rare cases the elastic ligature was of service. Twice the bladder was cut, but was immediately repaired, and no harm resulted. One case had a hemorrhage from a split of the broad ligament, which occurred the night following the operation, as a result of the patient starting violently during a dream. No trouble from silk as ligatures was experienced, but because of the evidence against it, catgut was substituted as soon as he learned to sterilize the latter by heat. The death rate of abdominal operations need not be over two per cent., and vaginal operations involving the peritoneal cavity should not be above one per cent.

Unusual Dilatation of Cornual Blood Vessels, with Rupture Into the Uterine Cavity Hysterectomy.—Dr. Frank F. Simpson, of Pittsburg, Pa., reported this interesting case, and stated that apart from their association with neoplasms, vascular changes are not infrequently found when persistent bleeding occurs near the menopause. Arteriosclerosis is rather common; but aneurism, aneurismal varix and varicose veins occurring within the myometrium are rare. In this instance there was an excessive vascularity of the uterus, with sclerotic arteries and varicose veins. The sclerosis is found in its several forms, varying from a slight nodular infiltration of the intoma to complete obliteration. In addition we have the unusual spectacle of greatly dilated varicose veins which were the subject of repeated spontaneous rupture with repeated spontaneous closure. In the author's case there was a clinical picture which portrays the perils of this disease in its most serious form. In the well-marked cases that have come under his observation arteriosclerosis of the uterine vessels has been accompanied by menorrhagia and metrorrhagia, which began between the ages of thirty-eight and forty-five. They grew more and more pronounced, and yielded only to hysterectomy. In this case, however, the first symptom was a furious hemorrhage due to the rupture of a large varicose vein into the uterine cavity. Within two months three other hemorrhages burst upon her without warning, and each imperiled her life.

The gross pathological findings make it clear that without surgical intervention hemorrhage or infection would inevitably have closed the scene within a short while.

Primary Bowel Resection Versus Artificial Anus in the Treatment for Strangulated Hernia.—Dr. John Young Brown, of St. Louis, Mo., limited himself to a discussion of the surgery of those neglected cases in which at the time of operation the intestine found in the hernial sac is so damaged that the operator is forced to resort to one of two procedures—the establishment of an artificial anus, or a primary bowel resection. During the last eighteen months he has operated upon seven cases of strangulated hernia; four of these were males, three females. In four the hernia was of the inguinal variety, and in three of the femoral type. In all primary resection was done, followed by a radical operation at the hernial site. Of the seven cases, six recovered and one died. The oldest patient was seventy years, the youngest twenty. The duration of strangulation, longest fifty-seven hours, shortest nine hours. Amount of gut removed, largest four feet, smallest eight inches. Gut involved small bowel. In each case the condition of the small bowel, which was the part involved, was such as to leave no question concerning the

advisability of its removal. In all the resection was done through a supplemental abdominal incision, and the anastomosis was made with the Murphy button. The results obtained he attributes to the careful attention to certain points in the operative technic, a neglect of which he believes has been responsible for the high mortality invariably accompanying the surgical treatment of this condition.

A Study of the Etiology of Floating Kidney with Suggestions Changing the Operative Technic of Nephropexy.—The President, Dr. Howard W. Longyear, of Detroit, selected this as the title of his Presidential Address.

December 17, 1903, while operating on a young girl of sixteen years of age for appendical disease, the writer accidentally discovered that the right kidney, which was normally placed, could be easily pulled down and held in a firm position of complete prolapse by making traction on the cecum. This led to further observation on the etiology of displaced, loose or floating kidney, both on the cadaver and on the living subject, and afterward, as a result of those observations, to efforts to devise an operation that should have for its object the retention of the kidney in its normal position, as well as the anchoring of the ascending colon in such a manner as to remedy the prolapse of the cecum, which usually obtains in these cases, so that it should not exert further traction on the kidney and through it on the duodenum and renal vessels. The object of the address is to record the results, though unfinished, of these observations. The fact that the kidney in question could be pulled down and held firmly in this position by traction on the cecum and ascending colon was an indication that there exists a more firm and positive attachment of this viscus to the kidney than is generally believed.

After considering the literature of the subject, the writer naturally assumed that the kidney of his patient was pulled down by the adhesion of the peritoneal attachment, or mesentery of the colon to the fatty capsule of the kidney, and yet the firmness of the attachment was an apparent contraindication. With the object of testing this point, three cases of floating kidney were operated upon. The peritoneal cavity was entered through the usual incision in the loin, the redundant mesentery gathered up and attached to the incision of the fascia close to the twelfth rib at the upper angle of the wound. In the first case of extreme ptosis, having had Dietil's crises for several years, the ease with which the operation was performed, the amount of slack mesenteric tissue brought out and attached, and the immediate result which it had of entirely replacing the kidney so it could not be pushed down into the abdomen, were very encouraging.

In the second and third cases, however, in both of which the displacement was less pronounced, there was practically no mesentery such as was present in the first case, so that the peritoneal fixation seemed to promise less. However, while drawing out the peritoneal attachment of the bowel and making efforts to push the bowel down, away from the kidney, it was noticed in both cases that there was a cord-like structure passing downward from the lower pole of the kidney, which prevented the separation of the kidney and bowel. This was included with the peritoneal tissue and attached with it. Further investigation of the literature failed to enlighten the author as to the presence of any tendinous prolongation from the lower pole of the kidney, so further investigation was made on the cadaver. The dissection on the cadaver was described at length. The whole upper half of the abdominal parieties being incised and turned downward, the cecum, ascending colon, with hepatic flexure and kidney on the right side, and part of the descending colon, with splenic flexure and kidney on the left side, were removed, the dissection being made from below upwards and the organs removed together in such a manner as not to interfere with their normal attachments to each other. On turning the specimens over the posterior surface of bowel and kidney on each side showed a similar formation of tendinous attachment to each other. This was found to be formed by the gathering together of fine longitudinal fibers from the fibrous network which forms the framework of the fatty capsule. The tendinous ridge, formed by its attachment to the posterior surface of the ascending colon, could be followed easily between the peritoneal reflections down to the margin of the lower peritoneal attachment of the bowel and close to the junction of the ileum—in fact, near the point of the so-called origin in the female subject of the suspensory ligament of the ovary. A specimen illustrating the presence of this phrenocolic ligament was exhibited.

How much of an etiological factor is this embryological remnant in the production of displaced kidney? This ligamentous union of the kidney and bowel, the author claims, is the most important factor in the etiology of nephroptosis.

An operation which he has found the most easy way of accomplishment is the fixation of this nephrocolic ligament into the upper angle of the wound without severing it from the colon, and also fastening the redundant mesentery, if it be present, in the lower angle of the wound. The convergence of the framework of the fatty capsule into this ligament makes a structure of sufficient strength to be depended upon to hold the displaced organs, if securely attached to the aponeurotic tissue, preferably where it is thick near the twelfth rib.

Intestinal Obstruction.—Dr. Lewis C. Morris, of Birmingham, Ala., said that delay in operating for the relief of ileus is due to one of two things: (1) Assuming that the diagnosis has been made, the adoption of expectant treatment with the hope that it will relieve the condition, or that it will recover spontaneously; or, (2) the delay resulting from a failure to make a positive diagnosis. The author reported six cases of intestinal obstruction, and believes that if all such cases could be given the benefit of operation the mortality in this conditions would be completely revolutionized. The fact that some cases exist for days and are relieved by operation leads, in cases in which there is an element of doubt, sometimes to delay in surgical interference until the chances for recovery are materially lessened. Occasionally a positive differential diagnosis is very difficult, but the conditions from which a dfferentiation cannot be positively made are almost invariably equally as imperative in their demand for surgical intervention as would be the existence of an ileus.

Diagnosis.—Dr. John B. Deaver, of Philadelphia, endeavored to place the matter of laboratory diagnosis in its proper light, showing that it is after all only one form of diagnosis by pathognomonic symptoms. He tried also to make a plea for the more thorough education of medical students in the principles of physical diagnosis and in the knowledge of the natural history of surgical diseases; while at the

same time advocating a postponement of laboratory methods until the former have been completely mastered. He endeavored to show the real danger which, as it seems to him, exists of the modern surgeon degenerating into a mere mechanical appliance subject to the controlling mind and will of the laboratory diagnostician. Yet, while above all things discountenancing haste and carelessness in reaching conclusions, and the judicious resort to the therapeutic test of exploratory operations, he pointed out what seems to him the legitimate fields of the exploratory incision.

Appendicitis as a Factor in the Diagnosis and Treatment of Abdominal and Pelvic Tumors; Also Complicating Pregnancy.—Dr. Rufus B. Hall, of Cincinnati, Ohio, believes that the diagnosis of appendicitis, when associated with pelvic and abdominal tumors, or in the pregnant woman, has not received the attention on the part of the general profession that the subject deserves. He wishes to call attention more forcibly to the early recognition of the cardinal signs of appendicitis in these cases. It is the common supposition on the part of the general profession that when a patient known to have an abdominal or a pelvic tumor, is taken suddenly ill with pain in the abdomen, that there is something wrong with the tumor and the cardinal signs of appendicitis are ignored or overlooked. Dr. Hall then discussed the differential diagnosis of appendicitis complicating fibroid tumors of the uterus and ovarian tumors; differentiated diagnosis of appendicitis complicating tubal disease; differential diagnosis of appendicitis associated with pregnancy; the treatment of appendicitis complicating fibroid tumors and ovarian tumors and tubal disease; also the treatment of appendicitis associated with pregnancy.

Cæsarean Section.—Dr. Henry Schwarz, of St. Louis, Mo., reported the case of a child wife who was in labor sixty hours, with repeated attempts at forceps delivery by the family physician. Apparently she was not infected. Instead of a Porro, as is usual in such cases, he did the classical Cæsarean operation, which was followed by recovery of the mother. The baby was asphyxiated; membranes and amniotic fluid yellowish green. His assistant worked over the baby an hour at artificial respiration before spontaneous breathing was established. Pressure marks on the scalp showed locking of the head between the promontory and symphysis; necrotic tissue dropped out a few days afterwards, and baby recovered.

Pregnancy Associated with Diabetes.—Dr. Magnus A. Tate, of Cincinnati, Ohio, mentioned the reports of numerous investigators, calling attention to sugar in the urine of pregnant women. He collected all cases that could be found in medical literature where pregnancy was complicated by diabetes. He reported an additional case, and presented a study of these tabulated cases as to their frequency, results, mortality and other similar data.

Cysts of the Mesentery.—Dr. Orange G. Pfaff, of Indianapolis, Ind., said that these growths are comparatively rare; their diagnosis is difficult, if not impossible; their pathology is not fully and clearly understood, but most of them, if not all, are of probable embryonal origin.

Abdominal Pregnancy Persisting Beyond the Normal Period of Gestation with Report of Cases.—Dr. Charles A. L. Reed, Cincinnati, Ohio, read a paper which was based, first upon three cases that occurred in his practice, as follows: (1) Extrauterine pregnancy with extraperitoneal development of gestation; operated upon fifteen months after conception by marsupialization, and terminating in recovery. (2) Exerauterine pregnancy with retroperitoneal development of gestation, operated upon by marsupialization eleven months after conception and ending in recovery. (3) Extrauterine pregnancy with development of gestation within the anterior abdominal wall, complicated with uterine fibroids, operated upon four years and nine months after conception, ending in recovery. The conclusion reached by the author was that the placenta presents the chief factor in operation upon these cases. In instances in which the fetus is already dead, and in which there are no symptoms of sepsis demanding immediate operation, a delay for a few weeks is desirable, as thereby the vascularity of the placenta will be greatly reduced, if not entirely destroyed. One case indicated that it might persist to an embarrassing degree after six weeks. The operation by marsupialization is recommended, as it avoids hemorrhage, facilitates perfect drainage, and places all conditions under control. The importance of the yeast ferment in eliminating attached fragments of placental detritus was emphasized.

Officers.—The following officers were elected: President, Dr. John Young Brown, St. Louis, Mo.; First Vice-President, Dr. James N. West, New York; Second Vice-President, Dr. Frank F. Simpson, Pittsburg, Pa.; Secretary, Dr. William Warren Potter, Buffalo, N. Y., re-elected; Treasurer Dr. X O. Werder, Pittsburg, Pa., re-elected; Members of Council Drs. Robert T. Morris, New York, and Howard W. Longyear, Detroit, Mich.

The next place of meeting will be selected by the Council.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-second Annual Meeting, held at Detroit, Mich., June 29 and 30, 1905.

Presidential Address.—This was read by Dr. W. F. R. Phillips. It took up the rôle of climate as modifying the animal and vegetable world; the influence on art, architecture, literature, philosophy and religion. The influence of climate on the course of phthisis was considered and the varying attitudes of the profession toward different climates. Definitions of climate were given and show a great want of harmony in what is understood to be embraced. It is a composite, and to study it requires a division into its elements and an investigation of their separate physiologic results. The laboratory must be the means by which climate as a therapeutic agent must advance. Dr. Phillips advocated climatological laboratories at sea-level and on mountains as the best method of solving the perplexing problems in which we are guided so largely by empiricism.

Southern California Health Resorts.—Gen. C. H. Alden, U.S.A., retired, contributed a paper on "Some Southern California Health Resorts, 1904-5." This report is founded on observations during the last eighteen months. The climate of Southern California is equable in its limited range of temperature and in its freedom from severe storms, but there is a sudden and marked fall of temperature at sunset which invalids and others must guard against. There is a great difference between successive seasons in the amount of rainfall and of sunshine, and, consequently, of temperature. The rainfall in 1904-5 was nearly three times what it was in 1903-4, and nearly four times that of 1901-2. The

facts are always suppressed by local boomers who would have the public believe that the region is one of cloudless skies the year round. The climate of Southern California is not a dry one, as some suppose. The humidity lessens as one goes from the coast inland, but the fogs, which in the absence of much rain, are a large factor in sustaining vegetation, penetrate many miles from the sea and add to the humidity. The fact that the humidity is not favorable for pulmonary tuberculosis which is at all advanced is evidently not appreciated as it should be. The interior towns are unpleasantly hot in summer; coolness can be secured only by going to the sea-shore which is too damp for many invalids, or to the mountains where there are scarcely any accommodations suitable for the sick. There is a hostile attitude toward tuberculous patients in hotels and boarding-houses; the best resorts will not admit them and so advertise. They are not now dependent on consumptives as formerly. Patients of this class, if they come to Southern California at all, would do much better if treated in sanatoria. They need daily supervision and cannot be trusted to take care of themselves. They generally make light of their affliction or even conceal it; they indulge in sight-seeing, in amusements and social functions and exhaust their strength. They take up with quacks in many instances. The principal resorts in Southern California were characterized, and data were given as to hygiene and vital statistics. Favorable mention was made of Redlands in winter and the foot-hills of the coast range near Pasadena or Santa Barbara in summer.

The Laurentians.—Dr. A. D. Blackader, of Montreal, read a paper on the "Climatology of the Laurentians." This region is situated north of Montreal and forms a plateau extending from Labrador to Lake Superior. It is made up of very ancient crystalline rocks; it is undulatory, the depressions are covered with detritus or drift, with here and there flats of light sandy soil. The flora and fauna were described and meteorological data given. Ste. Agathe is one of its best-known districts. It is cold in winter, but not subject to high winds. From December to March the clear days average 14, the partly cloudy 10, the cloudy 10 per month. The winter air is dry, but exact records over a long period are wanting. It was claimed to be an ideal place for all those showing any tendency to circulatory disturbance or throat complications, bronchitis or asthma.

Southern Florida.—Dr. E. L. Shurly, of Detroit, read a paper on "The Climate of Southern Florida for Chronic Cardiac and Vascular Diseases." He laid great stress on the regulation of the action of the skin and intestines in combating renal and cardiac diseases. He prefers the Southern climates to the usual measures such as the use of mineral waters, hydrotherapy or drugs. He excludes from consideration certain cases of valvular disease of the heart of recent origin or incipient aneurisms which appear to be more particularly relieved by a residence at an altitude, but for cases showing more than full compensatory hypertrophy, with more or less condensation or loss of elasticity of the arterial intima or walls, whether accompanied by severe or moderate renal lesion, great relief or a restorative to a condition of ease or usefulness will often follow a residence in subtropical regions. Dr. Shurly mentioned Palm Beach and Key West and Nassau favorably. The diet in these cases should be non-nitrogenous and non-stimulating.

North Augusta, South Carolina, as a Winter Resort.—Dr. Thos. D. Coleman, of Augusta, Ga., read this paper. The advantages of this suburb of Augusta were detailed. It has an altitude of about 600 feet and is 100 miles from the Atlantic Ocean and 16 miles from Aiken, S. C. It is on sandy hills about 400 feet above the city of Augusta. The accommodations are first class.

Influence of Climate on Gout.—Dr. C. C. Ransom, of New York, contributed a paper on "The Influence of Climate upon Gout." The geographical distribution of gout was considered and it was shown that where malt liquors and wines are largely used gout is much more common than in countries like Scotland, Ireland and Scandinavia, where spirits are more popular. It is very common, according to Dr. Ransom, in America The Hindoos of India are immune, but it is said to affect the Mohammedans notwithstanding that their religion prohibits the use of alcohol. The effect of climate is subsidiary to other factors in the continuation of the disease. Dr. Ransom does not believe that the atmosphere of the sea-shore has any unfavorable influence on gout, as he repudiates the notion that the humid atmosphere, by retarding elimination and thus favoring the retention of uric acid, will increase gout. Dr Ransom lays more stress on diet.

Human Blood Pressure and Pulse as Affected by Altitude.—Dr. Charles Fox Gardiner and Dr. Henry W. Hoagland, of Colorado Springs, read this paper. The authors used healthy college students from Colorado College and had the advantages of the new scientific laboratory and the professors of physics and biology. Five miles distant by electric railway was the summit of Pike's Peak, 14,130 feet. A normal pressure for each healthy individual was obtained for 22 college men at 6,000 feet altitude. The average as determined by the Riva Rocci and Janeway instruments during some weeks was 126 mm. Hg. and pulse rate 80. The men were taken by special train to Pike's Peak, 14,130 feet, and on arrival were taken to a room in the hotel. All excitement and excretion was avoided. They were then tested using the same technic as employed in the laboratory at 6,000 feet. Results showed an average pulse of 86 and blood pressure 121, again in pulse rate of 5 and a lessened blood pressure of 5 mm. After remaining three-and-a-half hours at this altitude they were again examined. The pulse rate had risen to 99 and the pressure had fallen to 118 mm. Some exercise, such as walking, had, however, been taken by all the individuals of this group during the interim. A few days after returning from this trip nothing unusual was noted. In other series of experiments it was found that as a rule blood pressure in men and women is slightly lower at 6,000 feet than at sea level after a residence of one year. Prolonged residence at this altitude, in 60 men who had lived twenty-five years at Colorado Springs, the measurements showed at least no excess of pressure. It was found that the more rapid the pulse the lower the blood pressure; when the pulse rate was but little affected by an altitude of 14,000 feet the blood pressure was also more constant; that cases of mountain sickness were accompanied by a fall in blood pressure and a rapid pulse. In any case where the blood tension is low on account of disease a removal to a higher altitude would be likely to aggravate it. It is highly probable that the right side of the heart and venous system play a more important part in the phenomena of altitude effects than we can at present verify.

Dr. Henry Sewall, of Denver, said that although it is laid down in the books that nephritis is influenced unfavorably by high altitude it is not altogether true. Dr. Sewall has had experience with cases of this class that do remarkably well at 5,000 to 6,000 feet on the slopes of the Rocky Mountains. Others do badly. He

quoted the case of a lady with tuberculosis of the lungs and larynx. She held her own in Denver, married and went to Honolulu. There her throat was greatly improved, but her lungs were worse. On her return to Denver her nephritis became aggravated and compelled her return to Honolulu. Dr. Sewall holds that those conditions of the kidneys in which increased venous blood pressure is deleterious are made worse in high altitudes.

Dr. Babcock, of Chicago, said that the difference in blood pressure is so slight, that on that fact alone he hardly saw any explanation of benefit or the reverse that might accrue. We cannot lose sight of the increased depth and vigor of respiration in its effect on patients. So that there are certain problems connected with it that ought to be worked out. Theoretically a case of compensated aortic regurgitation ought to be favorably affected, since any condition which would lessen peripheral resistance as could be done by decreased arterial tension ought to have a favorable effect.

Impalpable Sputum.—Dr. Norman Bridge, of Los Angeles, read a paper on "Impalpable Sputum as a Usually Overlooked Danger in Tuberculosis." He stated that direct infection rather than heredity was responsible for the disease. The infection invades first the lymphatic nodes of the throat, neck, chest or abdomen, where it may remain latent for months or years. Dr. Bridge believes with von Behring that the disease in the lungs is secondary to lymphatic infection and does not agree with him in ascribing the original infection so largely to milk from tuberculous cattle. Dr. Bridge called attention to the tangible sputum which is known and against which war is waged and which is so carefully destroyed; and to the intangible, impalpable sputum ejected by the consumptive in an explosive cough constituting more formidable because neglected and unthought of.

Sputum from Ambulant Cases.—Dr. De Lancey Rochester, of Buffalo, read a paper entitled "The Main Factor in the Spread of Tuberculosis—Sputum from the Ambulant Cases. What are We going to do about it?" He said patients who are unwilling to take the necessary precautions and those who by ignorance cannot be made to conform to instructions against indiscriminate spitting should be removed, by force, if necessary, to a proper institution, and he retained there under proper supervision until death or cure occurs. New York is the only city, as far as the author knows, in the world where this power is held and exercised by the Board of Health. In their experience there is rarely any real difficulty in the management of these cases, if the accommodations which are provided and the food and care given are of a superior character. The law is as follows: "Said Board may remove or cause to be removed to proper place any person sick with any contagious, pestilential or infectious disease; shall have exclusive charge or control of the hospital," *etc.* According to the General Health Officer, Dr. Hermann Biggs, the death-rate has declined 40 per cent. in twenty-five years. Dr. Rochester said that unless the ignorant and vicious spitters are taken care of in this way, consumption can never be got rid of. If, however, these measures are carried out he firmly believes consumption can be rid of in a generation. As Cornet has said: "The consumptive in himself is almost harmless and only becomes harmful through bad habits." Because of the intangibility of the poison as well as the natural skepticism of lay people and doctors such efforts will be difficult. To say that every hour, day and night the patient must remember to hold a shield in the shape of a cloth or paper before his face when he coughs, and then destroy the shield, is to impose a large tax on his attention and faithfulness; probably few patients are equal to such a task. With the best of intentions they forget and grow careless. Beards and moustaches should be removed; clothes and bed linen sterilized and sunned, and if sunlight is not to be had they can be hung in a formalin closet. In the latter case the clothes must be aired before they are used again. Carbolic solutions were recommended for floors and furniture. The popular chloride solutions are probably not very useful in this connection.

Dr. E. L. Shurly, of Detroit, Mich., said it might be a very desirable thing to use coercion for the isolation of early or incipient cases of pulmonary consumption, but he doubts whether that could be done in the western States, where the spirit of independence and individual liberty still exists, perhaps stronger than in the State of New York or other eastern States. The question came up in a way, a few years ago, in this State, and Dr. Shurly was unfortunately brought before the bar of the courts here for not reporting a case of pulmonary consumption. The question was pretty well aired by the attorney on both sides, and a great deal of testimony taken as to the communicability of the disease or diseases and the justice of the regulation of the State Board of Health classifying pulmonary tuberculosis with the pestilential diseases, such as diphtheria, variola, cholera, etc. The contention Dr. Shurly's attorneys made at these various times prevailed. Dr. Shurly concedes that such a thing would be desirable in the interests of the family and community as suggested, under certain circumstances, but before such measures are carried out generally, it seems to him that the State should first guarantee to the people honest and competent practitioners of medicine. In most of the States the law regulating medical practice is new, while ignorant faddists are given special privileges. He thinks in New York State the law is older and better than in Michigan, which is only four years old. There are probably not less than two thousand people practising medicine in the State of Michigan who scarcely know the difference between mumps and consumption. Now, under the diagnosis made by these persons a great deal of harm would come from coercive measures advocated. It seems to him the State must first, before adopting coercive measures of that sort, guarantee to the people competent and honest practitioners, and, as the paper suggests, the places to which they are removed must be well provided with good food and other facilities. But to deprive any individual, even a sick individual, of liberty in this country is a very serious step, even though there may be some compensation for it, and in the western States he does not believe such a thing is practicable at the present time. Indeed, the separation of a family in that way cannot be carried out easily.

The statistics of New York may be correct, but he knows the statistics in Michigan are not worth a snap, because the people, under the fear of trouble about their life or benefit insurance, and things of the sort, will hide their complaints, aided frequently by practitioners. For instance, Michigan has a State statute requiring a special burial permit, or certificate of the death of a patient of tuberculosis before removal from the State; now, everybody knows how these death certificates are made out, as pneumonia, whooping-cough, etc., so as to avoid the ordinance. That is done right along. It seems to Dr. Shurly that the medical profession ought to still further improve the laws regulating the practice of medicine, and be able to go to the people with definite data—facts—establishing the general communi-

cability of pulmonary phthisis before radically advocating coercive measures for the isolation of patients.

Dr. Henry Sewall, of Denver, Col., said he was very much disappointed in these discussions. He cannot help but feel that they have represented very little medical progress in the last fifteen years. It seemed to him that looking at this thing from a very practical point of view the curse of our country is illustrated in the enthronement of our notion of individual liberty, which practically amounts to liberty to do harm to your neighbor and not to do good to yourself. The health boards are continually ignored, and it is only through the health boards that we can meet the public. There is no direction in which this society can do more good than to work through the health boards, and to try to see to it that the health boards are constituted as they should be. He thinks the worst enemies of the health boards are the good, honorable well-meaning doctors who call themselves conservatives. They are represented right here in this association, and he believes they have done a lot of harm. A man who does things is bound to make mistakes; but for God's sake, don't stop everything because a man in going ahead is bound to go on the wrong track occasionally. Take an interest in every public health work, and help in that direction. He can see perfectly well how the registration of tuberculosis may be of enormous avail. The law does not yet authorize many things which ought to be done, but Dr. Sewall believes the community is rapidly approaching the point when they will allow the profession more authority—more power. He thinks it is quite a matter of dispute as to whether the germ of tuberculosis may not have to go through some intermediate stage. It certainly does seem to be required to be confined in the dark, and in ill-ventilated spaces. But at the same time there can be no doubt but isolation is a wise thing, to control the sputum that is coughed up by the patient, palpable or impalpable. Our veterinary friends have set a good example in that respect. Good work has been done in Denver with tuberculous cattle simply by adopting intelligent methods of isolation, taking the cattle that were valuable for breeding purposes and allowing them to be used for that purpose; taking the calves and isolating them, putting them out by themselves, not destroying anything except in the advanced cases of the disease; they have thus practically stamped out tuberculosis inside of fifteen years. And Dr. Sewall would be very sorry to admit that what can be done for cattle cannot be done for human beings. As far as the feeling of western independence of the individual is concerned, he has had some little experience on both coasts of this country, and has no hesitation in saying that while there is, in a sense, more individuality in the West, there is also a much higher intelligence and so much better development of what he thinks may be called the common consciousness in western communities that they are more ready to take up with these things, when seen to be necessary, than they are in the East, and that there should be less difficulty in enforcing a rule of this description in an intelligent western community than in the eastern. The death-rate of tuberculosis has decreased in Denver about 35 per cent. in the last twenty years, but the pneumonia death-rate has increased at a little more rapid ratio than the tuberculosis death-rate has declined, and Dr. Sewall does not want to impute any unnecessary ignorance to anyone, but it is becoming a very unpopular thing to have a death certificate signed as having been due to tuberculosis. Many of these patients are members of small industrial and insurance organizations, and if it had been reported that their death was due to tuberculosis the company would refuse to pay on the ground they had the disease before they were insured. There has been an unconscious influence in that direction, and many of the so-called cases of pneumonia are really tuberculosis. By all means teach the public as far as possible, and isolate all necessary cases.

Dr. Roland G. Curtin, of Philadelphia, Pa., said the subject of the contagion or infection of tuberculosis, if the term is permissible at the present time, is yet a disputable one; there is one class of cases which is in the direct trend of those cases mentioned by Dr. Glasgow. They are the supposed to be cured cases of pulmonary tuberculosis. I think they are the most prolific cause of infection, for the very reason that they are supposed to be entirely well; and they are not so. I had a patient, a young man who had married three wives, and he did not live with either one of them two years; they all died. One in one year, one in a little over a year, and one in a little less than two years. This young man was deaf in one ear, and upon examination I found he had a tuberculous disease of the internal ear, and I suppose he communicated it to his wife through his mouth. I said to this young man, "Are you going to get married again?" and he answered, "The truth is, Doctor, the women are afraid of me, otherwise I would." This case was followed by a man who also had lost three wives, and it was found upon inquiry that he had a cough in early life, and he always had some little cough after that. Upon examination of his sputum bacilli were found, and he probably poisoned his wives in exactly the same way. Since that time I have been particular to inquire about the previous history and examine the lungs carefully of all patients coming to me who have lost two or more wives, and in these cases almost always there is a history of chronic cough, and evidence upon an examination of the lungs of previously existing organic disease. Patients of this class go around spitting anywhere and everywhere during their whole lives, and these are the cases you cannot control by any means suggested. And it seems to me this class of cases is more prolific in spreading the disease and more likely to spread disease than any other class.

Dr. Babcock said that a few weeks ago he saw a Lithuanian priest in Chicago, a very intelligent young man, who had pulmonary tuberculosis. The doctor questioned him with the utmost particularity as to his family history, his previous diseases, and could obtain no clew to the source of his infection. And finally he said to him, "Did you ever live in a room with a consumptive, or did you ever occupy a room in which a person with a chronic case of consumption had lived?" He said, "Yes, Doctor, I lived for two years in a room in which a young man had died of consumption." Dr. Babcock said, "Was he careful with his expectoration?" He said, "No, he spit anywhere he chose." Dr. Babcock said, "Was that room ever thoroughly cleaned after his death?" He said, "No, Doctor; you know that that class of people don't clean their rooms." Now, Dr. Babcock said, one swallow does not prove a summer, and perhaps those who do not believe in direct infection may maintain that that young man

did not get tuberculosis from that room. But Dr. Babcock believes that in the light of the investigations which have been carried on, that that young priest, who was healthy, who had no family taint, who had had no depressing diseases, obtained his infection from living in that room which was infected with tubercle bacilli. Furthermore, the Doctor believes it is shown beyond any question that in families with tuberculosis the disease is communicated as frequently from the children to the parents, as from the parents to the children. In his argument against inherited tuberculosis Cornet gives the tables of cases where the parents are free from tuberculosis at the time of marriage, and free from tuberculosis until after a child had contracted it. And anyone who has read Cornet's work, Dr. Babcock thinks, will bear him out in his conclusion that the disease is communicable and communicated in these instances from the children to the parents. If a single case or group of cases goes to prove anything that the disease is communicable from one patient to another, then I say we are justified in all measures calculated to limit infection. It is only a question of just how far we shall go in order not to antagonize the public too strongly at first. And the Doctor believes that if this question of infection were put to a vote to-day in this Association you would find that the majority, if not all the men, believe it is infectious and it is communicable from one person to another through the medium of something, say the sputum, just as much as smallpox is communicable from one individual to another.

Dr. Norman Bridge said some of the members who have discussed this paper seem to have imagined the possibility that the officers of the law might try to segregate large numbers of invalids in the community; that there is a general belief that in matters of this sort the profession ought to go slow, not to terrify the public, not to scare the people. Dr. Bridge does not know just how Dr. Rochester feels about it, as to whether, if he had his own way he would have a great number of people gathered in by the health officers and segregated, but it seems to him (Dr. Bridge) that here is a truth that should be considered, the value, for the popular understanding of this disease, of having occasionally a man arrested and taught by the courts, as well as by the officers, the force of law. One man's arrest for promiscuous spitting, spitting on the sidewalk, or in the street car, and fining will do more toward educating the public to the dangers of tuberculosis than some of our discussions and a great deal of our literature. If occasionally a known tuberculous patient, a patient known to be a consumptive, were arrested because he is careless in his expectoration and were sent to a hospital or fined, or put under supervision, it would do a vast deal of good. None of us will live long enough to see a great number of patients reached by the heavy hand of the law in that way. But an occasional case of that sort, the Doctor believes, will help mightily toward the intelligent understanding, not only of the force of the law, but of the value of these preventive measures toward the spread of tuberculosis.

"Inspection of the Eastern State Penitentiary of Pennsylvania with Special Reference to Tuberculosis."—Dr. Guy Hinsdale made this report. This prison was built in 1827 and has been famous for the system of solitary confinement. There were 1,010 convicts at the time of the inspection two years ago, and the death-rate from tuberculosis had been large. Out of 475 deaths from all causes during the previous 25 years, over 60 per cent. had been from pulmonary tuberculosis. There were about forty cases of pulmonary and glandular tuberculosis at the time the visits were made. The pulmonary cases were segregated in the hospital department and afforded more air and liberty than others. The cases of adenitis were not segregated, but put to work outisde the cells. The ordinary cell has about 1,100 cubic feet of contents, and has a window in the roof 24 x 24 inches. Ventilation is also permitted through the door into the corridor, which, during later years, has been left ajar six inches and secured by chain and rod. There are doors opening into the little yards attached to the cells, and these doors are opened half an hour daily for men and three hours for women. The plumbing and drainage is most primitive, and is for the most part without traps in the cells. About 20 per cent. of the convicts occupy cells in the upper tier. Through the efforts of the prison physician, Dr. W. W. Leach, and one of the inspectors, Dr. W. D. Robinson, who had invited Dr. Hinsdale to make the report, improved methods were carried out for the treatment of the tuberculous cases, and attempts were made by rigorous disinfection to eradicate the disease from cells which were probably infected. Very satisfactory results were obtained during the past two years, especially in reference to the number of cases originating in the prison. Dr. Hinsdale reviewed the excellent work done at Clinton Prison at Dannemora, N. Y., by Dr. Ransom. It is the practice of the New York State authorities to send tuberculous convicts from other prisons to Dannemora, which is situated on the eastern border of the Adirondack Mountains. The lives of many prisoners have thus been saved.

Dr. John Winters Brannan, of New York, contributed a paper on "The Sea Air Treatment of the Bones and Glands in Children." (See a subsequent issue of the MEDICAL NEWS.)

Permanency of Results.—Dr. F. M. Pottenger, of Los Angeles and Monrovia, Cal., read a paper on The Permanency of Results in Pulmonary Tuberculosis: The After-History of Twenty-seven Cases Treated by the Combined Hygienic-Dietetic-Open-air and Tuberculin Treatment. German insurance companies which maintain sanatoria have issued statistics which show that when treatment is provided for only two or three months and the patients returned to work permanent results were not very satisfactory, as they soon broke down again. A much longer period is required for an economic cure. The report of Dr. Pottenger concerned 27 cases which had been discharged as far back as six years or as recently as twenty-six months. Of these cases twelve were classed as in the first stage, and all were apparently cured or had their disease arrested and remain cured to-day. Of those classed as in the second stage, six were apparently cured or had their disease arrested and remain cured to-day; while of the third stage cases, two had their disease arrested and remain cured. Thus twenty have been cured. Of the seven cases discharged as improved, six are dead. In no instance was there a relapse in any of the twenty discharged as cured.

Hemoptysis in Heart Disease.—Dr. Roland G. Curtin, of Philadelphia, read a paper on "The Significance of Hemoptysis in Heart Disease." It was Dr. Curtin's twenty-first annual paper before the

Association. Bleeding from the lung structure proper *i.e.*, the air vesicles, may be caused by a stasis of the blood, which may be due to the constriction of an orifice in the heart, thus retarding the blood in the lungs; or to a partial cessation of the action of the heart, so as to produce a stoppage of blood in the lungs, thereby causing a congestion and an escape of blood through the lining membrane of the air vesicles. The usual causes are mitral constriction, rupture of degenerated blood-vessels and, less frequently, slowly rupturing aneurysm of the aorta. The diagnosis of the origin of the blood was given. Mistakes in this respect lead sometimes to a diagnosis of lung disease. Examples were given. Dr. Curtin has seen cases of hemoptysis apparently caused by administering nitroglycerin and by the prolonged use of potassium iodide. The blood in all cases should be carefully examined. If the heart disease is acute and the blood is pure the prognosis is bad. If the blood is bright red and quite profuse the prognosis is much more favorable than when dark or purple, showing it to be stale from a slow oozing. If the bleeding is caused by a condition of the blood engrafted upon a previously existing heart disease, the prognosis is not so serious. Death is seldom, if ever, produced by a profuse hemorrhage from this cause alone.

Respiratory Movements of the Bronchial Tubes.—Dr. E. Fletcher Ingals, of Chicago, read this paper. These were first noticed by Dr. Ingals while doing bronchoscopy in a child two years old, and later in a boy thirteen. In a patient, an adult who had had asthma all her life, having had two or three attacks every night for years, the vesicular murmur was not more than one-sixth or one-fourth as loud as normal in either lung, although there were no râles or no signs of emphysema or other disease of the lungs; and the question arose whether the feebleness after vesicular murmur was not due to deficient innervation of the bronchial muscles, and whether the attacks of asthma were not due to irritability resulting in excessive paroxysmal action of the contractile muscles. Dr. Ingals has observed that in inspiration the diameter of the tube was sometimes more than twice as great as in expiration. The investigations of Einthoven, Dixon and Brodie were quoted.

Anthracosis.—Dr. Henry Sewall, of Denver, reported an "Extraordinary Case of Anthracosis Simulating Thoracic Aneurism." The patient was an adult, aged forty-six, who had a systolic *bruit* confined to an area represented by the lower half of the right scapula when the shoulders were thrown back. He had worked when twenty years old for a year in the coal regions of Pennsylvania. His breathing became progressively difficult, and there was evidence of a moderate degree of consolidation at the right apex. Radioscopic examination showed a rather dense shadow projecting into the right lung, but its true character was not suspected. Rest in bed and iodides for six months did not improve him. His sputum showed a few tubercle bacilli, and he coughed up some light blood, and had severe pains about the heart. The patient died shortly afterward, and at the autopsy the right ventricle was found dilated and rather hypertrophied. The heart valves were all normal and competent. No sign of aneurism. At the root of the right lung a hard solid, ovoidal mass, 4 x 3¼ x 2½ inches, black and gristly, was found. Analysis showed it to be coal dust.

Immobilization of One-half of the Thorax.—Dr. Charles Denison, of Denver, Col., read this paper. He showed a process of applying bandages for preparing and applying *traction plasters*, to arrest pulmonary hemorrhages, to relieve pleurisies, to contract lung excavations, and to adjust rib fractures.

Election of Officers.—At its business session the Association elected the following officers: President, Dr. E. L. Shurly, of Detroit; vice-presidents, Dr. A. D. Blackader, of Montreal, and Dr. Henry Sewall, of Denver; secretary and treasurer, Dr. Guy Hinsdale, of Hot Springs, Va.; councillor, Dr. W. F. R. Phillips, of Washington, D. C. It was decided to hold the next meeting at Atlantic City in May, 1906.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, held June 7, 1905.

The President, Arthur V. Meigs, M.D., in the Chair.

Three Cases of Cerebrospinal Meningitis, Probably Due to the Pneumococcus.—Dr. Robert N. Willson, Jr., reported these cases because they demonstrated, in a manner apparently beyond cavil, that the general teaching of the fatality of meningitis caused by the pneumococcus is not always borne out by experience; and, because from the similarity of their clinical pictures, the cases offered a method of discriminating between this and other spinal inflammations. The cases were all treated by lumbar puncture and then expectantly. Case 2 was operated upon twice. In all of the cases there was extremely high tension, and through a rather large canula the fluid spurted out some distance from the spinal column. In every case there was immediate relief to some extent. In Case 2 ptosis disappeared from the eyelids, headache disappeared, and convalescence seemed to date from that point. A week later there was entire return of the symptom complex, and lumbar puncture again had the same effect. In all three cases there was an enormous amount of cerebrospinal fluid. The result of the cases—recovery in all three—was contrasted with the statement found in Osler, that pneumococcus meningitis is fatal, and with Dr. J. C. Wilson's last article, in which it is stated that the pneumococcus form is the most fatal of all forms of spinal meningitis. In all three of the cases it was proved as nearly as possible that the pneumococci were present.

Dr. F. P. Henry thought it extraordinary that the complication is not more prominent in cases of pneumonia, considering that the pneumococcus has been found in cases of pneumonia and traced from the lung to the nasal passages. In cases of pneumonia in children, he has found difficulty in the differential diagnosis of meningitis and pneumonia. He thought Dr. Willson's cases seemed to substantiate his view that pneumococcus meningitis was not so fatal as said to be by the authorities quoted.

Dr. J. Allison Scott called attention to the fact that practically every symptom and sign of meningitis could be found in various affections and yet the meningitis be not present. He thought the diagnosis in the first case reported not altogether secure, because of the bacteriological results, and that the second case was not proved to be one of meningitis, because in almost every case acute leucocytosis is a characteristic of the disease. In

the pneumococcic cases studied recently at the Pennsylvania Hospital, he said that the cerebrospinal fluid was usually somewhat turbid, and that the pneumococcus was demonstrated without difficulty and differentiated from other organisms by culture. He has had two such cases under his care; one fatal in twenty-four hours, and the second within a few weeks. The second case was the result of ear disease without the presence of pneumonia. He was disinclined to a diagnosis of meningitis until the condition is proven by all known means. In a large percentage of cases he believed that the pneumococcus can be demonstrated in the circulating blood, and apparently derived from some other source than the pulmonary tissue.

Dr. Willson, in closing, referred to the statement of one authority, that there is a constant intercommunication between the intraspinal circulation and the blood circulation. He has found the subject interesting in connection with his experiments with reference to the pressure of the fluid. He felt that the most interesting case was that of the boy in which undoubtedly the pneumococci were found. The point in question was whether meningitis was the result of the pneumococci found in the cerebrospinal fluid. In a recent case of dislocation of one of the vertebræ the staphylococci were found. In this case the meningitis was considered to be due to internal traumatism.

A Case of Bacillus Pyocyaneus Septicemia After Surgical Operation.—Dr. John B. Roberts reported a case of infection with the blue pus bacillus occurring in a young colored girl of nine years who had been subjected to a plastic operation upon the arm and shoulder for cicatricial deformity resulting from a burn. The patient did well after the first plastic operation, but, just before a second one was undertaken, had tonsillitis and high temperature. This lasted for a few days and recovery apparently took place. After the second operation she developed symptoms of bronchitis, which was followed by sloughing of the axillary flap, the occurrence of blue pus and severe general symptoms. Investigation showed that blue pus had been observed also during convalescence from the first operation. The patient gradually went down hill with grave secondary anemia, a toxic nephritis which gave rise to blood casts as well as hyaline and granular casts, and finally died. The cause of the grave general symptoms was not recognized, but was supposed to be due to some form of infection of the wound, because typhoid fever, malaria and other ordinary conditions were considered and found to be untenable as diagnoses. Some time after the patient's death, it was found that a number of cases of blue pus had occurred in the hospital, and in one of them bacteriological study showed a pure culture of the *Bacillus pyocyaneus*. The clinical diagnosis of pyocyaneus septicemia was therefore made by Dr. Roberts only after the child's death. A discussion of the symptomatology of the disease and reference to recorded cases concluded the paper. The case was reported, because general septicemia of this origin in the human subject is quite rare, or at least, if more common, is seldom recognized by surgeons.

Dr. J. Allison Scott referred to a case which indicated that not all cases of this infection were necessarily fatal. The case was one of extrauterine pregnancy practically exsanguinated. After transfusion in all parts of the body, especially underneath the breasts, she developed a severe infection, which proved to be pyocyaneus in origin. There was great damage to the immediate neighborhood of the salt solution injection, causing necrosis and sloughing. The difficulty, however, was entirely local, and the woman recovered.

BOOK REVIEWS.

Lectures on Diseases of Children. By Robert Hutchinson, M.D., F.R.C.P., Assistant Physcian to the London Hospital and to the Hospital for Sick Children, Great Ormond Street. Edward Arnold, London.

Those who have enjoyed the author's previous work on "Food and the Principles of Dietetics," will know what we mean when we say that this work is written in the same highly agreeable style. It is in the form of lectures which were delivered at the London Hospital, and is not quite an exhaustive treatise on childhood maladies. There are but few of us who will not glean from its pages many valuable suggestions. In rather a conversational way the author goes on to speak of colic and vomiting and diarrhea, and many of the so-called "little" complaints, that the ordinary textbook passes by in a most unsatisfactory manner. Then he wanders over the fields of wasting diseases, nervous diseases, blood diseases, etc. One lecture is devoted to some of the common symptoms of children's disease and their significance, and another to certain medical aspects of adenoid vegetations. The pictures are exceptionally illustrative, and particularly striking is the one of splenic anemia in twins. The author finds that adenoids are responsible for a great many of the ills that infants' flesh is heir to: snuffling, epistaxis, laryngeal stridor, wasting from the difficulty in swallowing milk, bronchitis, asthma, dyspepsia, mental dulness, night terrors, nocturnal incontinence of urine, headache, torticollis, etc. The lectures are eminently practical and show the author's intimate knowledge of children and their ills.

The American Year-Book of Medicine and Surgery for 1905. A Yearly Digest of Scientific Progress and Authoritative Opinion in all branches of Medicine and Surgery, drawn from journals, monographs, and text-books of the leading American and Foreign authors and investigators. Arranged, with critical editorial comments, by eminent American specialists, under the editorial charge of George M. Gould, A.M., M.D. In two volumes. Volume I, including General Medicine; Volume II, General Surgery. Two octavos of about 700 pages each, fully illustrated. W. B. Saunders & Company, Philadelphia and London.

Dr. Gould's year-book continues to grow in favor from year to year, and there is no doubt at all that the abstracting for it is conducted with a serious conscientiousness that sets it far above the plane of the mere routine glossing of medical literature. The best evidence of this, of course, is the prominent character of the contributors to the volume, among whom are found some of the most progressive of the younger medical men. We miss this year in the volume on Medicine the numerous illustrations that have usually been provided. There are some illustrations, but there might have been more with decided advantage. An excellent feature of this work is the very complete index which accompanies it. This is doubtless due to the experienced editors.
